Such an explanation demands that anomalous intensities should depend on the properties of the states, not of the transitions. On examination of the data one finds that in every case the lines starting or ending at a given rotational state are either all strong or all weak; there are never some strong and some weak lines from a single state. This holds both for the lines belonging to the various branches of a single band originating from a given state, and for lines of different bands which have the state in common. On the basis of this it is plausible that the effect should come from anomalous *a priori* probabilities of the alternate levels

If the alternating intensities come from symmetrical rotations, some polyatomic molecules containing two or more like atoms might show them. For example, H_2O has the shape of an isosceles triangle, with the O at the apex. If this rotated about the axis passing through the O and bisecting the base perpendicularly, we should have a condition similar to what has been described, so that one rotational degree of freedom should show the effect, not the others. In NH_3, which forms a tetrahedron with the N at an apex and the three hydrogens in an equilateral triangle, a similar rotation would disclose a three-fold symmetry, which might lead to bands with every third line strong. Methane, CH_4, which is presumably a regular tetrahedron of H atoms with the C in the middle, would have a mode of rotation in which it had a two-fold symmetry, and this may explain why in the spectrum of methane two kinds of bands are observed, one with lines spaced about twice as far apart as in the other.

It is a pleasure to acknowledge my indebtedness to Dr. R. S. Mulliken and Prof. E. C. Kemble for very valuable advice and suggestions.

The Real Meaning of the New Conception of Time.

The fascinating presidential address of Dr. Jeans to the Royal Astronomical Society, published in Nature for February 27, with its poetical allusions to children chasing a rainbow over the hills, and to what seems the successive extinction of the shires as one gazes at the country from the windows of an express, must have helped many of us to make fast our hold upon the principles of the general theory of relativity. Yet it is doubtful whether the full implications for the doctrine are generally realised—of such a statement, for example, as "The year 1927 has the same sort of existence as the county of Cornwall." The legitimate inference surely amounts to nothing less momentous than this: that everything that has ever existed or happened, or that ever will exist or happen, in the universe, is immanent in physical space-time or 'ether'; and that what to us participators in the drama being enacted on the space-time stage appears to be the *special* differentiation of the present—of *now*—from the past and the future, is merely an illusion due to our experiencing changes in a certain dimension of the four-dimensional continuum, which imparts the impression of travelling along that dimension and hence the idea of flowing time

Let us now imagine ourselves, not as pieces in the drama, as actors on the space-time stage from which we can only obtain a limited view of the picture, but as looking on to the stage from an external point of vantage. By the very terms, apparently, of the doctrine of relativity, we should be witnessing the whole evolutionary drama of the physical universe *coexisting* from 'beginning' to 'end,' beholding our ancestors of a thousand years ago with the earth as it then was in the same picture with our actual selves in 1926 and with our descendants of a thousand years hence with the earth as it will then be. The year 1926 would be differentiated in this synoptic view merely in this: that we should recognise from our non-spatial, non-temporal, point of vantage that what in the physical space-time landscape we are calling the present time—our present life—so far from constituting the fullness of life is but an eclipsed view of it.

I submit that, unless words have broken down under the strain to which expositions of relativity have subjected them and have lost their force and vitality, all this is a necessary deduction, signifying to the universe a realism of the grandest kind. Moreover, if space-time ether is thus the scroll, so to speak, upon which everything is recorded, including our own deeds and misdeeds, do we not find a purely *natural* interpretation of certain widely held tenets in religion? The point is, that if the geometry and the mechanics of the world are one, then every *physical* event must fit into the scheme, including our own physical lives and actions. The question of the *nature* of our higher mental or spiritual faculties, operating through matter, is not involved in these implications, but is obviously raised more insistently than ever.

March 23.

A Planarian Species new to Britain.

Specimens of *Planaria albissima*, Vejd., a Triclad Turbellarian not hitherto known to occur in Britain, have been collected in the environs of Aberystwyth, Wales. My preliminary identification was confirmed by the kindness of Mr. E. Percival, of the University, Leeds. The species was found by Vejdovsky in spring-brooks in Bohemia, and Steinmann refers to it as 'rare'; thus the occurrence in the mid-Cardiganshire area is of especial interest. In this area it is very general in distribution; I have found it in rivers and brooks of all types, and at altitudes ranging from practically sea-level to 1250 feet above. Many of the specimens are sexually mature, and asexual reproduction by transverse fission appears to be common.

Kathleen E. Carpenter.

Department of Zoology,
University College of Wales,
Aberystwyth, March 20.

Dr. Carpenter has kindly allowed us to examine specimens which were undoubtedly mature *Planaria albissima*, Vejd. On comparing these with drawings of immature specimens taken near Leeds in May and October 1922 and March 1923, and Pateley Bridge, we feel convinced that the specimens from Yorkshire belong to this species. So far we have failed to find examples in which the sexual organs are developed

The Rugby Wireless Station.

By Dr. W. H. Eccles, F.R.S.

THE Government wireless station at Rugby, now almost completed, is the only one of its class in the British Empire, and is the most powerful wireless station in the world. It was designed by the Wireless Telegraphy Commission and erected by the Wireless Section of the Engineering Department of the Post Office. During design and erection many new problems arose, partly because thermionic valves had not been used on so large a scale before, and partly because extreme efficiency was imperative in order to meet the Government's demand that the station should communicate with every part of the Empire. Many features of the station are novel and of wide interest.

The station occupies a site one and a half miles long and nearly a mile wide, containing about 900 acres, at 340 feet above sea-level. It has twelve masts, each 820 feet high, spread round the edges of the site a quarter of a mile apart. In the middle of the site are the buildings. The machinery hall is 185 feet long × 47 feet wide × 32 feet high, and contains electrical machinery of total power 800 kilowatts, fed from the public supply. A parallel hall measuring 103 feet × 40 feet × 68 feet contains the thermionic triode valves on the ground-level, the condensers on the next level, and the inductances on a still higher level. There are a number of smaller rooms for auxiliary machinery, together with offices, workshops, and testing rooms.

As a rule the steel lattice masts at big wireless stations are earth-connected at their bases and, in consequence, the oscillatory current in and out of the antenna induces oscillatory current up and down the masts. This induced current diminishes the radiation. To ameliorate this defect, insulated masts have been proposed. In fact, insulated masts have been erected in two or three cases, but after being tried have ultimately been connected to earth. The Commissioners thought these failures with insulated masts were due partly to the large electrical capacity between the foot of the mast and the foundation, and partly to bad insulation. They therefore arranged to erect masts on platforms 16 feet above the ground, and made a search for good insulators of small dielectric loss at high frequency. This work was started at Finsbury Technical College by aid of a grant from the Research Department, was continued with more powerful plant at the Admiralty Signal School, Portsmouth, and was concluded at the Post Office arc station at Northholt. As a result, the Commission selected Norwegian granite for the bulky portion of the insulating foot, and porcelain 'cheeses' for the part requiring the greatest electrical strength. As a mast weighs 180 tons, and as the downward component of stress from the stays amounts to more than 100 tons in a gale, these insulators were put through crushing tests as well as high-frequency insulation tests before being accepted for use. The insulation is designed for a quarter of a million volts; the measured voltage during the test of the station has reached 185,000 volts without causing trouble.

The antenna is of novel construction. The traditional 'flat top aerial' consists of a large number of parallel wires running across horizontal triatics which are slung between pairs of symmetrically placed masts; the antenna at Rugby consists merely of one conductor running round nearly the whole circumference of the site by passing from one mast top to the next. The underlying idea is that the electrical capacity to earth of a conductor round the edge of a horizontal elevated area is little less than that of the whole area—that is to say, the interior area adds little to the capacity. A study of the formation of the radiant field enables one to extend the idea to the emission of energy from an antenna. The results achieved by the Rugby station in recent months justify this departure from established practice. Actually, the conductor running round the edge of the site is a composite one consisting of eight phosphor bronze wires arranged as the generators of a cylinder 12 feet in diameter, of which the axis is a steel rope. The wires are supported by the rope on spiders resembling bicycle wheels 12 feet in diameter, which are threaded at equal intervals upon the rope. This skeleton cylinder has an electrical capacity about equal to that of a solid continuous cylinder 7 feet in diameter. It is supported from the masts by halyards each worked by an electric winch near the bottom of the mast. The winches each possess a slipping device set at 10 tons, so that when in a gale or snowstorm the tension in a halyard reaches this figure, the halyard is automatically paid out until the tension is lessened. Rehoisting is done after the storm. Although there is about three miles of this composite conductor hanging in flat festoons each a quarter mile long at a height of 800 feet between the consecutive masts, the slipping device has saved the aerial from breakdown several times during the heavy weather of the past winter.

The method of supplying the antenna with oscillatory current is new and has been developed entirely within the Wireless Research Section of the Post Office. The source of the oscillations is a tuning-fork of frequency 2000 per second, sustained in vibration by a small triode valve such as is used in broadcast receiving apparatus. The sustaining current is distorted by applying a constant negative potential to the grid, and is magnified by passing through two small triodes in cascade with about 150 volts on the anodes. The eight-fold harmonic, that is to say, the oscillation of frequency 16,000 per second, is selected by resonance in a circuit of that natural frequency. The oscillatory current, still very feeble, is now passed through a three-step amplifier using T30 triodes with 1000 volts on the anodes; and the strengthened oscillations then pass to a 600-watt glass triode with 10,000 volts on the anode. The oscillations now go to the grids of three water-cooled metal-glass triodes, from the anodes of which 30 kilowatts of high-frequency power can be drawn. This power is applied to the grids of fifty-four similar water-cooled triodes, also working in parallel, which deliver about 540 kilowatts to the main high-frequency circuit. The anodes of these triodes are supplied with direct current at 10,000 volts by means of motor generators delivering 1000 to 1500 kilowatts at a voltage variable from 10,000 to 18,000 at will. The thermionic current may exceed 100 amperes.

It will be seen that the magnification of the original harmonic in the tuning-fork circuit is enormous; in fact, if we assume that the harmonic is only a few microwatts to start with, the magnification is of the order of magnitude 10^{11} (one hundred thousand million times). Obviously the screening of each circuit from the more powerful one succeeding it in the chain is of the utmost importance and must be carried out thoroughly.

At Rugby the fork has a frequency of 2000 per second and can be slightly adjusted by the inertia effects of small set screws in the prongs. When the temperature in the fork box alters by 1° C. the frequency of the final oscillations changes from 16,000 to 16,001·5, an amount imperceptible in the ordinary receiving apparatus of wireless telegraphy. The advantages of constant frequency are many; but the principal one is that exceedingly selective receiving apparatus can be employed, and all the refinements of accurate note tuning can be utilised, in order to prevent interference by other wireless stations working on nearly the same wave-length.

The design of the high-frequency circuits has presented many problems. These circuits comprise an inductance coil and condensers forming a closed circuit, which is connected on one hand to the anodes of the bank of fifty-four triodes, and on the other hand excites the antenna by means of mutual inductance.

The condensers must withstand a quarter million volts, must pass a thousand amperes at high frequency, and must not cause appreciable loss of energy. Condensers using thoroughly dry and clean oil would probably be best, as oil has a power factor less than one-twentieth of one per cent.; but, in order to save space, mica condensers were adopted, and these have a power factor less than a quarter of one per cent. They weigh more than ten tons. They are carried on a partial flooring about 20 feet above the ground floor on which the triodes stand.

The high-frequency coils in the closed circuit and in the antenna are made of stranded cable containing 6561 separately insulated copper wires of 36 gauge made up by twisting in threes. The coils are of various sizes; the antenna tuning coil, for example, consists of five flat spirals of eight turns each, the outer turn of each spiral being 15 feet 6 inches in diameter. The total weight of the coils is about 6 tons. They are carried on great beams of fir 20 feet above the level of the condensers, and are flanked by flying galleries along which men can pass for inspecting and adjusting the coils. This isolated position is chosen for the coils because the inductive effects of the large high-frequency currents they carry might lead to great energy losses and even to destructive rises of temperature, if any metallic masses were near. The roof trusses, the beams, the supporting framework of the coils, are all of selected wood. The most suitable wood for this purpose, that is to say, the wood with the smallest dielectric loss at high frequencies, is American white wood—a discovery made after long and close investigation in the Post Office laboratories.

The features above described are only a small selection of the numerous novel details with which the station abounds. But the space available permits of no further descriptions. There is just room for a few remarks upon the performance of the station as judged by observers who happened to be listening in at great distances during the tests of the past few months. For example, Newfoundland reported "signals thundering in"; New York said "signals readable through heavy atmospheric and jamming" and "copyable at 75 words per minute"; Cape Town reported "note good and steady"; in the Red Sea "Rugby effectively drowns all interference"; Java reported "key action excellent, frequency very constant"; Dutch East Indies said "Rugby splendidly received, far more distinct than any other European station." The Commander-in-Chief of the China station stated "all ships report note good, clear and steady." Among other Australian stations, Sydney reported "Rugby was only European station readable through atmospherics." These results, it should be noted, have been obtained with less than the full power available. For up to this date only eight of the twelve masts have been utilised on these telegraphic tests, owing to the other four masts being temporarily set aside for the trans-Atlantic telephony trials. The eight mast aerial will take only about 600 amperes without exceeding a voltage of 200,000, and at this rate only about two-thirds of the possible high-frequency power is being drawn from the triodes. But the complete equipment will doubtless be required to ensure communication at all hours of the twenty-four and under severe conditions.

The Stratigraphical Value of Micro-organisms in Petroleum Exploration.

By HENRY B. MILNER.

DURING the last decade of rapid development of technique of petroleum geology, problems of sub-surface stratigraphical correlation have forced themselves to the front, and have engaged the closest attention of geologists operating principally in late Cretaceous and Tertiary oil-fields all over the world. Formerly, and to some extent now, drillers' recognition and classification of rock-chips collected either from bailer or sample box served as a crude guide to underground conditions, though the limited vocabulary and superficial petrological knowledge of the average driller led to some quaint determinations and technically to still more fanciful structural interpretations. 'Gumbo' and 'shell,' for example, cover a multitude of geological shortcomings, while clay, shale, silt, and sand vary in diagnosis largely according to their degree of wetness when they arrive at the surface; anything productive of white powder to the bit is termed 'chalk,' and so on. Such casual nomenclature and equally casual sampling has been part of the long-established code of the oil-well driller, and sufficed until the advent of a more exacting petroleum geology signified the impending and much-to-be-desired change.

The closer study of productive rocks and sub-surface structures concerned with the preservation of petroleum pools has gradually led to the adoption of refined methods of differentiating and correlating strata, and of actual zoning within given formations deep down in the earth's crust; to this end the geologist has been thrown back on his first principles for the requisite desiderata and the aid both of palæontological and petrological data invoked. The frequent divorce between surface and sub-surface structures has to a large extent influenced this trend of field-technique, so that to-day no geologist worthy of the name would dream of interpreting his key-structures on the basis of mere lithological comparison and description, and certainly not in terms of drillers' evidence.

There are four principal methods now employed for studying sub-surface deposits from samples; three are direct, namely, micro-palæontological, microscopical (the examination of rock-cuttings under the microscope), and petrographical (correlation by means of 'heavy' mineral residues extracted from the sediments); the indirect method is that based on comparison of chemical analyses of subterranean (often connate) waters peculiar to certain porous formations. Of these methods, micro-palæontological investigations theoretically take precedence, though in practice this is not always substantiated if the necessary organisms are rare or wanting; the other methods, while capable of considerable precision and accuracy in competent hands, can only be regarded as local and confirmatory, though they are none the less valuable on that account. We dismiss them here, however, in favour of the much-debated problem of the value of micro-organisms as indexes not only of formations, but also of the more restricted developments such as oil-sands.

For obvious reasons, the macro-organic content of oil-well samples is seldom preserved, however prolific the rocks may actually be in molluscan or brachiopodan faunas, etc., though the recent introduction of the core-barrel, and particularly the use of the diamond drill, tend to heighten the possibility of whole shells reaching the surface. For the most part, however, samples from wells are obtained in a comminuted state, so that whatever fragile remains may be originally enclosed in the rocks drilled through, these soon succumb to the drastic action of the cutting bit. Therefore only the initially minute organic bodies stand a chance of escaping disintegration, and consequently their presence in any sample is of paramount stratigraphical importance. The micro-organisms which have received most attention in the course of exploratory work for petroleum are the Foraminifera, Bryozoa, Ostracoda, Radiolaria, Diatomacea, in that order of interest and importance; sponge spicules and echinoderm spines have occasionally proved useful 'indicators.'

It will be at once apparent that, quite apart from a special aptitude for palæontological investigation, the study of these micro-organisms constitutes the work of the specialist; accuracy in diagnosis, dependent on an intimate knowledge of the organisms as regards their morphology and variations, precision in assigning species or groups of species to particular stratigraphical horizons, and vision in detecting the subtler steps in the evolutionary chains involved: all these, among others, are the qualifications for this type of research. Specialisation is to-day the essence of progressive palæontology; the tendency to resort to 'species splitting' is a concrete result of this intensive study, of which there exists no finer example than contemporary work on Ammonoidea, an example fast being emulated by those engaged with micro-organisms, especially the Foraminifera. If, in view of much recent criticism, such technical procedure stands in need of independent defence, the work of certain expert palæontologists engaged on micro-palæontological research for a purely commercial end, coupled with the measure of success already realised, surely provides some vindication.

The organised investigation of foraminiferal assemblages as a basis of zonal stratigraphy, particularly as applied to sub-surface exploration for oil, has derived considerable impetus, if it has not actually evolved, from the intensive work of American palæontologists, more especially those in the employ of oil companies operating in the Gulf Coast region of North America. Considering the comparatively short time taken in developing necessary technique and accumulating the data to work on, the results already achieved are as surprising as they are significant. It is not as though the Foraminifera claimed at the outset of this intensive work a long-established reference library: on the contrary, the literature was scanty compared with that of many other fossil faunas, though the study had at least the example of Chapman and the inspiration of Cushman to guide it. In this connexion Dr. Dumble has written of these palæontologists that they "had very little knowledge to start with and had to build up their own methods" . . . while another expert, Miss H. T. Kniker, now states, "Examination of thousands of well samples has shown which species have limited vertical ranges and therefore which forams can be relied on to make correct stratigraphic correlations. We have learned to do this even on single species, and all of our correlations are made in the main on undescribed forms."

On the other hand, Dr. T. W. Vaughan says that it "appears very doubtful if there is a zonal distinction" of value among the Foraminifera for the discrimination of geological horizons. Further, he says, "In any event, 25 per cent. is about the maximum percentage of the smaller Foraminifera to which any stratigraphic significance may be attached, and it is more probable that the significant percentage is between 3 and 12 . . . 88 to 97 per cent. of the fauna . . . does not possess zonal value. . . . From available evidence, similar faunas of small Foraminifera are indicative rather of similarity in ecologic conditions than of identity in age." This has, on the whole, been the attitude of European oil geologists and certain palæontologists, who have not hesitated to criticise Cushman for his "tendency to split species to a much greater degree than has been done by others," to which 'splitting' he attributes a large part of his success in stratigraphic correlations on the basis of Foraminifera.

Such scepticism as exists regarding the correlative value of Foraminifera finds root in the general impression of the wide space and time distribution of these organisms, and is legitimately maintained so long as we view them from the point of view of world-distribution and their general literature. Until recently, in the absence of local terms of reference such as those emanating from the Texas laboratories, a Cretaceous or Tertiary species of Foraminifer, if still living to-day in the sea, has naturally been regarded as worthless from the zonal or even correlative aspect, and thus has Schuchert sought to explain the critical attitude of Vaughan and others. The whole point of the detailed work, however, is its intensiveness, as is the case with petrographic research under similar conditions, and the fact that local assemblages, rather than precise species, constitute the basis of study; zoning is effected by recognition of slight variations in morphology, ornament, etc., by creating new species or new varieties much as in the case of the ammonites previously cited. The question of percentage of living Foraminifera in any faunule, a point on which Vaughan has laid some stress, is entirely subordinated by the specialists to the question of the actual species present and their manner of combination in any particular faunule. According to Cushman, "the time value of forams . . . is entirely dependent on this splitting (of species), for putting together species which are of short range into one long one would entirely defeat the purpose of close correlation."

Mesozoic and Cainozoic Bryozoa have long been recognised as important indexes of horizon, though in the Gulf Coast oil-field region they are of far less frequent occurrence than the Foraminifera. Schuchert has no doubt whatever regarding their true value for sub-surface correlation, and advocates strongly their use on the basis of Canu and Bassler's classical work. According to Bassler, of the two orders of Bryozoa, namely, Cyclostomata and Cheilostomata, the former has potentially little value in sub-surface work, from the fact that precise diagnosis rests on the preservation of the ovicell, almost an impossibility with oil-well samples. The Cheilostomata, however, can be determined from minute fragments and all characteristics can be ascertained, even though only a few individuals or zoœcia are preserved. They tend to indicate limited time-zones over wide areas, and various structures shown on the zoœcium are significant of depth of water, temperature, nature of ocean bottom and character of marine habitat. Add to this that the calcareous structures are generally highly ornate and variable in that ornament, and the possibility of treating them on the same intensive lines as the Foraminifera is apparent. Canu and Bassler describe 742 forms of North American Early Tertiary Bryozoa in their work, many of which are beautifully illustrated.

Ostracods, as we now realise from the Wealden formations of Great Britain, are potentially valuable as time-indicators, though here again much intensive work has yet to be done before they are fully appreciated. Analysis of well-cuttings from the Gulf Coast region reveals their presence and significance, and Schuchert has directed attention to the highly ornate forms of the valves of these minute crustacea, but the Texan species have yet to be worked out. Ulrich and Bassler have demonstrated their potentiality as guide-fossils to limited portions of certain American palæozoic formations, which research at least forms an adequate basis of future investigation.

In so far as Radiolaria, Diatomacea, sponge spicules and echinid spines are concerned in sub-surface work, at the present time we must regard them in much the same light as petrographers regard sporadically occurring mineral species in oil-well samples: of local and possibly direct differential or confirmatory value. As Schuchert says, "each worker must learn what local dependence can be placed upon these isolated occurrences."

Thus it is clear that while a degree of scepticism regarding the use of micro-organisms in stratigraphical correlation may still be maintained on certain technical grounds, the results so far achieved by the American school are worthy of general attention. It is yet one further example of how much the pure science may owe to one phase of its economic application. Readers are referred to the volumes of the American Association of Petroleum Geologists for 1924 and 1925 for several important papers in connexion with the above, and particularly to Schuchert's excellent summary of the subject in volume 8, 1924, pp. 539-553; these volumes are available for reference in the Science Library at South Kensington.

Sterility and Rejuvenation.

It has been known for a long time that the sexual activity and characteristics of the individual depend on the presence of the sexual glands in an actively functioning condition. Their removal or atrophy as in old age leads to loss of sexual vigour together with changes in the secondary sex characters which may result in the development of a neutral individual, or even in the assumption of certain of the characteristics of the opposite sex, according to the species studied.

Various methods have been used for supplementing a deficiency in the individual's own secretions, such as grafting glands from another member of the same or an allied species, the injection of extracts of the glands, and in males, the ligature of the duct which conveys the sperm from the testes to the urethra: the latter operation (vasoligation) has been performed on the assumptions that the secretions on which the secondary sex characters depend arise from the interstitial cells of the sex glands, and that ligature of the duct, by causing atrophy of the sperm-producing cells, will allow the interstitial cells to hypertrophy, owing to the increased space and nutriment provided. The return of the secondary sexual characteristics does not imply a return of fertility, since, for the latter, the sex glands themselves must be actively functioning *in situ*: that is, atrophied or diseased glands must be reactivated. Grafting alone, therefore, will not restore fertility, except, perhaps, in the case of the female, unless the animal's own sex glands are also reactivated or rejuvenated by means of the secretions from the graft.

Sterility in the female can be caused not only by atrophy (or removal) of the ovaries, but also by persistence of the corpora lutea. During pregnancy these bodies persist and prevent ovulation, and occasionally this occurs apart from pregnancy as a pathological phenomenon and produces sterility, fertility being restored by their removal. It is of interest, in connexion with recent work on the isolation of an ovarian hormone, that W. P. Kennedy (*Quart. Journ. Physiol.*, 1925, vol. 15, p. 103) has found that cold saline extracts of fresh frozen or dried corpora lutea, intravenously injected, prevent ovulation in rabbits: the effect persists for several months after a number of injections. Continued injections cause degenerative changes, not only in the ovaries, where the number of Graafian follicles is reduced, these changes being probably specific, in part at any rate, but also in the liver and adrenal glands, where the effect may be due to the injection of toxic foreign proteins, or alternatively to changes in the carbohydrate metabolism produced by the degeneration of the ovaries. Since extracts of ovarian tissue are being used for the production of the opposite effect, namely, the return of fertility and the secondary sexual characteristics, it is obvious that care should be taken to use only glands in which there are no corpora lutea, or from which these bodies have been removed, for the preparation of such extracts.

The main interest of some recent work by Steinach and his collaborators on the ovarian hormone appears to lie in the true reactivation or rejuvenation of the ovaries of senile animals (E. Steinach, H. Heinlein, and B. P. Wiesner, *Akad. d. Wissensch.*, Wien, 1925, No. 19, p. 189). These investigators have injected extracts of ovary and placenta into animals castrated both before and after puberty, and into senile specimens, using the vaginal smear method to follow the return or not of the œstrual cycle. Extracts from either source favour the development of the secondary sexual characteristics, but only those from the ovary arouse the sexual cycle. In all cases the normal condition of the animal is restored. The effects observed are produced by only a few injections in young animals, and occur within a few days in both rats and guinea-pigs. The fertility of stock female rats ceases when they are about eighteen months old, and the sexual cycle vanishes a few months later. Injections now restore their vigour and produce a reappearance of the œstrual cycle, the latter continuing regularly after the injections have been discontinued: in other words, the ovaries are reactivated. The next step should be the application of a purified ovarian extract in human therapeutics.

Most of the work on rejuvenation has been performed on mammals. Crew has turned his attention to birds. He has found (F. A. E. Crew, *Proc. Roy. Soc. Edin.*, 1925, vol. 45, p. 249) that unilateral vasoligation in senile cocks is not accompanied by any rejuvenating effect. The only change observed microscopically in the testes was continuation of the degenerative processes seen to be occurring at the time of the operation in a preparation of a portion of the testis on the side of the ligature removed for histological study. No change was observed in their plumage. On the other hand, this author has been successful in obtaining rejuvenation in birds of both sexes by the administration of dried thyroid (*ibid.* p. 252). The doses given corresponded to 0·2-0·8 mgm. iodine daily. The first effect noted was moulting by all birds, and this was followed by an increased egg production by the females, the eggs being fertilised by the males; none of the former, however, became broody. The plumage of cock-feathered cocks became henny, but that of the hens and of hen-feathered cocks remained almost unchanged. The author considers that these results can be explained on the assumption that the sexual glands exert their influence on the plumage, not directly, but by means of an action upon the thyroid. Thus there are two classes of fowls: those whose thyroid responds to a certain low degree of stimulation from the testes with the production of cock-feathering, and to a higher degree of stimulation from the ovaries with the production of hen-feathering; and those whose thyroid responds to the greater degree to testicular stimulation, the cocks thus being hen-feathered. The difference between the thyroids of the two classes is a genetic one. The administration of thyroid can only produce a marked effect on those birds the thyroid gland of which is not normally fully stimulated, that is, cocks with cock-feathering.

Obituary.

PROF. K. LHOTÁK.

ON January 27 there died in Prague, at the relatively early age of forty-nine years, Dr. Kamil Lhoták, professor of pharmacology and pharmacognosy and director of the institute for the said sciences in the Charles' (Bohemian) University. Prof. Lhoták published many scientific investigations in physiology, in which he had a sound training, in pharmacology and pharmacognosy, but the most prominent are his researches on the active substances of digitalis (digitalin, digitoxin). Lhoták also published the first Bohemian treatise on pharmacognosy (1908); but especially noteworthy is his voluminous "Pharmacology" (1924), including also the theory and art of prescribing.

As a teacher Prof. Lhoták turned his attention to the practical work of students in his laboratory, based on his experience in England. But one of his greatest merits, from the international point of view, is that he gave an impulse to the reprinting of the scientific papers of the Bohemian genius Ian Purkyně (Purkinje), who founded the first physiological research laboratory in Germany, so that his researches, scattered in less accessible journals, could become accessible to the scientific world. They are published by the Bohemian Society of Medicine, together with two volumes of the very interesting correspondence of a many-sided scientist. Prof. Lhoták was not only of a real, deep scientific nature, but also a great connoisseur of painting, music, and the world's literature. He was a member of the Bohemian Royal Society of Science, the Bohemian Academy of Science and Art, the Ministerial Institute for the Examination of Medicinal Matters, and of the State Hygienic Council, etc.

BOHUSLAV BRAUNER.

WE regret to announce the following deaths:

William J. Green, a pioneer in horticultural investigations and for many years horticulturalist at the Ohio Experiment Station, aged seventy-six years.

A. Witz, formerly professor of physics in the Catholic University of Lille, corresponding member of the Paris Academy of Sciences, who was known for his work on thermodynamics and on internal combustion engines, on January 25, aged seventy-seven years.

News and Views.

The Prime Minister is one of the all too rare administrators who fully appreciate the importance of the part played by science in modern life, and his sympathies in this connexion found expression in the address with which he opened the Optical Convention at South Kensington on April 12. In pointing out the vital rôle of optical science in the everyday life of peace no less than of war, he gave as a homely but arresting illustration the fact that even a glass of beer depends for its satisfactory manufacture on the use of at least three optical instruments—the microscope, the polarimeter, and the refractometer. He added that in the last century British optical work was predominant in the world's industry, but during its closing years the industry was nearly overwhelmed by foreign competition, especially on the part of Germany. In that country optical manufacturers at that time enjoyed three great advantages: (1) a stronger tendency amongst German than among British industrialists to invoke the aid of scientific research; (2) the demand for optical goods created by the existence of a large standing army; and (3) a protective tariff. At the end of the War, which demonstrated the danger of allowing this key industry to atrophy, the Government of the day decided that its fate must no longer be left to chance, and introduced the two remedies of 'safe-guarding' and a money grant allotted through the Department of Scientific and Industrial Research. Since the War, several new difficulties have had to be faced by the optical industry—a general depression of trade, large surplus stocks of optical material, and the abnormal rates of exchange which made foreign competition acute. In the Prime Minister's view, the Exhibition indicated that in spite of these difficulties the quality of British optical manufactures has again been raised to the highest level of achievement.

Among the varied topics touched upon by the Astronomer Royal in his presidential address to the Optical Convention, delivered on April 12, not the least interesting was the part which British optical designers and manufacturers have played in providing the instruments with which outstanding discoveries have been made in the history of astronomy. Thus the fact that cross-wires could be inserted in the Kepler telescope was first noted by Gascoigne, the possibility of making achromatic combinations of crown and flint glass was discovered by Chester Moore, and re-discovered and published by Dollond, and for a time the manufacture of these was an English monopoly; but in the earlier part of the nineteenth century the industry was crushed by an exorbitant tax on flint glass. In due course this was removed, however, and in the second half of the century British opticians played their part in the provision of objectives of increasing size. A 40-inch refracting telescope is now being constructed in England for Russia. As regards reflecting telescopes, the art of grinding and polishing mirrors was due to Newton, and the parabolic mirror to Hadley. The great development of the reflecting telescope in the second half of the eighteenth century was the work of Sir William Herschel The silvered mirror was a German invention, but was first constructed on a large scale by Dr. Common and Sir Howard Grubb. Good work by British firms was also described in connexion with astronomical photography: for example, an English amateur, Franklin Adams, with a lens made by H. D. Taylor, has photographed the whole sky in 206 exposures. As regards instruments for stellar spectrography, it is of interest to learn that the échelon spectroscope is made only by a British firm.

The breakdown in the negotiations between Mr. John D. Rockefeller and the Egyptian Government over the terms of the proposed gift by the former of a sum of ten million dollars for the construction and maintenance of a new archæological museum and institute at Cairo does not come altogether as a surprise. For some time past the Egyptian public and its representatives have tended to become increasingly assertive of their prerogatives in relation to foreigners engaged in archæological research within their jurisdiction. The official action which interrupted the excavation of the tomb of Tut-ank-Amen, merely gave effect to a widespread and growing feeling among the Egyptians which was brought to a head by methods of securing publicity which many archæologists and others felt to be ill-judged. Undoubtedly among the extremists some would have wished to see Egyptian archæology for the Egyptians as the ruling principle.

In the present case it has been stated that difficulty has arisen over the composition of the committee in whom control of the museum and institute is to be vested for a period of thirty years. While Mr. Rockefeller has explained that this provision is to allow time for a generation of trained Egyptians to grow up who would be fully qualified to take over the custody of the national treasures, the Egyptian Government objects to management by a committee on which two Englishmen, two Frenchmen, and two Americans would sit with two Egyptians only, even though one of these should be the chairman of the committee. Apart from the desire of every archæologist that the advantage to scientific research which must follow from Mr Rockefeller's munificent gift should not be endangered, the importance of Egypt in the history of civilisation gives it a position which is unique and of universal moment. Its records and cultures justly demand the highest skill in investigation, in interpretation, and in preservation To take measures to secure such skill is a duty incumbent on those in authority, which transcends the bounds of nationality.

The airship *Norge* arrived at Pulham on April 11 from Rome, en route for Oslo, where a mooring mast is available, and Spitsbergen, where a mast and partial shelter are being prepared. From Spitsbergen an attempt will be made to transnavigate the north polar regions. The *Norge* was built to the designs of Col. Nobile, in the Italian State Airship Factory at Rome. It is a semi-rigid airship of displacement 20 tonnes, length 106 m., height 26 m., width 9 5 m., power 3 × 190 kw., maximum speed 100 km. per hour. The direct distance from Rome to Pulham is about 1250 km., but the actual course through the Valley of the Garonne, between the Pyrenees and the extensive highlands of Southern France was about 2250. Thanks to favourable meteorological information, the airship did not re-fuel at Rochefort on the west coast of France, but continued the flight to Pulham, covering the 2250 km. without stop in 30 hours, giving an average speed of 75 km. per hour, a very satisfactory performance. The co-latitudes of the most northerly points of Spitsbergen and Alaska are about 10° and 20°, and the polar distances are therefore about 1000 km. and 2000 km. respectively. The transnavigation of 3000 km. of polar wastes without the possibility of intermediate landing and without meteorological information seems a bold undertaking; but it is not in the nature of pioneers to count risks in relation to the results obtainable, and it may be hoped that a combination of favourable circumstances will bring the maximum possible success to these adventurers in the most modern style.

ON April 8 Mr. S. Mavor read a valuable paper to the Institution of Electrical Engineers on the applications of machinery at the coal face He pointed out that, in mining, labour accounts for 75 per cent. of the total costs of production. Many palliatives of the existing situation have been suggested, but, apart from increasing the number of working hours, the only way to effect a substantial increase of the output per man and a consequent reduction of costs is the systematic application of labour-saving machinery. In England the proportion of machine-cut coal to the total output is 14 per cent., but in Scotland the proportion is 47 per cent. The difference is due partly to economic pressure compelling a reduction in the costs of production, but mainly to the fact that electricity can be applied safely at the coal face in most of the Scottish mines. In Scotland more than 93 per cent. of the coal cutters in use are electric, the remainder being compressed air machines

A VERY important factor in the rapid extension of machine mining in the United States is that the comparative freedom from gas in the mines renders electricity permissible In Scotland, however, the rate of increase during recent years in the proportion of machine-mined coal has been even greater than in the United States. Mr Mavor advocates intensive mining on the unit system. The methods must be standardised and a daily cycle of operations established, so that the work becomes comparable to repetitive processes in workshops The principles which have so greatly increased the productivity of labour in other industries should be applied to mining organisation and operations. The output per underground worker is too low, therefore too many men are in the industry, and hence wages are low and costs are high. By mechanical and electrical aids to production the output per man can be increased, wages and the status of the miner can be raised, and the cost and price of coal can be reduced.

THE intimation that Mr. Alan A. Campbell Swinton is retiring from the electrical and general consulting engineering practice that he has carried on for the past thirty-seven years at 66 Victoria Street, Westminster, will not come as a surprise to those who are acquainted with his activities in other directions. Last year his failing health caused grave anxiety to his friends, and they will be glad to know that it is now restored sufficiently to enable him to continue his special consulting work and his electrical and engineering directorships. His address, as formerly, will be 40 Chester Square, S.W.1. There are few men who have maintained touch for so long and so intimately with so many learned societies, technical institutions, social clubs, and commercial administrations. It is of interest to recall that Mr. Swinton was one of the earliest workers with X-rays; and we believe that the X-ray photograph of a human hand, published in NATURE of January 23, 1895, with an article by Mr. Swinton and a translation of Prof. Rontgen's paper "On a New Kind of Rays," was the first radiograph reproduced in Great Britain. The lecture which Mr. Swinton gave at the Royal Society of Arts a few months ago upon persons of distinction in the world of science and engineering, will always be remembered as a valuable and amusing contribution to the history of the scientific men of his time His own part in the advance of electrical science and electrical industry, as a liaison officer between scientific, engineering, and commercial enterprises, has been of considerable value, and good wishes from all these centres of progress will go with him in the comparatively restricted activities which he now contemplates.

THE problem of stage lighting, discussed at the meeting of the Illuminating Engineering Society on March 29, is one in which artistic perceptions and knowledge of scientific principles need to be carefully blended. Mr. H. Lester Groom, in an introductory paper, reviewed recent progress in the design of stage-lighting apparatus, referring particularly to the 'cyclorama' as one of the most important developments during recent years. By its aid the stage is provided with an artificial horizon, and clouds, storms and atmospheric phenomena can be imitated with a fidelity unrealisable in the past. It was mentioned that, on the Continent, cinema theatres are now beginning to introduce such apparatus as an auxiliary to the showing of films, and it forms a valuable aid, provided the dimensions of the stage enable a proper perspective to be obtained. The consumption of energy for the complete apparatus ranges from about 20 to 100 kw. according to the size of the theatre. Other interesting applications of scientific principles include the use of changing coloured light to bring about apparent transformations in scenery, the applications of ultra-violet light impinging on dresses of dancers impregnated with fluorescent solutions, and the possibility of projecting luminous stage scenery instead of using painted canvas. Recently devised apparatus enables the colours to be blended and graduated at will, and any design gradually built up to suit the scenic artist; in addition, the method has the advantage that the contrasts are more vivid—in the same manner as occurs when a lantern slide is substituted for a photographic print. The discussion raised a number of interesting points, such as the desirability of promoting highly diffused illumination and 'soft' shadows, and the difference in the sharpness of definition of objects illuminated respectively by red and blue light.

In view of criticisms levelled against the proposed expenditure of the Boxer indemnity on Chinese education, Mr. Harold Balme's account of educational progress in China under the Republic, in the *Nineteenth Century and After* for April, is opportune. Under the old regime the enthusiasm for learning which was characteristic of the Chinese, or at least such of them as had the leisure for its pursuit, was accompanied by a supreme contempt for the knowledge of the foreigner. Owing to several factors, and particularly to the influence of missionary schools and colleges and of such Chinese as have been trained abroad, this spirit has now disappeared. The old private school with its purely literary training was abolished in 1902. Its place has been taken by 200,000 Government and private schools of all grades, offering modern courses to some seven million scholars of both sexes, and staffed with teachers mostly trained along modern lines. Since 1912, when the new Republican Government reformed the educational system, education has gone forward by leaps and bounds. The difficulty of securing trained teachers has been one of the gravest of a number of causes of difficulty; but this is now being met by the output from the training colleges, of which Mr. Balme speaks highly from personal knowledge. Associations for the reform of education have been formed throughout the country, of which the most important is the National Association for the Advancement of Education. It is significant that these associations have welcomed and invited expert advice from outside China—a fact which augurs well for any system of co-operation between West and East on a permanent basis which it may be possible to set up in the future.

What is described as the greatest live game collecting expedition ever attempted is being sent out by the Smithsonian Institution, in co-operation with Mr. Walter P. Chrysler, the motor car manufacturer, to British East Africa, for the primary purpose of obtaining living examples of African big game and other animals for exhibition in the National Zoological Park at Washington. The expedition will be under the leadership of Dr. William M. Mann, the Superintendent of the National Zoological Park; and other members of the party include Mr. Arthur Loveridge, of the Museum of Comparative Zoology at Harvard, who, as a former game warden in Tanganyika Territory for eight years, possesses a peculiarly intimate knowledge of the country; Mr. S. Haweis, and Mr. Frank Lowe, one of the keepers at the Washington Zoo, as well as artists, photographers, and a kinematograph operator. Among the animals to be sought for are giraffe, black rhinoceros, sable antelope, topi, hartebeest, zebra, guereza monkey, Syke's monkey, lion, eland, and other antelopes and gazelles. Birds and reptiles will also be collected. Opportunity will be taken to make as extensive collections as possible, for scientific purposes, of the general fauna of the country, and valuable results from this point of view may be expected. The expedition will land at Dar-es-Salaam and proceed inland to Tanganyika Territory, and it is expected that at least five or six months will be spent in the field. Memories of the results obtained by the Roosevelt Expedition to Africa in 1909, sent out also under the auspices of the Smithsonian Institution, raise expectations of equally successful results from the Smithsonian-Chrysler Expedition.

In February last it was decided that an address should be presented to Sir Howard Grubb in recognition of his skill and long-continued labours in the production of large objectives for astronomical instruments. Many of these are now famous: they include the 28-in. at the Royal Observatory, Greenwich, the 27-in. at Vienna, the 26·5-in. at the Union Observatory, Johannesburg, the 26-in. at Greenwich, the 24-in. at Cape of Good Hope and also at Oxford, and eight (of the eighteen required) 13-in. objectives for the Astrographic Catalogue and Chart, besides the reflectors—the 40-in. at Simeis, the 24-in. at Edinburgh, and the 24-in. at Daramona. Accordingly an address was drawn up congratulating Sir Howard Grubb on the approach of his eighty-second birthday, in which the signatories recalled "with admiration his devoted application of his resourcefulness and ingenuity to the development of the instrumental equipment of astronomers through more than sixty years." Especial reference was made to the service which Sir Howard Grubb's firm has rendered to science "in the provision of suitable object glasses, and of the refined clockwork needed for the accurate movement of the telescopes," in order to undertake the photographic survey of the heavens. The address was signed by the Astronomer-Royal and the leading representatives of astronomy and astrophysics in Great Britain.

The council of the Royal Anthropological Institute has awarded the Huxley Memorial Medal to Dr. Aleš Hrdlička of the Smithsonian Institution, Washington, and has invited him to deliver the Huxley Memorial Lecture of the Institute for 1927. This invitation Dr. Hrdlička has now accepted. Of the wisdom of the award there can be no two opinions. Dr. Hrdlička has a world-wide reputation as one of the foremost physical anthropologists of the day, and is one of the outstanding men of science in America. His researches on the origin of the American Indian and on the antiquity of man in America are mainly responsible for the present position of our knowledge relating to these important problems, and it is due to his critical and careful examination of the evidence bearing upon the age of the ancient human remains found in America that the extravagant claims for high antiquity which have been put forward from time to time have been demolished. During last year Dr. Hrdlička visited the principal sites in India, Java, Australia, and South Africa on which remains of early man have been discovered, and gave an account of the results of his tour to the Royal Anthropological Institute while passing through England on his return to the United States.

MR. F. W. LANCHESTER has been awarded the gold medal of the Royal Aeronautical Society in recognition of his pioneer work in aviation, and has also been elected an honorary member of the Society.

PROF. CHARLES FABRY, professor of physics at the Sorbonne, Paris, will deliver the eleventh Guthrie Lecture of the Physical Society of London on April 23. The title of the lecture will be "The Absorption of Radiation by the Upper Atmosphere"

SIR JOHN ROSE BRADFORD, formerly professor of medicine at University College, London, has been elected president of the Royal College of Physicians, in succession to Sir Humphry Rolleston, who retires after four years of office.

THE sixteenth annual May Lecture of the Institute of Metals will be delivered on May 19 at the Institution of Mechanical Engineers, Storey's Gate, Westminster, London, S.W.1, by Prof. H. C. H Carpenter, professor of metallurgy at the Imperial College of Science and Technology, South Kensington, who will take as his subject, "Single Metallic Crystals and their Properties."

AMONG the changes in place-names announced in recent years by the Soviet Government we notice, in the *Weekly News Bulletin*, No. 34, of the U.S.S.R. Society of Cultural Relations with Foreign Countries, that Nicholas Land, which was discovered in 1913 to the north of Cape Chelyuskin, in future is to be known as Northern Land and the adjoining Tsarevich Alexis Island is to be Little Taimir.

THE Council of the Iron and Steel Institute has awarded the Bessemer Gold Medal for 1926 of the Institute to Sir Hugh Bell, Bart. The medal, the award of which is made in recognition of outstanding services in the advancement of the art of the manufacture of iron and steel, will be presented to Sir Hugh Bell at the annual meeting of the Institute on May 6, by the incoming president, Sir W. Peter Rylands.

IT is stated in *Science* that the John Fritz Medal Board of Award, representing the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, the American Society of Mechanical Engineers, and the American Institute of Electrical Engineers, has presented the John Fritz gold medal to Edward Dean Adams, "engineer, financier, scientist, whose vision, courage and industry made possible at Niagara Falls the birth of hydro-electric power."

THE annual meeting of the British Science Guild will be held at the Mansion House, London, E.C.4, on April 29, at 4.30 P.M., under the presidency of Lord Askwith. Addresses will be delivered by Sir Richard Redmayne on the future of the coal mining industry; by Dr. E. F. Armstrong, managing director of the British Dyestuffs Corporation, Ltd., on dyestuffs; and by Capt. P. P. Eckersley, chief engineer of the British Broadcasting Company, on broadcasting and the electrical industry in Great Britain.

THE Academy of Natural Sciences of Philadelphia announces that the 1926 Hayden Memorial Geological Award will be made to Dr. William Berryman Scott, professor of geology at Princeton University, in recognition of his "many researches and publications in the field of vertebrate paleontology." The award, which consists of a gold medal, is made once in three years, and was founded as a recognition of pre-eminent work by "publication, exploration, discovery, or research in the sciences of geology and paleontology."

WE have received from the British Museum (Natural History), South Kensington, London, S.W.7, some further series of picture post-cards which are admirably executed by the three-colour process. Set E. 39 portrays *Papilio dardanus* and its four remarkable forms of the female butterfly: E. 40 illustrates some exotic moths, E. 41 exotic beetles, and E. 39 some of the more interesting and striking Hymenoptera. Each of these sets comprises five cards and is priced at 1*s*. The cards are of very definite educational value, being prepared under the supervision of specialists in the subjects dealt with, who are also responsible for the explanatory letterpress. A great variety of other subjects are described and illustrated in the same manner, and the cards are obtainable from the Museum or from London booksellers.

HIS Majesty the King has approved the following awards of the Royal Geographical Society:—*Founder's Medal*: to Lieut.-Col. E. F. Norton for his distinguished leadership of the Mount Everest Expedition 1924 and his ascent to 28,100 feet, *Patron's Medal*: to Sir Edgeworth David for his work on the Funafuti atoll, and with Sir Ernest Shackleton's Antarctic Expedition of 1907-9, as leader of the first ascent of Mount Erebus and of the party which first visited the South Magnetic Pole. The Council has made the following awards:—*Victoria Medal*: to Dr. John Ball for his desert surveys and memoirs on the geography of Egypt; *Murchison Grant*: to Mr. Frank Debenham for his contributions to the scientific exploration of the Antarctic; *Back Grant*: to Afraz Gul for his surveys in Central Asia and Hunza, *Cuthbert Peek Grant*: to Major Kenneth Mason to assist his further exploration of the Himalaya; *Gill Memorial*: to Dr H. Gordon Thompson for his journey on the Tibetan and Mongolian borders of China with Brig.-General George Pereira.

THE fifth report of the Executive Committee of the Universities' Library for Central Europe, covering the period April 1924 to March 1925, shows that there is a demand in every country in Europe for English books and a desire for information as to English culture and ideals. The Committee has striven with some success to satisfy the calls which have been made, but it is evident that it is hampered to some extent by want of funds. The most valuable service performed by this Committee appears to be in filling gaps in serials occasioned by the breakdown of exchanges during the War period and the satisfaction of definitely ascertained wants—but a certain amount of forwarding and reciprocal exchange work was also undertaken. We read, for example, of 400 volumes of German classics being forwarded to Berlin. During the year under review gifts of books and periodicals valued at 150*l.* were received by the Committee and sent abroad. The work of this Committee deserves increased support.

A useful list of 138 atlases, maps, and books of geographical interest has just reached us from Mr. F. Edwards, 83A High Street, Marylebone, W.1. Its number is 486, and it supplements Catalogue 475—"Old Time Cartography." It can be obtained free upon application to the publisher.

Applications are invited for the following appointments, on or before the dates mentioned:—Two laboratory assistants in the biochemical department of the Low Temperature Research Station, Cambridge—The Superintendent of the Station, Downing Street, Cambridge (April 24). An assistant bacteriologist at Queen Mary's Hospital for Children, Carshalton, for research work on acute rheumatism in children—The Clerk, Metropolitan Asylums Board, Victoria Embankment, E.C.4 (April 26). A principal of the South Staffordshire Mining Schools—The Director of Education, County Education Offices, Stafford (April 27). An assistant inspector under the Ministry of Agriculture and Fisheries, in connexion with agricultural and horticultural education and research—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (May 3). A lecturer in charge of the Economics and Commerce Department of University College, Southampton, and an assistant lecturer in geography in the same institution—The Registrar (May 3). A probationer naturalist and a technical assistant under the Fishery Board for Scotland—The Secretary, Fishery Board for Scotland, 101 George Street, Edinburgh (May 9). A male assistant superintendent of traffic (Class II.) in the London Telephone Service, and a male assistant traffic superintendent in the Provinces, G.P.O.—The Secretary, Civil Service Commission, Burlington Gardens, W.1 (June 2) A director of the Amani Institute, Tanganyika Territory—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (August 1). Two temporary research assistants under the Foot-and-Mouth Disease Research Committee—The Secretary, Foot-and-Mouth Disease Research Committee, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W 1. A director of research for the Linen Industry Research Association—The Secretary, Research Institute, Lambeg, Belfast.

Our Astronomical Column.

Ensor's Comet.—Mr. S. Seliwanow, of the Observatory of the Russian Society Mirovédénié, Leningrad, writes to say that the Society organised an ascent in a captive balloon on the night of February 22-23 in which he took part. He passed low clouds at a height of 350 metres; above them the air was clear. Using a powerful binocular, the comet was located after a twenty minutes' search south-west of ε Equulei It appeared as a dim indistinct spot 8′ to 10′ in diameter, of about the fifth magnitude. The time was $3^{h}\ 22^{m}$ U.T., the height 700 metres A faint tail, 20′ long, was suspected. A later ascent by G. A. Langé and B. W. Okunev confirmed these results.

Search was made with a 175 mm. refractor on March 6 and 7 without result.

Dr. W. H Steavenson notes that these results, combined with his own, appear to fix the collapse of the comet's light as having occurred between February 23 and 28.

A slide from the Bergedorf photograph of March 16 was shown at the meeting of the Royal Astronomical Society on April 9. It showed a tail 30′ in length, forking into two branches about 20′ from its eastern extremity. The tail made an angle of 80° with the radius vector.

Brilliant Solar Outburst.—At the meeting of the Royal Astronomical Society on April 9, Mr. Evershed showed some spectroheliograms of the sun taken by Dr. Royds at Kodaikanal on Feb. 22, which indicated that an extremely brilliant chromospheric outburst occurred over a sunspot during the course of the observations It was photographed both in hydrogen and calcium light. Some similar outbursts in the past were referred to, including that observed by Hodgson and Carrington in 1859, another observed by Young in 1872, and one observed by Mr. Evershed in Kashmer. Mr. Evershed suggested that the outburst resembled on a small scale those that occurred in novæ. There was the same reversal of lines, and the same indication of rapid radial motion On some of the occasions quoted, magnetic fluctuations have been observed simultaneously with the outburst; he suggested that the magnetic traces should be examined on this occasion. Mr. Newton noted that there was a large magnetic disturbance on February 23, and promised to examine the record of the preceding day.

Measures of the Sun's Diameter.—The facts that the curve of sunspot activity bears some resemblance to the Cepheid light curve, and that a widely held explanation of the variability of the latter stars is that their diameters pulsate, render it quite a pertinent inquiry whether any similar pulsation can be detected in the sun's diameter. G. Armellini, in *Astr. Nach.*, No. 5419, describes a research of this kind made at the Campidoglio Observatory, Rome, from 1877 to 1900, some six hundred measures being made each year by three different observers. The method of projection on a white screen was employed. The mean horizontal semidiameter of the sun for the whole series is 961″·18, agreeing with that used for the bright limb in the "Nautical Almanac" (but not with that of Auwers, corrected for irradiation, which is 959″·63). The measures when plotted by annual means lie on a sinuous curve with maxima in 1878 (961″ 46) and 1891 (961″·76), minima in 1886 (961″·00), and 1897 (960″·70). The fluctuations are large enough to suggest a real change, but the period dealt with is too short to assert with confidence that it is connected with the sunspot variation. Results for the years following 1900 are promised shortly.

Research Items.

The Stone Age of Ceylon.—An important study of the stone implements which have been found in Ceylon, and of the evidence for their antiquity, by Dr. Fritz Sarasin, appears in Nos. 1-2 of vol. 36 of *L'Anthropologie*. As in the case of other finds in subtropical or tropical Asia, owing to the absence of such indications of age as is afforded by glaciation in western Europe, or the presence of extinct fauna, it is difficult to correlate the implements with the recognised phases of the Stone Age in Europe. Of the views that have been put forward by various writers, that which assigns these implements to the Neolithic period is scarcely likely to be correct. It is precluded by the absence of polished implements, of pottery, and above all of the typical neolithic axe, both from the implementiferous strata in the caves which have been explored, and from the similar surface finds. The author's view is that they must be assigned to the Upper Palæolithic. This is confirmed by the results of a recent visit to Ceylon in 1924 to test the conclusions put forward by Mr. Wayland that he had discovered implements belonging to the Lower Palæolithic. The resemblance of certain types to Early Palæolithic implements is accounted for in part by the material employed, which does not lend itself to the manufacture of the smaller and more delicate type; in part by a sporadic survival of a ruder form in contemporary use with the later type, as commonly happens; and in some cases by the misinterpretation of nuclei as implements. Further, only isolated examples of the so-called early types are found instead of series of implements which could be referred as a whole to any one of the Early Palæolithic cultures, as should be the case had they really belonged to such a culture.

Pottery Styles and Periods in Peru.—Mr. A. L. Kroeber describes in vol. 21, pts. 5 and 6, of the *University of California Publications in American Archæology and Ethnology*, two more of the collections of Peruvian pottery made by Dr. Uhle and now in the University Museum—one from Moche and one from Supe. These Dr. Uhle himself assigned to four periods at Moche. Proto-Chimu, red and white ware associated with long skulls, Tiahuanaco and Epigonal; post-Tiahuanaco, black ware and, possibly separate, red, white, and black ware; and Chimu, black ware with Inca admixture. In the course of his analysis of this material to test Uhle's conclusions, Mr. Kroeber discusses the question of how far distinct style is necessarily proof of distinct period in time—a question of considerable general interest. He finds that, so far as pre-Hispanic America is concerned, there is abundant evidence that distinct styles did repeatedly co-exist. Thus at Pachacamac, Uhle's Tiahuanaco and Epigonal, though valid stylistically, are found in association, and good and debased Tiahuanaco are found in the same household. As regards periods traceable through a large part of Peru, not more than four are at present recognisable These are: pre-Tiahuanaco, including proto-Nazca, proto-Chimu, early Ancon (shell-mound), and probably Supe shell-mound styles, advanced in development in northern, and backward in central Peru; Tiahuanaco and Tiahuanacoid (Epigonal); pre-Inca era, a period, like the first, of local styles, some vigorous and original, others degenerate, though no sharp line can be drawn between this and the Tiahuanaco styles; and lastly, the Inca era, which includes not only classical Inca styles, but modified and mixed Inca styles such as late Chimu. All known styles of Peruvian pottery can be fitted into these eras.

European Corn Borer in the United States.—Among the numerous bulletins and papers issued on the European corn borer in America, the most recent that has come to hand is by Mr R. H. Pettit. He writes on the status of this insect in Michigan in *Circ. Bull 70 Agri. Expt Station, Michigan State College of Agriculture* (Nov. 1925). This State is threatened by the increase of the corn borer, like so many other parts of the United States. No measure in the light of existing knowledge can prevent the pest from eventually establishing itself wherever corn is grown Probably the worst infestation up to the present time has occurred in Ontario, where in some cases fields have shown a total loss. The author lays stress upon the value of State quarantine and the adoption of certain defined farm practices as affording the only possible means of restraining the insect, as it is too early to hope for results from parasite introductions.

Hibernation of a Succinea.—Dr. S. L Hora (*Records Indian Mus.*, 27, part v, Sept. 1925) gives a short account of the hibernation of a Succineid mollusc, *Succinea arboricola*. Living specimens were found at the end of August 1924 adhering very tenaciously to the bark of mango trees, and in form and coloration resembled wart-like outgrowths of the bark. Dead vegetable growth, chiefly of lichens, covered the bark and also the shells, which were very difficult to see, and in fact were first discovered by mere chance. When a specimen was forcibly detached a scar remained on the bark and a thin white epiphragm was found to cover the aperture of the shell. On removing the epiphragm the animal was seen to be in a comatose condition Other specimens were found on the under surface of leaves of the mango; they were sluggish, but their shells were not covered with vegetable growth. The peculiarity about this species is that it is found in a comatose condition during the rainy season, when most of its relatives are known to be active. The rainy season at Lonavla (in the Western Ghats), where the specimens were collected, is very long and the annual rainfall about 400 inches, and the author suggests that the peculiar habit of hibernation during the rains is a device for protecting the animal from being washed down by heavy rains. Dr. H. S. Rao gives an account of the anatomy of this new species.

The Vredefort Granite.—In the *Trans Geol. Soc. S. Africa* (vol. 28, 1925, p. 135), Dr A L Hall brings forward convincing evidence to show that the Vredefort granite is not intrusive into the Witwatersrand system, and is therefore not responsible for its metamorphism. The granite bears no resemblance to the Buschveld granite, but is more like the 'Older' granite of South Africa. Its outcrop covers a circular area twenty-five miles in diameter, and surrounding it is a concentric girdle of amygdaloidal lavas now converted into a granulite. Above the basal amygdaloid are the Lower Witwatersrand formations, which have also become intensely metamorphosed. Two causes in succession appear to be responsible for the metamorphism: (*a*) regional static metamorphism, due to the load of overlying sediments, and aided by the additional pressure generated during the updoming of the area; and (*b*) local thermal metamorphism, eccentric to the Vredefort granite, and due to the intrusion of a younger, still largely concealed, igneous body, the presence of which is indicated by several exposed bosses of alkali granite. The second cause has reinforced the effects of the first by producing coarser crystallinity of the rocks in general, and increased abundance of some of the typical metamorphic minerals.

Platinum in Southern Rhodesia.—The recent discovery of platinum in the Transvaal has stimulated interest in the possibility of finding payable platinum deposits in the norite of the so-called Great Dyke of Southern Rhodesia. Nearly twenty years ago, Mr. F. P. Mennell suggested that this enormous intrusion appeared to form a promising belt of country to prospect for platinum, and his prophecy has now been justified by the discovery of the metal in three large areas. A publication of the Southern Rhodesia Geological Survey (Short Report, No. 19, March 1926) by Mr. B. Lightfoot is devoted to the description of these areas and the associated rocks. The intrusion is composed essentially of the four minerals labradorite, augite, enstatite, and olivine, producing by their possible combinations fifteen different types of rocks. The platinum occurs, as in the Transvaal, in bands of pyroxene-rich norite containing disseminated sulphides and overlain by felspar-rich norite. The intrusion appears to be a greatly elongated laccolith, possibly fed by a true dyke below. Pronounced joint planes dip towards the 'Dyke' in many localities along its course, suggesting that the invaded granite lies beneath the flanks of the intrusion on both sides. The actual structure has long been a puzzle to geologists, and as it has now become of economic as well as of scientific importance, since it enters into the question of the future development of both chromium and platinum ores, it is likely soon to be further elucidated as prospecting work proceeds.

Arctic Ice in 1925.—The Danish Meteorological Institute has published its annual report on the state of the ice in the Arctic seas. As usual, the data are most numerous from the Barents Sea, Spitsbergen, the west coasts of Greenland and Alaska, but in 1925 a good deal of information was available from the east coast of Greenland. From the Beaufort Sea and the coast of Siberia practically no data came to hand. The most notable feature of the year was the unusually small amount of ice observed in practically all the Arctic seas that were visited. During the summer, the Barents Sea was free from ice and the Kara Sea was remarkably open. Spitsbergen waters were very clear, and during August there was open water round practically the whole of the group. Franz Josef Land, as usual, was more or less inaccessible, but there was open water on the north of Novaya Zemlya in August. On the east coast of Greenland the ice-belt was narrow, and there appears to have been less drift from the north than usual. Bering Strait was open in June, but the north coast of Alaska not until late in July. Commander C. I. H. Speerschneider, the editor of the report, comments on the facts that for several years, and particularly in 1925, little old ice was found in the east Greenland or east Spitsbergen currents, and that most of the ice was of one winter's formation. The report is illustrated with distribution charts for the months of April until August.

Vapour Pressures of Hydrogen Cyanide.—A series of vapour pressure measurements of solid and liquid hydrogen cyanide is published in the *Journal of the American Chemical Society*, February. The observed values are compared with those obtained by calculation and, in the case of the liquid, with some isolated results of previous works. Values of the latent heats are given which have been calculated from the Clapeyron equation.

Protein Digestion by Enzymes.—Under the general guidance of R. Willstätter, German chemists are making a great effort to isolate purer enzyme preparations, and in *Die Naturwissenschaften* for Feb. 19, 1926, Ernst Waldschmidt-Leitz gives a general account of the manner in which work of this type with proteases tends to modify current views as to protein hydrolyses by enzymes. By a laborious method of fractional precipitation, ereptase and tryptase have been obtained completely free from contamination with each other, and a study of their catalytic action has necessitated the revision of earlier conclusions drawn from work with less pure enzyme preparations. It is now found that ereptase is without action upon any but simple di- or tri-peptides; peptones, etc., being left quite unattacked. In addition to ereptase, the conclusion is drawn that at least three other types of protease must be distinguished, namely, peptase, tryptase not activated by enterokinase which is without action on the more complex proteins, and tryptase with enterokinase, a system which will attack such proteins. On the other hand, working with these purer enzymes, the ereptase from different sources appears to be identical in nature, and the differences reported in the behaviour of the same protease towards synthetic and naturally produced polypeptides have disappeared. In the light of this experimental study of proteases with which he has been associated, Waldschmidt-Leitz points out that the constitution of the protein molecule may have to be reconsidered from the point of view that it contains different types of chemical linkage, accessible to different types of hydrolytic enzyme.

Shock-Waves of High Explosives.—Certainly one of the most interesting and suggestive of the papers issued by the Safety in Mines Research Board is that numbered 18, "On the Pressure-Wave sent out by an Explosive," by Messrs. W. Payman and H. Robinson. To investigate the nature and the velocity of the invisible 'shock-waves' transmitted through the air by the sudden expansion of a confined volume of gas, the authors employed a modification of the 'Schlieren' method first developed by Töpler. The light of a brilliant, but very rapid, spark from a battery of Leyden jars is focussed on to a camera by means of a concave mirror of stainless steel—the beam of light crossing the field in which the shock-wave is transmitted. In front of the camera an opaque diaphragm is fixed so as to cut off the light from one half the lens. When a wave of compressed gas passes between the mirror and the camera, the light passing through it is refracted so that one half the beam is stopped by the diaphragm and the other half enters the lens. One half of the image of the wave comes out bright on the photograph and the other half is dark. With this apparatus photographs have been taken of the shock-waves produced both by the sudden release of compressed gases and by the firing of gas-mixtures and of high explosives. The authors have caught a shock-wave, started from a spark-ignition in electrolytic gas, as it emerges from a tube ahead of the flame, and in succeeding photographs have shown the flame overhauling this pressure-wave and swallowing it up in the explosion-wave. The photographs beautifully illustrate the slowing down both of shock- and explosion-waves as they emerge from a tube and develop spherical waves. They show also the heating effect when a shock-wave strikes an obstruction—and this will form the main subject of the large-scale experiments to be carried out on the shock-waves produced by firing modern explosives in coal.

Production and Properties of Large Single Crystals of Metals.

THE study of matter in the crystalline state is of importance at the present time to workers in so many branches of the pure and applied sciences that a paper by P. W. Bridgman, in vol. 60 of the *Proceedings of the American Academy of Arts and Sciences* of October 1925, on "Certain Physical Properties of Single Crystals of Tungsten, Antimony, Bismuth, Tellurium, Cadmium, Zinc, and Tin," will be read with far more than usual interest. With the exception of tungsten, all these metals crystallise in systems other than cubic, zinc and cadmium being hexagonal; bismuth, antimony, and tellurium trigonal, and tin tetragonal. The tungsten crystal, prepared in another manner, was included in the research merely as a result of the fact that a large crystal was placed at the author's disposal.

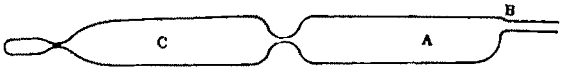

FIG. 1.—The mould used in producing single crystals.

Although much work has been done on single crystals of metals lately, the major portion has related to crystals which have been produced by some form of mechanical treatment followed by an appropriate annealing. It is not yet definitely known to what extent the mechanical deformation has impressed on the material specific characteristics which have persisted despite the reheating. Work, therefore, which is done on virgin crystals, never at any stage of their history stressed above their elastic limits, is not only of fundamental interest in itself, but has also a by no means unimportant value in connexion with the interpretation of results obtained on crystals produced by some form of work.

The method used by the author, by means of which single crystals up to nearly an inch in diameter have been made, consists in melting the metal in a suitable mould of quartz or refractory glass tubing and allowing the tube to pass slowly out of the furnace into the air or into a bath of oil. Solidification then starts at the bottom of the tube and proceeds slowly upwards, keeping pace with the lowering. If this be sufficiently slow, and provided that only one nucleus forms at the bottom of the tube, the metal will usually crystallise as one grain, having the cylindrical shape of the mould. This still holds even where the metal passes through an allotropic change point between the temperature of solidification and that of the room. Further, it is of interest that in almost all cases, especially where the diameter of the tube is fairly great, the crystal formed has the plane of easiest cleavage, or slip, parallel to the axis of the casting.

Various details require attention if consistent success in the production of a single crystal is to be attained, and the shape of the mould finally used is indicated in Fig. 1. The bottom of the tubing is drawn down to a separate chamber connected to the main part *C* by a capillary 0·1 mm. or so in diameter. This fine orifice acts as a 'filter,' allowing one only of the several grains which may have formed to pass through into the mould proper. It is essential that fresh nuclei should not form in *C*, which demands complete freedom from particles of oxide or specks of dirt. The melting of the metal, therefore, is done in a pre-melting chamber *A* connected with *C* by another capillary and provided with a tube *B* by means of which the metal may be introduced in the first place, and by which connexion may later be made with a vacuum pump, allowing the metal to be melted without oxidation. The process employed thus consists of first placing in *A* the metal to be examined, evacuating the vessel and placing it in a horizontal position in an electric furnace. It is essential that all traces of gas should be removed from the melt, and this is done by rocking the furnace and washing the metal backwards and forwards in *A*. Bismuth is particularly difficult to free from the last trace of gas, and it may be necessary to manipulate the molten metal for an hour or more before all has been eliminated. The furnace is now rotated into a vertical position and the metal allowed to filter into the mould, admitting air, or some other gas under pressure, to accelerate the process. The mould may now be lowered from the furnace at a speed depending on the metal and the size of the casting. For crystals of 2·2 cm. diameter a speed so low as 4 mm. per hour is desirable, while for small castings, 60 cm. per hour may be used. Except for bismuth and tellurium, however, there is no danger in using too small rates of lowering. A shield to prevent draughts striking the tube is helpful and, in the case of cadmium, cooling in a bath of oil is preferable to cooling in air. To prevent the metal sticking to the mould, the latter is treated with oil before use; this is then removed with ether, and the latter removed by evaporation with a gentle flame played on the surface.

TABLE.

SUMMARY OF RESULTS.

Metals *	Initial Linear Compressibility at 30° C. Pressure Unit 1 kgm./cm.².	Elastic Constant C G S	Linear Thermal Expansion at 20° C.	Specific Resistance 20° C.	Average Temperature Coefficient of Resistance 0-100° C.	Initial Pressure Coefficient of Resistance at 0° C. Pressure in kgm
Zinc II	$12·98 \times 10^{-7}$	$26·38 \times 10^{-12}$	$57·4 \times 10^{-6}$	$6·13 \times 10^{-6}$	0·00419	$-10·87 \times 10^{-6}$
I	1·95	8·23	12·6	5·91	0·00418	− 6·55
Cadmium II	18·3	36·9	52·5	8·30	0·00428 (?)	−15·1
I	2·1	12·9	20·2	6·80		− 8·7
Bismuth II	15·92	28·7	13·96	138	0·00445	+24·5
I	6·62	26·9	10·56	109		+ ·75
Antimony II	16·48	33·8	15·56	35·6	0·00595	+17·2
I	5·26	17·7	7·96	42·6	0·00511	+ 1·05
Tellurium II	−4·14	25·4	−1·6	56000	—	—
I	27·48	48·7	27·2	154000	—	—
Tin II	6·72	11·8	30·50	14·3	0·00447	−10·96
I	6·02	18·5	15·45	9·9	0·00469	−10·28

* II, in a direction parallel to the axis of rotational symmetry.
I, in a direction perpendicular to the axis of rotational symmetry.

In the examination of the crystals, it was necessary to determine the orientation, and a very simple manner in which this is done is described, depending on the small 'negative' crystalline facets formed on the surface, the necessity of resorting to X-ray examination being avoided.

A short list of the more important values obtained will be found in the table above, but there are very many points of general interest which are recorded. The author agrees with other workers in mentioning that the elastic limit of many of these single crystals is often "unbelievably" low. It is much to be regretted that so far no attempt has been made to examine the behaviour of the crystals at stresses higher than the elastic limit, an aspect of the work which is much to be desired.

It will be seen from the table that, broadly, the linear compressibility, the extension under tension (save in the cases of tin and tellurium), the thermal expansion, and the specific resistance are greater in a direction along the axis of rotational symmetry than in one at right angles. There are certain exceptions, however, and for tellurium the compressibility along the trigonal axis is negative, so that on subjecting the crystal to hydrostatic pressure it actually elongates in that direction; in the same direction also this element has a negative value for the thermal expansion. Antimony also furnishes an exception to the last of the generalisations, though here the exception may be regarded as being of a temporary nature, since at high pressures the metal becomes normal. With the exception again of antimony, which, however, behaves normally when the pressure is sufficiently increased, the temperature coefficients of resistance are not much affected by the orientation of the crystal. The effect of pressure on the resistance is, however, more affected by the direction of the current It may be noted that, although pressure diminishes the resistance of cadmium, zinc, and tin, it increases that of both bismuth and antimony. In general, the statement may justifiably be made that the electrical properties show much less variation with the orientation of the crystal than do the mechanical ones.

Little work is recorded so far as the magnetic properties of these crystals are concerned, but a few, by no means uninteresting, observations are made. In the cases of bismuth and antimony there is a very definite directional effect. Bismuth sets itself with the trigonal axis parallel with the lines of force, the permeability being greatest along this axis, thus confirming the observation first made perhaps by Tyndall In the case of antimony the crystal arranges itself with the cleavage plane parallel to the lines, the effect being even stronger than that in the case of bismuth. Tin also showed rather curious properties. On making the field (about 15,000 gauss) there was no observable effect, but when the field was broken, a kick occurred in such a direction as to tend to cause the tetragonal axis to come into line with the magnetic field. When the axis was already aligned with the field this kick was not shown.

The results of the specific resistance measurements are of general interest in connexion with the resistances of aggregates of the same metals. Knowing the specific resistances for a crystal along and perpendicularly to the axis of rotation $\rho_\parallel$ and $\rho_\perp$ respectively, Voigt has shown that the resistance ρ of a haphazard aggregate should be given by the equation

$$\frac{1}{\rho}=\frac{1}{3}\left[\frac{2}{\rho_\perp}+\frac{1}{\rho_\parallel}\right].$$

This calculated value for the aggregate is given in several cases and is consistently lower than that directly determined. Thus for cadmium the value for the aggregate thus calculated is $7 \cdot 24 \times 10^{-6}$ ohms per cm. cube, while observed values are 7·51 and $7 \cdot 54 \times 10^{-6}$ ohms. Again, for tin, the results give a calculated value for the aggregate of 11·06 microhms per cm. cube against the determined figure (Bureau of Standards) of 11·5 ohms. The author[1] explains the differences by assuming that his own material was purer than any hitherto measured, which to some extent may be sufficient. There is, however, an alternative explanation. In the aggregate there are crystal boundaries the resistance of which, it is highly probable, is higher than that of the crystalline matter itself. The calculations in the paper under review cannot take into account any such changes brought about by boundary conditions within the mass, and the differences between the calculated values and those observed may therefore be regarded as offering confirmation of the idea that the crystal boundaries are regions of relatively high electrical resistance.

Prof. Bridgman's work has also fully demonstrated the fact that under pressure cadmium can be transformed first into one and then into a second allotrope. One such transformation had already been suspected, for example by Greenwood, but the new work makes the transformation certain and shows that two changes can be induced. The space lattices of the new forms are not yet known, but there is here in some ways the first absolutely direct evidence that under stress a change of lattice may be produced. In Fig. 2 the effect of temperature on the stress required to effect the modification is shown. Volume changes of the order of 2 per cent. may occur, which may be either positive or negative. At first the transformations are more or less reversible, but after several changes of (hydrostatic) pressure in reversed directions, the discontinuity usually becomes gradually less marked and finally almost disappears.

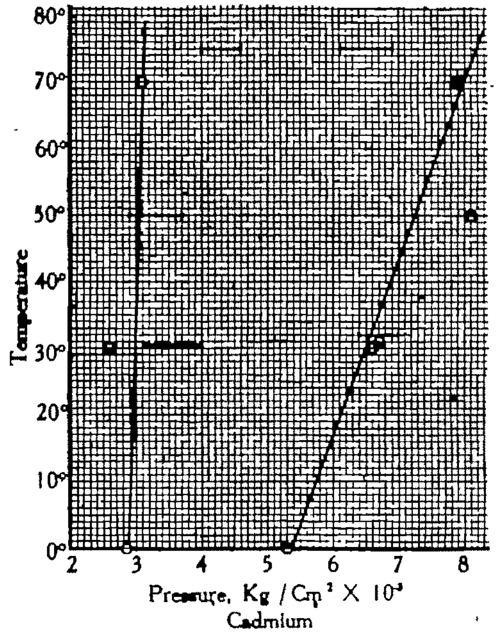

FIG. 2.

Finally, there are two statements which are of importance in connexion with the crystallographic changes which occur when a metal is forced through an orifice. In extruded wires of cadmium, the properties suggest that there is a preponderance of crystals with the hexagonal axis lying more or less parallel to the axis of the wire Tin shows a similar effect very clearly. The temperature coefficient of specific resistance of a single crystal, for example, measured in a direction parallel to the tetragonal axis is 0·00447 and perpendicular to this axis 0·00469. The corresponding value obtained for an extruded wire of Kahlbaum tin was 0·00447, *i.e.* that which would be obtained if this wire was so orientated that the tetragonal axis of all the constituent crystals had been rotated into parallelism with the axis of the wire.

The Courtship of Birds.

PROF. JULIAN HUXLEY and his co-workers have recently made some further contributions to the subject of the courtship of birds, dealing with three species of waders which were kept under close observation during two visits to the Texel

The extent to which special courtship performances are developed in the order differs widely as between one species and another. Thus, the avocet (J. S Huxley, *British Birds*, 1925, 19, 88) has no courtship at all. There is an invitatory attitude adopted by the female immediately before coition, responsive excitement on the part of the male, and a post-nuptial ceremony in which the pair run forwards together with the cock's half-spread wing over the hen's back—but of true courtship nothing.

On the other hand, the black-tailed godwit (J. S. Huxley and F. A. Montague, *Ibis*, 1926, 1) exhibits an elaborate courtship behaviour. There is a ceremonial flight accompanied by a special call, which is performed by the male and is probably associated with the territorial instinct. Then there is a tail display by the male, performed on the ground before the female, which is a true courtship activity. There is also a scrape ceremony, mainly performed by the male, which is obviously derived from the nesting instinct. Both birds, further, take part in a joint flight, and there is pursuit of the female by the male, hostility between rival males, and a coition ritual. The whole makes up a complex series of events.

The oyster-catcher (J. S. Huxley, assisted by F. A. Montague, *Ibis*, 1925, 868) seems to occupy an intermediate position in regard to the development of courtship activities. Special interest attaches to the piping performance, which consists of continuous piping while the neck is thrust forward and the head and the open beak are directed downwards: this may be accompanied by bobbing of the body or, more often, by dancing movements. It is shown that this is not of purely courtship significance, and that it is performed by both sexes and in varying circumstances. "It may be merely an expression of general sexual excitement, performed by a single bird without special relation with other birds. Or it may be a display definitely directed at another bird, which may or may not be the mate, and may or may not join in; or it may be a definite sign of hostility, either by one bird of a pair to a single intruder of the same sex, or by one pair to another. Or, finally, it appears that sometimes, where hostility might be expected, extra birds may be allowed to join a performance, in which case social excitement also seems to come into play."

The League of Nations Cancer Inquiry.

THE death rate from cancers of the breast and uterus in England is much higher than it is in Holland or Italy. The Health Organisation of the League of Nations appointed an international committee, with Sir George Buchanan as chairman, and also a committee of statisticians, presided over by Dr. M Greenwood, to look into the matter, and the first results have now been published[1] The greater part of the reports is occupied by elaborate statistical surveys of the available data for England by Dr. Greenwood, for Holland by Dr H. W. Methorst, and for Italy by Prof. A. Niceforo, and their analysis is directed particularly to the relation of marriage age and place to the incidence of these forms of cancer. The non-technical reader will find the introductory summary easier to follow, and there is room for a still simpler abstract which, with a few diagrams, would deserve wide circulation among medical men

The Committee finds that the three countries differ in their mortalities as stated, and significant differences of rate occur in the different divisions of each country: in England, cancer of the breast is most prevalent in the east and south, in Holland on the western coast, in Italy north of Rome The Committee agrees in providing very full confirmation of the belief that cancer of the breast falls most heavily on unmarried women, cancer of the uterus on those who have been married. It is also shown definitely that women who develop cancer in either site are less fertile than those who do not.

These results are something more than confirmations of what was already known or suspected, for they are based on such comprehensive considerations that they reach an order of validity, exceptional in medical literature, which makes it necessary that any hypothesis on the cause of cancer should not be incompatible with, and should ultimately explain, them. Having securely established the facts, the Committee proceeded to look for an explanation of them. So far the results of this inquiry have been uniformly negative: the circumstances investigated have been; those personal factors which are dealt with in hospital records, more may be obtained when the domestic and social sides of life are considered. The whole report is an excellent example of what the League can do in such matters, and we hope for much more of the same kind of solid work.

University and Educational Intelligence.

ST. ANDREWS.—The Senatus Academicus has resolved to confer the Honorary Degree of LL.D. on Dr. E. F. Armstrong, Director of the British Dyestuffs Corporation; Dr. George Forbes, distinguished by his pioneer work in electrical engineering and popular writings on astronomy; Mr. E. S. Harkness, of New York, founder of the Commonwealth Fund; and Prof. E. T. Whittaker, professor of mathematics and Dean of the Faculty of Arts in the University of Edinburgh. The degrees will be conferred at the Graduation Ceremonial to be held on June 29.

THE Air Ministry announces that Sir Charles Wakefield, Bart., has generously offered to continue the 'Sir Charles Wakefield' Scholarships, founded by him in 1920. These scholarships are each of 75*l*., tenable for one year at the R.A.F. Cadet College, Cranwell, and are intended to give financial assistance to successful candidates for entry into the College. Two scholarships are awarded at each half-yearly entry. One of these is awarded on the result of the open competitive examination for admission to the Cadet College held in June and November, and the other to one of the aircraft apprentices who at the conclusion of their training at the R.A.F. training establishment at Halton are selected twice a year for flight cadetships at Cranwell.

THE Ministry of Agriculture and Fisheries is prepared to receive by, at latest, May 15, applications for grants in aid of scientific investigations bearing on agriculture to be carried out in England and Wales during the academic year beginning October 1, 1926. A prescribed form of application (A.*53/TG) giving particulars of the conditions under which the grants are offered, may be obtained from the Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 The Ministry also invites applications for a number of research scholarships in agricultural and veterinary science which will be tenable for three years and be of the annual value of 200*l*, plus, possibly, allowances for travelling and subsistence abroad. Copies of application form 900/TG are obtainable from the Secretary, and must be returned not later than June 30.

Pp. 168 Rapport sur les résultats de certaines enquêtes, clinique se rapportant aux différences de mortalité cancéreuse dans certains pays choisis spécialement. (C.H. 333, Vol. 2) Pp. 392. (London: Constable and Co., Ltd, 1925.)

WE have recently received the report for the year 1924-25 of University College, London, which shows a total student enrolment (3033) exceeding by 198 the total for the preceding year. The enrolment for the current session is likely to be still larger. The total includes 388 evening students and 214 attending vacation courses Excluding these there were 1911 undergraduate and 520 post-graduate and research students. More than one-fifth came from homes beyond the British Isles, including 230 (83 post-graduate and research) from various parts of the Empire. India and Ceylon contributed 124 (43), Australia 24 (14), Canada 10 (5), New Zealand 12 (7), South Africa 27 (7), the figure in brackets indicating the number of research students. Among foreign countries, the United States of America were represented by 52 (24), Japan by 41 (11), Germany by 51 (3), Switzerland by 39 (1), France by 32, Holland 21 (2). The large number (148) of post-graduation and research students from beyond the British Isles is noteworthy. Free public lectures have for many years been a conspicuous feature of the work of the College. In 1924-25 they were attended by more than 6,000 persons. The list of appointments in other countries obtained by members of the College, staff and students, during the year includes professorships at McGill, Dalhousie (Halifax), Mysore, Cape Town, and Vassar.

IN a pamphlet entitled "The New University of Reading: some ideas for which it stands," Principal W. M. Childs gives prominence to the idea that the collegiate or residential principle, so characteristic of Oxford and Cambridge, is indispensable to the fulfilment of the highest functions of a university. Among these functions is training in character and living as well as opportunity for acquiring knowledge, and the corporate life of the students is the most favourable medium for such training. An instructive parallel is drawn between the academic and the economic worlds: "The whole world is sick because in getting rich and progressive something essential to human contentment has been lost or greatly mutilated; namely, personal relations. . . . Is it proposed to transfer this sickness from the sphere of economics to the sphere of education?" If not, it is essential that conditions should be favourable for the development of individual personal contact of teacher with student, and student with student The residential halls of Reading, accommodating no less than 70 per cent. of the full-time students, represent the greatest achievement of the movement for establishing such conditions in the modern provincial universities and university colleges. Another subject dealt with in the pamphlet is "Universities and Research," in connexion with which attention is directed to the recent constitution of a Research Board with a general responsibility and mission for promoting and stimulating research in fields other than that covered by the work of the National Institute for Research in Dairying (which is a part of the University of Reading) and of administering to that end funds entrusted to it by the Council (for 1925–26, 500*l*.).

Contemporary Birthdays.

April 17, 1863.	Dr. George Grant MacCurdy.
April 21, 1871.	Sir Sydney John Chapman, K C.B.
April 22, 1840.	Mr. Richard Inwards.
April 23, 1869.	Prof. Percy Edward Newberry.
April 24, 1841.	Prof. Charles Sprague Sargent.

Dr. MACCURDY, the distinguished American anthropologist, was born at Warrensburg, U.S.A. Graduating at Harvard, he studied afterwards at the Universities of Vienna, Paris, and Berlin. His connexion with Yale University dates back some thirty years Since 1923 he has been accorded the status of professor and curator of the anthropological collections in Yale. Dr. MacCurdy was the first director (1921) of the American school in France for prehistoric studies. He is the author of "The Eolithic Problem" (1905), and "Human Origins" (1924, 2 vols.).

Sir SYDNEY CHAPMAN, permanent secretary of the Board of Trade since 1919, was born at Wells, Norfolk. He was educated at Manchester Grammar School and Owens College, graduating from thence at Trinity College, Cambridge. Lecturer in economic and political science in the University of Cardiff from 1899 until 1901, he returned to Owens College to take up the post of professor of political economy, retaining this for sixteen years Sir Sydney was president of Section F (Economic Science and Statistics) at the British Association's Winnipeg meeting in 1909. The general topic of his address related to the value of leisure, the bearing of industrial development upon it, and its effectiveness in shaping economic arrangements. He has been a recipient of the Guy medal of the Royal Statistical Society.

Mr. INWARDS was born at Houghton Regis For many years engaged in mining engineering and kindred enterprises in Bolivia, Mexico, and other parts of the world, he finally settled in England. Joint editor for two decades of the *Quarterly Journal of the Royal Meteorological Society*, he was the Society's president in 1894–95.

Prof. PERCY NEWBERRY, honorary reader in Egyptian art at the University of Liverpool, was educated at King's College School, London, and King's College. Beginning the study of Egyptology in 1884, his acquirements and exactitude in procedure qualified him to be officer in charge (1890) of the archæological survey of Egypt, conducted under the auspices of the Egypt Exploration Fund. Brunner professor of Egyptology in the University of Liverpool from 1906 until 1919, Prof. Newberry was president of Section H (Anthropology) at the British Association's meeting in that city in 1923. He gave an address on "Egypt as a Field for Anthropological Research."

Prof. SARGENT, the veteran American botanist, who is a foreign member of the Linnean Society of London, was born at Boston, U.S.A., and graduated at Harvard University. Sometime director of the Boston Botanic Gardens, it was Sargent who organised the Jesup collection of North American woods for the American Museum of Natural History, New York. He was one of the commissioners (1896) detailed to report upon a forest policy for the forestry lands of the United States. He is the author of "A Manual of the Trees of North America," and "The Forest Flora of Japan."

Societies and Academies.

London.

Linnean Society, March 4.—**E. Heron-Allen**: The iconography of a myth. The legend that the stalked barnacle, *Lepas anatifera*, upon trees overhanging the water, or upon rotten timber, and, at maturity, produces a goose or duck, permeates scientific literature from the eleventh to the seventeenth centuries, and since the invention of printing has been fancifully illustrated. The myth appears to have passed current in the Near East in 1000 B.C., and is illustrated upon Mykenæn pots.—**C. J. Stubblefield**: Notes on the development of the trilobite, *Shumardia pusilla* (Sars). A large number of complete specimens have been collected, ranging in length from 0·24 mm. in the earliest or 'Protaspid Period' to 4·91 mm. in the latest or 'Holaspid Period.' The six thoracic segments are released one by one from dorsal fusion in the posterior shield or 'transitory pygidium' *S. pusilla* offers new evidence in favour of the hypothesis, advanced by Beecher in 1896, that the growing point of the new segments in trilobites was in front of the most posterior or anal segment.—**H. Graham Cannon**: On the post-embryonic development of the fairy shrimp (*Chirocephalus diaphanus*). The development of *Chirocephalus diaphanus* is essentially similar to that of Estheria. Cœlomic sacs are formed as in the latter, but do not attain any considerable size owing to the precocious development of the pericardial cavity. The method of heart-formation differs in different parts of the body. The development of the maxillary gland shows no essential differences from that of Estheria. The antennal gland shows very clearly, between end sac and duct, a sphincter consisting of three cells connected directly to the cuticle. The musculature is more complex than that of Estheria, there being a series of 'connective muscles' between the dorsal and ventral longitudinal muscles. The dorso-ventral muscles, the proctodæal dilators, and probably the stomodæal dilators are of ectodermal origin.—**H. W. Pugsley**: Further notes on Fumaria and Rupicapnos. The material, largely the fruit of recent French botanical expeditions into parts of Morocco hitherto unexplored, has yielded some new species both of Fumaria and Rupicapnos. New forms were also discovered in Algeria during a visit to that country in 1922.

Geological Society, March 10.—**J. E. Marr**: The Pleistocene deposits of the lower part of the Great Ouse Basin. A period of aggradation in Lower Palæolithic times intervened between two periods of glaciation of the district, and after the second glaciation, erosion occurred, with minor periods of aggradation in Upper Palæolithic times. An appendix by **A. S. Kennard** and **B. B. Woodward** deals with the non-marine mollusca.—**W. G. Woolnough** and **Sir T. W. Edgeworth David**: Cretaceous glaciation in Central Australia. Evidences of glacial action in Central Australia were recorded more than forty years ago, mostly in the form of numerous erratics and occasional beds of tillite. The occurrences are now known to belong to two distinct geological horizons, the older almost certainly Permo-Carboniferous, and the newer probably Jurassic to Cretaceo-Tertiary. Recently, one of the authors (W. G. W.), when exploring the salt-lakes of Central Australia on behalf of Brunner, Mond and Co., discovered good evidence as to the age of the later glaciation. The most recent expedition (by W. G. W.) has led to the discovery by him of marine fossils in the same matrix as that in which the erratics are embedded. The erratic-bearing beds, together with a thick series of freshwater strata with lignites, which mostly overlie the glacial deposits, are termed the Winton Series. They are followed by strata making locally a distinctly unconformable junction with them and probably of early Tertiary age. These latter beds belong to the Eyrian Series, which in places carries fossil leaves of Eucalyptus. F. W. Whitehouse opines that the age may approximate to Albian. If so, it would accord with the New Zealand evidence of a great orogenic movement in those islands soon after the close of Neocomian time. It is suggested that the crust-movements, which were orogenic in New Zealand, expressed themselves as epeirogenic uplifts in Australia and accounts for the fact that the Cretaceous Mediterranean of Australia gave place soon after the close of Aptian time to a vast freshwater lake: for marine sedimentation, although in places represented by small patches of Albian, mostly ceased even before Albian time.

Physical Society, March 12.—**A. H. Davis**: The analogy between ripples and acoustical wave phenomena. The analogy between cylindrical sound waves and waves on the surface of a liquid is studied. For inviscid media, as regards velocity potential, the differential equations are similar provided the disturbance is small and is harmonic in type. The effect of moderate viscosity is of the same type for sound waves and for surface waves; it is most marked for short wave-lengths, and it decreases amplitudes without appreciably altering the wave-length. Viscous effects are generally negligible in the case of sound, but they are appreciable for the water waves that would usually be used in a small ripple tank not greater than, say, 10 feet in size. Mercury waves are much less affected by viscous damping than water waves. Experiments with model obstacles in a ripple tank show that the effects of the meniscus around the obstacle and of the amplitude of the source are not important. When the water becomes stale on exposure—and presumably contaminated—the relative distribution of ripples around obstacles is appreciably modified, but not to an extent which would correspond to any very marked change in the loudness of a sound. Experiments have also been conducted using an impulsive disturbance instead of a maintained train of waves. When it is recognised that a sound pulse travels out singly, whereas with ripples subsidiary wavelets accompany the main pulse, the correspondence between ripple photographs and sound pulse photographs is most striking.—**R. M. Archer**: On the evaporative losses of vacuum-jacketed vessels of the Dewar type. The evaporative losses of metal Dewar vessels are discussed, and particulars given of experiments made by the author in Oxygen Laboratory of the Air Ministry. The separation of neck and radiation losses is described, and also a method of testing adsorbents under working conditions.

Cambridge.

Philosophical Society, March 15.—**A. Sommerfeld**: Some controversial points in the theory of spectra. (Lecture.)—**J. A. Crowther**: A theory of the action of X-rays on living cells.

Manchester.

Literary and Philosophical Society, March 9.—**G. Elliot Smith**: The brains of apes and men (Wilde Memorial Lecture). Without the cultivation of manual dexterity, which involves the aptitude to learn by experimentation, man's ancestors could not have acquired the seeing eye and the understanding ear. Man's intellectual pre-eminence is based upon his ability really to see the things and events around him, to understand something of their significance and to appreciate their æsthetic qualities. Vision became also the chief instrument for determining his sexual selection and affecting his social behaviour in an infinite variety of ways. But it affects human thought and action in much more subtle and obtrusive ways. Apart altogether from the phenomena of consciousness, it helps unconsciously in controlling posture and regulating the tone of muscles, a function upon the effective performance of which skill is so largely dependent. The attainment of the erect attitude in the human family was intimately bound up with the increasing influence of the eyes and the cerebral cortex in the control of posture. The special interest of the apes' brains is that they provide the evidence to help us to get some idea of how vision acquired its ascendancy. The casts obtained from the brain-case of extinct members of the human family—in particular those of Pithecanthropus, Eoanthropus, and the Rhodesian man—provide important evidence in confirmation of the fact that the processes of growth and elaboration of the brain, which can be studied in the lowlier primates, were continued within the human family itself. Moreover, they agree with the order of development of the cerebral cortex revealed in the brain of the modern child. The real importance of the interesting fossil ape found at Taungs in 1924 is that it reveals the earliest stage in this process of cerebral development and facial refinement.

PARIS.

Academy of Sciences, March 8.—**A. Lacroix**: The classification of leucite rocks: the types of the syenite family.—**C. Matignon** and **J. Cathala**: The action of phosgene on glucina. The work described by the authors in a recent communication was anticipated by Ed. Chauvenet in 1911.—**Ch. Moureu, A. Lepape, H. Moureu**, and **M. Geslin**: The composition (ordinary and rare gases) of the gases spontaneously evolved from some thermal springs of Madagascar and Réunion. Of the eleven waters examined, eight were from Madagascar, and all except one consisted mainly of carbon dioxide. All contained argon, but only one, from Ranomafana, contained appreciable proportions of helium (0·56 per cent.). The gases evolved were very similar to those obtained from the bicarbonate springs of the Central Plateau in France. This was rather unexpected, since the subsoil in the Antsirabé basin, from which seven out of eight of the Madagascar samples were obtained, is rich in radioactive minerals (betafite, euxenite, etc.), and consequently rich in helium.—**Léon Guillet** and **Jean Cournot**: The influence of thermal treatment on some silver alloys. A study of silver-zinc and silver-cadmium alloys. The alloys with zinc show very clearly the increase of hardening by reheating, in this resembling duralumin: for the silver-cadmium alloys the results are less evident.—**R. de Forcrand**: The action of thallium on alcohols or on dilute acids and on water and ethyl alcohol in excess. Thermochemical determinations.—**Jean Baptiste Senderens**: The etherification of the aromatic alcohols. Study of the conditions under which sulphuric acid can convert benzyl, phenylethyl (primary and secondary), and cinnamic alcohols into the corresponding ethers.—**R. Swyngedauw**: The velocity of the slack and taut fibres of a belt.—**J. Ottenheimer** and **R. Dubois**: A wave preceding the explosive wave.—**Marcel Laporte**: The measurement of the mobility of ions in gases. The method is analogous to that used by Fizeau for measuring the velocity of light. Experiments were conducted with air, oxygen, nitrogen, carbon dioxide, and argon. For all these cases it is necessary to conclude that there exist ions of different mobilities, the values of which are comprised between two clearly different limits. Values given by other experimenters fall between these limits.—**Max Morand**: Study of the working of a positive ray tube.—**G. Ribaud**: The influence of the external temperature on the temperature of standard pyrometric lamps.—**R. de Fleury**: Pistons of aluminium, alpax, and magnesium.—**W. Perschke**: The study of triboluminescence.—**P. Job**: The spectrographic study of trihalogen salts of potassium. The method described has indicated the existence of KI_3, KBr_3, $KBrI_2$, $KClBr_2$, and $KClI_2$.—**A. Bigot**: Kaolins, clays, etc. Formation of the clay schists of the coal measures.—**Clément Duval**: Preparations of the nitrite of *cis*-dinitrotetrammine and of some bodies derived from it.—**— Lespieau**: The action of acrolein on the mixed dimagnesium derivative of acetylene. One of the products of this reaction is a new penteninol $CH \equiv C - CH(OH) - CH = CH_2$, the physical and chemical properties of which are described.—**Marcel Guerbet**: The asymmetric dialkylarsinic acids and, in particular, methylethylarsinic acid.—**Mlle. Y. Brière**: The existence of uraninite (pitchblende) in certain pegmatites from Madagascar. Although many radioactive minerals have been found in Madagascar, this is the first occasion of finding pitchblende.—**M. Kovitch**: The existence of leucitic lavas in southern Serbia.—**A. Demay**: The tectonic signification of lustrous gneiss of the Pilat massif, near Saint-Etienne.—**Ch. Maurain**: Magnetic measurements in the west of France.—**Jean des Cilleuls**: The phytoplankton of the Loire.—**V. Lubimenko**: The physiological rôle of the starch deposited in the green parenchyma of leaves.—**H. Lagatu** and **L. Maume**: The diagnosis of the food of a plant by the chemical evolution of a suitably chosen leaf.—**A. Dognon**: The biological action of X-rays of different wave-lengths. Reply to a criticism by M. Dauvillier.—**P. Petit** and **Richard**: The mechanical liquefaction of starch paste.—**M. Bridel** and **C. Béguin**: The action of emulsin from almonds on *l*-arabinose in solution in ethyl alcohol of different strengths.—**G. Guittonneau**: The microbial oxidation of sulphur. Further experiments confirming the view put forward in an earlier communication that the first product of the oxidation of sulphur in soil by micro-organisms is a thiosulphate.—**Georges Truffaut** and **N. Bezssonoff**: The influence of metallic aluminium on the activity of nitrogen-fixing bacteria. Larger proportions of nitrogen are fixed in the presence of metallic aluminium.—**M. Marage**: The defence of the organism against medicaments.—**Roucayrol**: The action of diathermy in blennorrhagia.

VIENNA.

Academy of Sciences, February 4.—**G. Stetter**: (Communication of the Radium Institute, No. 181.) The determination of the ratio charge to mass for natural H-rays and atomic fragments from aluminium. (No. 182.) The components of the $K\beta_1$ line of iron.—**K. Przibram**: On the interpretation of the colour changes in salts; preliminary communication dealing with colours of alkali haloid crystals.—**P. Weiss**: (Communication of the Biological Experiment Institute of the Academy of Sciences in Vienna, No. 128.) The origin of the skin in regenerated extremities of *Triton cristatus*.—**L. Abolin**: (Communication of Biological Institute, No. 129.) Influence of chemicals on the colour changes of fishes. The influence of central and peripheral nerve-poisons on the whole chromatophore system of the minnow, *Phoxinus laevis*. Strychnine and other poisons produced a darkening of the fish due to expansion of the melanophores.—R. **Muller**, F. **Griengl** and J. **Mollang**: The electro-chemistry of nonaqueous solutions (vii.). Conductivity measurements in dilute solutions of silver nitrate in twelve organic solvents and determination of the limits of molar conductivity.—M. **Eisler** and L. **Portheim**: Further researches on hæmagglutinines in plants. Extract of the ripe seeds of *Phaseolus multiflorus* has the power of coagulating red blood corpuscles. Hæmagglutinin also occurs in seeds of *Ricinus communis*, seeds of *Datura Stramonium* and tubers of artichoke, *Helianthus tuberosus*.—V. **Oberguggenberger**: Earth current observations in the mountains.—F. E. **Suess**: The structure of variscic primitive rocks.

February 11.—T. **Kautz**: (Radium Institute, No. 183.) Determination of the half period of radium D by measuring the heat evolved by an old radium preparation.—E. **Rona**: (Radium Institute, No. 184.) Determinations of the absorption and range of natural H-rays.—E. **Gebauer-Fulnegg** and **Riess**: Quinone-sulphur-imines.—C. **Diener**: The fossil deposits in the Hallstatter limestones of the Salzkammergut.—L. **Kober**: New contributions to the geology of the eastern Tauern and the Salzkammergut.

February 18.—J. **Lense**: Special ametric manifolds.

Washington.

National Academy of Sciences (Proc. Vol. 12, No. 2, February).—Charles E. **St. John**: The red shift of solar lines and relativity. The general displacement of spectral lines towards the red required by relativity is found, but there are noteworthy discordances between theoretical and observed values. The deviations are correlated primarily not with intensity but with the level in the sun's atmosphere at which the lines in question are produced. Generalised relativity provides a general displacement due to the slowing-up of the atomic clock. The Doppler effect, due to radial movements in the solar atmosphere, explains systematic deviations of high- and low-level lines. Differential scattering, owing to the longer path in the solar atmosphere traversed by light from the limb, accounts for the increased displacement of lines from the limb (limb effect).—G. W. **Keitt**: Some relations of environment to the epidemiology and control of apple scab. Apple scab (*Venturia inæqualis* (Cke.) Winter) has been studied in the field and under controlled conditions. In Wisconsin, the fungus winters in infected leaves on the ground and in spring ascospores are shot out and carried by air currents to the trees, where infection is spread by conidia. The optimum temperature for infection and ascospore germination is about 20° C. Fluctuations in humidity have little effect. Sulphur fungicides are most effective against scab.—E. O. **Salant**: Infra-red absorption of the N-H bond. Examination of a series of symmetrical dialkyl and trialkyl amines indicates that the N-H bond has a characteristic fundamental vibration frequency varying between wave-numbers 1400 and 1700, according to the other atoms in the molecule.—F. R. **Bichowsky** and H. C. **Urey**: A possible explanation of the relativity doublets and anomalous Zeeman effect by means of a magnetic electron. It is assumed that the electron is a charged magnetic doublet of the magnetic moment of half a Bohr magneton and the perturbing effect of other electrons is neglected. Half-quantum numbers are adopted, the total magnetic moment of an atom being assumed to be contributed half by the electron rotating on itself and half by its rotation round the nucleus.—F. **Zwicky**: Theory of the specific heat of electrolytes.—T. **Lyman** and F. A. **Saunders**: The spectrum of neon in the extreme ultra-violet. Lines between $\lambda 630$ and $\lambda 590$ appear to be due to normal neon (Ne I); the spectrum of ionised neon (Ne II) extends to $\lambda 430$.—Arthur J. **Dempster**: The free path of protons in helium Protons accelerated through 900 volts potential difference pass freely through atoms of helium with only slight changes in velocity or direction. It is suggested that these protons, having much smaller velocities than the electrons in the atom, cause only a slow modification of the electronic orbits without producing permanent disturbance or ionisation.—W. M. **Davis**: Subsidence rate of reef-encircled islands. The formations in the open Pacific support the view that reef upgrowth occurred on foundations which subside at (1) a slow rate which can be counterbalanced by lagoon aggradation as well as by reef upgrowth, or (2) at a rapid rate which cannot be counterbalanced. Reef upgrowth is slower than coral upgrowth.—H. S. **Vandiver**: Summary of results and proofs concerning Fermat's last theorem.—G. V. **Rainich**: Mass in curved space-time. In the general relativity theory, the electric charge appears as a residue of a field derived from the curvature field; an expression of the type of a residue is obtained for mass in the centro-symmetric case. This mass constant appears to be connected with the complete Riemann tensor, and it seems that, in order to introduce mass, it is necessary to separate space and time.—Aristotle D. **Michal**: Concerning certain solvable equations with functional derivatives.—Joseph Miller **Thomas**: First integrals in the geometry of paths.—Luther Pfahler **Eisenhart**: Einstein's recent theory of gravitation and electricity. Equations which should replace Maxwell's equations are obtained in tensor form.—Oliver R. **Wulf**: Evidence for the existence of activated molecules in a chemical reaction. The heat of reaction when ozone decomposes does not afford sufficient energy for the excitation of the radiation emitted. This radiation agrees closely with the emission spectrum of ozone molecules, suggesting the presence of activated ozone molecules.—John J. **Abel**: Crystalline insulin. An insulin solution (40 rabbit units to the milligram) is taken up in acetic acid, and impurities are precipitated with brucine and removed. Treatment of the clear liquid with pyridine give a crystalline precipitate Larger crystals are obtained by re-crystallisation from disodium hydrogen phosphate. Amounts so small as 0·01 mgm. per kilo of the crystalline substance reduced the blood sugar of rabbits to the convulsive level.

Official Publications Received.

Union of South Africa. Department of Mines and Industries: Geological Survey. Memoir No. 23: The Economic Geology of Sabie and Pilgrims Rest. By W. J. Wybergh. Pp. 124+5 plates. (Pretoria: Government Printing and Stationery Office.) 5s. 6d.

Legislative Assembly, New South Wales. Report of the Director-General of Public Health, New South Wales, for the Year 1924. Pp. v+191. (Sydney: Alfred James Kent.) 8s. 8d.

Ministero dell' Aeronautica: Aviazione civile e traffico aereo. Ufficio presagi. Annuario 1926. Pp. 142. (Roma.)

Department of the Interior: Bureau of Education. Bulletin, 1925, No. 23: Statistics of Teachers Colleges and Normal Schools, 1923–1924. Pp. 60. 10 cents. Bulletin, 1925, No. 35: Review of Educational Legislation, 1923–1924. By William R. Hood. Pp. 22. 5 cents. (Washington, D.C.: Government Printing Office.)

Aeronautical Research Committee. Reports and Memoranda, No. 964 (Ae. 196): The Representation of Aircraft Performance Tests, using Non-Dimensional Variables, with special reference to the Prediction of the Effects of Change of Loading on Performance. By R. S. Capon. (A.4, a Full Scale Work—Aeroplanes general 125—T. 2096 and A.) Pp. 7+2 plates. (London: H.M. Stationery Office.) 4d. net.

Havsforskningsinstitutets Skrift. No. 28: Isarna vintern 1922–23. Referat: Das Meereis im Winter 1922–23. Av Gunnar Granquist. Pp. 121. 30 Fmk. No. 30: Thalassologische Beobachtungen im Alands- und Schärenmeer im Juli 1922 und Juli 1923. Herausgegeben von Rolf Witting und Hans Pettersson. Pp. 89. 7 Fmk. No. 32: Talassologiska vårexpeditionen 1924. Referat: Die thalassologische Terminfahrt im Jahre 1924. Av Risto Jurva. Pp. 27. 4 Fmk. No. 33: Beobachtungen von Strom und Wind an den Leuchtschiffen im Jahre 1923. Von Erik Palmén. Pp. 26. 6 Fmk. (Seattle, Wash.: University of Washington Press.)

The Institution of Mining and Metallurgy. List of Members (with Topographical Index), Constitution and By-Laws and Royal Charter of Incorporation. March 1926. Pp. 158. (London.)

Reports of the Council and Auditors of the Zoological Society of London for the Year 1925, prepared for the Annual General Meeting to be held on Thursday, April 29th, 1926. Pp. 79. (London.)

Diary of Societies.

SATURDAY, April 17.

North of England Institute of Mining and Mechanical Engineers, at 2.30.—Dr. R. Thiessen: The Contributions made by the Microscopical Study of Coal (Address).—Discussion on Paper by P. S. Lee on Haulage Accidents, and one by S. Burns on Winding Costs: A Plea to the Purchaser of Electric Winding Plant for Withdrawal of Stipulations which are not conducive to Economical Working.

Royal Institution of Great Britain, at 3.—Dr. W. T. Calman: The Shipworm (1).

MONDAY, April 19.

Institution of Post Office Electrical Engineers (at Royal Technical College, Glasgow), at 2.30.—Films: Travelogue of London and Rural Districts, with Special Reference to Telephone and Cable Development.—Creating the Instruments of Speech.

Royal Geographical Society (at Lowther Lodge), at 5.—Dr. Vaughan Cornish. Harmonies of Tone and Colour in Scenery determined by Light and Atmosphere.

British Psychological Society (at London Day Training College), at 6.—A. G. Hughes: Number Games: their Value as Drill in Arithmetic

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (Annual General Meeting) (in Liverpool University), at 7.—Prof. S. P. Smith: An All-Electric House.

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.15.

Royal Institute of British Architects, at 8.

Aristotelian Society (at University of London Club), at 8.—Dr. C. D. Broad: Kant's First and Second Analogies of Experience.

Royal Society of Arts, at 8.—C. R. Peers: Ornament in Britain (Cantor Lectures) (1).

Chemical Industry Club.

TUESDAY, April 20.

Royal Statistical Society (at Royal Society of Arts), at 5.15.—H. W. Macrosty: Statistics of British Shipping.

Society of Chemical Industry (Chemical Engineering Group) (jointly with Birmingham Section) (at White Horse Hotel, Birmingham), at 6.30.—W. A. Benton: Measuring and Weighing Apparatus as applied to Chemical Works.—W. Hall-Simmons and F. C. Sutton: Rotameters in Chemical Industry.

Royal Society of Medicine, at 5.30.—General Meeting.

Institute of Marine Engineers, at 6.30.—W. Griffiths: Bearing Metals.

Royal Photographic Society of Great Britain, at 7.—C. Fabry: The Photographic Plate as a Measuring Instrument for Visible and Invisible Radiations (Hurter and Driffield Memorial Lecture).

Institution of Automobile Engineers (at Royal Society of Arts), at 7.30.—H. S. Rowell: Experiments on Laminated Springs.

Royal Anthropological Institute (Indian Section), at 8.30.—L. H. Dudley Buxton: Ethnic Relations in India and the Near East.

Medico-Legal Society (at 11 Chandos Street, W.1), at 8.30.—C. Ainsworth Mitchell: Some Aspects of the New Regulations on Preservatives.

WEDNESDAY, April 21.

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: Organs of Multiple Function: (2) The Spleen.

Royal Meteorological Society, at 5.—Dr J. Glasspoole: The Driest and Wettest Years at Individual Stations in the British Isles, 1868 to 1924.—C. E. P. Brooks: (a) The Meteorological Conditions during the Glaciation of the present Tropics, being some Remarks on the Climatological Basis of Wegener's Theory of Continental Drift; (b) The Variations of Pressure from Month to Month in the Region of the British Isles.

Geological Society of London, at 5.30.—L. R. Cox: *Anthracopupa britannica* sp. nov., a Land Gastropod from the Keele Beds of Northern Worcestershire.—H. P. Lewis: On *Bolopora undosa* gen. et sp. nov.: a Rock-Building Bryozoan with Phosphatised Skeleton from the Basal Arenig Rocks of Ffestiniog (North Wales).—Dr. C. A. Matley: The Geology of the Cayman Islands (British West Indies), and their Relation to the Bartlett Trough.—Sir T. W. Edgeworth David: Exhibition of Lantern-Slides illustrating the proposed new Deep Boring on the Great Barrier Reef, off Cairns (Queensland).

Institution of Electrical Engineers (Sheffield Sub-Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.—Major E. I. David: Electricity in Mines.

Royal Society of Arts, at 8.—Major-Gen. Sir George McMunn: Some Aspects of the Business Side of an Army.

Institute of Chemistry (London Section).

Society of Glass Technology (Annual General Meeting) (at Sheffield).

THURSDAY, April 22.

Royal Institution of Great Britain, at 5.15.—Prof. O. H. P. Prior: Anglo-Norman Literature: An Introduction.

Institution of Electrical Engineers, at 6.—Sir J. J. Thomson: The Mechanics of the Electric Field (Kelvin Lecture).

British Astronomical Association (West of Scotland Branch) (at Royal Technical College, Glasgow), at 7.30.—Dr. J. K. Fotheringham: Early Astronomical Observations and their Value.

North-East Coast Institution of Engineers and Shipbuilders (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 7.30.—H. Thomson. Humber Arm Hydro-electric Scheme.

Chemical Society, at 8.—W. C. Reynolds: An Analysis of the Ether. Part II. The Magnetic Fields in Atoms.

C.B.C. Society for Constructive Birth Control and Racial Progress (at Essex Hall, Essex Street, Strand), at 8.15.—Lord Morris and Dr. Marie Stopes: Debate on Birth Control.

Royal Society of Medicine (Urology Section), at 8.30.

Oil and Colour Chemists' Association.

FRIDAY, April 23.

Physical Society of London (at Imperial College of Science and Technology), at 5.—Prof. C. Fabry. The Absorption of Radiation by the Upper Atmosphere (Guthrie Lecture).

Society of Chemical Industry (Manchester Section), at 7.—Sir Arthur Duckham: The Profession of the Chemical Engineer (Lecture).

Institution of Mechanical Engineers (Informal Meeting), at 7.—F. J. Hookham and others: What our Foreign Competitors are Doing.

Royal Photographic Society of Great Britain, at 7.—S. Turner: An Explorer in the New Zealand Alps (Lecture).

Institute of Metals (Swansea Local Section) (at University College, Singleton Park, Swansea), at 7.15.—Annual General Meeting.

Junior Institution of Engineers, at 7.30.—Question and Discussion Evening.

North-East Coast Institution of Engineers and Shipbuilders (at Newcastle-upon-Tyne), at 7.30.—W. S. Burn: High-Powered Oil Engines.

Royal Institution of Great Britain, at 9.—Prof. R. Whiddington The Luminous Discharge through Rare Gases.

SATURDAY, April 24.

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 3.—J. G. Taylor: Coal anc its Banded Constituents.

Royal Institution of Great Britain, at 3.—Dr. W. T. Calman The Shipworm (2).

CONVENTION, ETC.

April 12 to April 27.

International Forestry Exhibition (at Milan).

April 16 to April 20.

International Society of Medical Hydrology (Annual Meeting wil be held in Czecho-Slovakia). (Particulars from Dr. E. P. Poulton, a 36 Devonshire Place, W.1.)

April 17.

Optical Convention (at Imperial College of Science and Technology):—At 10 to 12.—Reading and Discussion of Papers; at 12—Concludin General Meeting.

The Position of Naval Engineers.

IT was the late Lord Goschen who, forty years ago, remarked in the House of Commons that "discontent in the public service is a great calamity to the country." Curiously enough, he was then referring to the efforts being made to raise the status of engineer officers in the Royal Navy. Were he alive to-day he would have greater cause to utter the warning, for if ever there was a matter calling for inquiry and remedial measures, it is the discontent which has arisen through the treatment of the engineer officers of to-day, and especially those who have been trained at Osborne and at Dartmouth. These are the officers who, instead of electing to remain on the upper deck and to become navigating, torpedo, and gunnery officers, have specialised in engineering duties and are therefore known as lieutenants 'E' and commanders 'E.' Numbering between two and three hundred, these officers have been promised over and over again that by specialising in engineering their position as executive officers should in no way be jeopardised, and that they should be considered eligible for appointments as admiral superintendents of dockyards and similar posts. They were, in fact, to remain on an absolute equality with the navigating, torpedo, and gunnery officers, except that by becoming engineer officers they abandoned the right to command sea-going ships and, of course, fleets. Of these things there is no shadow of doubt whatever. There never was a clearer case of what was promised and intended, and the officers in question have nothing to fear by the fullest publicity.

The discontent to which we refer is the result of the Fleet Order No. 3241 of last November, an Order which will go down to history as one of the most sinister pieces of internal legislation recorded in any of our public services. Meanly conceived, provocatively worded and aggressively promulgated, that Order has created dissatisfaction throughout the engineering world, and the remonstrance uttered by Sir William Ellis at the recent dinner of the Institution of Naval Architects, when two members of the Board of Admiralty were present, is without precedent in the history of naval affairs. This great Institution was founded in 1860, but we believe a search through its index would fail to find any similar reference to any body of officers employed under the Admiralty, much less to a body of officers who come under the Naval Discipline Act. The remonstrance of Sir William Ellis had been preceded earlier in the day by the speech of the Duke of Northumberland, who, as president of the Institution, voiced the opinion of the council on which serve some of our greatest naval architects, shipbuilders, and engineers, and among whom are Admiralty officers.

We have already, in our article of February 6 on "The Status of the Naval Engineer," given a fair and impartial account of the circumstances leading up to the grant of military status to all engineer officers, and we there referred to the deputation which, with Sir William Ellis as its head, waited upon the First Lord, the Right Hon. W. C. Bridgeman, M.P. Mr. Bridgeman's reply unfortunately revealed no spirit of conciliation or sympathy. He practically told the deputation they had no case, there was nothing in the order derogatory to the position of the engineer officers, and that there was no cause for any feeling of injustice. If Mr. Bridgeman really meant what he said, then he could not have taken the trouble to get down to the bottom of things, while if he simply acted as the mouthpiece of the executive officers on the Board, he was wanting in the first attribute of a statesman.

The further action of the deputation is justified in every respect. It immediately published in full the memorandum which had been handed to Mr. Bridgeman; it stated that Mr. Bridgeman's reply was viewed with grave concern, and it said it would take steps to raise the question in Parliament and the public press. Since then a debate has taken place in the House of Commons in which Mr. Bridgeman treated the matter as of little moment and, among other things, said, "I do not think that those who have raised this question are doing any service to the Engineer Officers in the Navy by trying to magnify what I think is a very trifling irritation," so that which every engineer both inside the Admiralty and outside consider a gross injustice, Mr. Bridgeman regards as a "trifling irritation."

The more one knows of the Order the more one is astonished; and how the distinguished men on the Board could have put their names to such a document is inexplicable. The Order, if it meant anything, meant that it took away the special standing granted to engineer officers by the Selborne Scheme and by the Admiralty action in 1915. The granting of military status to engineers in the Navy was welcomed right throughout the land, but to-day, with the echo of the guns still in our ears, the very Admirals who gained their earldoms and their knighthoods and their grants of public money through the successes which in the first place depended on the efficiency of the engineering branch of the Navy, are content to see the engineers again reduced to the inferior position they occupied for so long.

Were all their eulogies of the engineering department so much lip service? Here is one such eulogy: it was written after the Battle of Jutland. "During action the officers and men of that department perform their most important duties without the incentive which the knowledge of the course of the action gives to those on deck. The qualities of discipline and endurance are taxed to the utmost under these conditions, and they were, as always, most fully maintained throughout the operations under review."

During the War, the Engineer-in-Chief was responsible for a personnel exceeding eighty thousand, and yet to-day his department can be treated as if of little account; an Order adversely affecting the whole of his staff can be drawn up without consulting him, and all the guarantees given can be converted into scraps of paper.

To all this there is no answer. The pages of the engineering press and the columns of the *Times* have recorded again and again the protests of the engineers who have served in the Navy and are of the engineering profession, and though there are some three hundred retired flag officers and some six hundred retired captains, none of them come forward to uphold the Admiralty or to explain the need for the deprivation of the engineers of their military status. Could there be any more significant fact? The Order of last November had as its sole object the belittlement of the engineers, and it was known at the time that the want of military status would load the scale against the engineer on every possible occasion.

It would be a slander to say that the Order of November reflects the general attitude of the executive officers of the fleet toward the engineer officers, for there is plenty of evidence to the contrary. If the Board of Admiralty is resolved not to rescind the Order, it will be the duty of the Engineering Institutions to take the matter higher, for clearly the injustice of the whole thing will inevitably foster that discontent which Lord Goschen stated to be "a great calamity to the country."

Egyptology in Victorian Dress.

Descriptive Sociology: or, Groups of Sociological Facts. Classified and Arranged by Herbert Spencer. Division 1, No. 11: Ancient Egyptians, Compiled and Abstracted upon the Plan organised by Herbert Spencer by Prof. Sir W. Flinders Petrie. Issued by Mr. Spencer's Trustees. Pp. iii + 3 Tables + 79. (London: Williams and Norgate, Ltd., 1925.) 25*s.* net.

"IN preparation for *The Principles of Sociology,* requiring as bases of induction large accumulations of data, fitly arranged for comparison, I, in October 1867, commenced by proxy the collection and organisation of facts presented by societies of different types, past and present: being fortunate enough to secure the services of gentlemen competent to carry on the process in the way I wished. Though this classified compilation of materials was entered upon solely to facilitate my own work; yet, after having brought the mode of classification to a satisfactory form, and after having had some of the Tables filled up, I decided to have the undertaking executed with a view to publication: the facts collected and arranged for easy reference and convenient study of their relations being so presented, apart from hypothesis, as to aid all students of Social Science in testing such conclusions as they have drawn and in drawing others."

The quotation is from Herbert Spencer's "Provisional Preface" to the second volume in the series which he began to publish under the general title of "Descriptive Sociology," and the date subscribed to it is 1874. Another volume appeared in the same year, and a third in 1876. Fifty years later Sir Flinders Petrie gives us "Ancient Egyptians," and we learn from his preface that two further volumes are in the press, besides a reprint of one of the earlier volumes. Their ultimate purpose is explained in the passage quoted above. The idea of collecting data from all known civilisations (divided into three groups: "uncivilised societies,"—in which ancient Egypt is included !—"civilised societies, recent or decayed," and "civilised societies, present or still flourishing"), analysing their contents, and evolving generalisations from the results, was a colossal conception even for the Victorian Age, when the limits of knowledge in any one sphere were comparatively small.

To-day, no one man would contemplate such an undertaking as an ideal, still less as a practicable possibility. It is now more than twenty years since Spencer died, and the introductory volumes of material, originally intended "solely to facilitate my own work," are still to be completed. What was to be his own work, "The Principles of Sociology," will never appear. In the days when solidity was as essential in furniture as it was in morals and literature, and when to make a book look as much like an office ledger as possible seemed to give it a guarantee of respectability, a book 19½ in. × 12½ in. may well have been considered fitting. But the publishers can scarcely be forgiven for offering their public, in 1926, a work of archaic form and appearance, modelled on the standards of 1850, which for inconvenience of size makes a ledger look almost like a pocket edition! The cover and arrangement of the letterpress within are in keeping, and give the book so antiquated an appearance that one can only suppose it possible that Mr. Spencer's trustees and their publishers are tied up by testamentary red tape in the matter.

If in such a volume the information is considered to have been arranged "for easy reference and convenient study," what should we have had to expect from the great work of which it is only one of the foundation stones?

Yet if we are relieved at our loss, we have to consider that it was essentially the plan that was wrong—and not the purpose. Much in the paragraph quoted at the beginning of the review is strongly reminiscent of the objects for which the Royal Anthropological Institute now exists. The method which Spencer here originated was the method of modern anthropologists. His aim was essentially scientific—to collect all possible data; without which no conclusions were valid. Only, he proposed to do by himself what we now know cannot be done by one man.

In the collection of his material, however, he accepted the principle of specialisation. The bulk of each volume consists in quotations from trustworthy published works, with references, giving all the facts concerning the Society under discussion which can be grouped under the heading sociological. To these were appended tables (generally three or four) giving an analysis of the chronological development of the main sociological factors.

Sir Flinders Petrie began to prepare the volume under consideration in 1910. But, as he points out in his preface, a great deal of our knowledge of ancient Egypt is—and at that time still more was—not yet published in books, but is inherent in the objects in our museums and in the inscribed and painted walls of the buildings of Egypt. Thus, in addition to the extracts from published works (most of which were made by Miss M. A. Murray), a great deal had to be written up by Petrie himself. In this respect it may be noted that, though the work was begun sixteen years ago and its publication only stopped by the War, he has been conscientious in bringing this additional matter of his own up-to-date, at all events in reporting the results of recent excavations. Although in the opinion of the reviewer Petrie is not prepared to give its due to the documentary evidence—on stone inscriptions and papyri—from the ancient Egyptian civilisation, yet no one could deny that we owe a far greater proportion of our knowledge of its sociology to the objects found in the country; and as it was a rich and powerful civilisation which lasted over thousands of years, the variety of those objects is immense.

This has resulted in the production of a book even more of the nature of an encyclopædia than Mr. Spencer's principles necessitate. It is, in fact, a glorified handbook to Egyptology, very thorough in its intention to cover all the ground, but hopelessly inadequate in detail—as it needs must be—on some of the most interesting points. Thus while Herodotus is quoted to prove that gymnastics were practised in honour of a

Greek hero in Panopolis, the inventor of the system of "sequence-dating" has confined his remarks on pottery to two quarter columns which are largely mutually inclusive. But our quarrel here is not with Petrie, for if the work was to be done no one was better qualified for it than he. Rather, the question is: What is the justification for an encyclopædia of this sort? To the specialist in Egyptology it is waste of labour to turn to it. The matter under any given heading is necessarily so general that he already knows it, and the list of reference books, to which he is sent for greater detail, contains nothing with which he is not familiar. In other words, he would go straight to whichever of these works he requires without thinking of consulting "Descriptive Sociology."

For the layman it is more promising—at first sight. For those who have no particular interest in Egypt it may sometimes be necessary to consult Egyptian practice, mainly in connexion with other facts. They have only to refer to the "Contents" of this book, which gives all the headings and sub-headings in the order in which they occur, and takes the place of an index. They can turn up the main facts on the spot and discover where to find a fuller treatment of the subject when they want it. Unfortunately this has been done far better long ago. Erman's "Life in Ancient Egypt" covers all the ground (frequently, of course, in bare detail) and presents a consistent and readable story, efficiently illustrated, and supplies references and bibliography. It does all this in a volume of convenient size for handling, which was quite recently re-edited by Ranke. It is indeed difficult to see how anybody should buy Sir Flinders Petrie's book unless it be that he is anxious to have a complete series of the "Descriptive Sociology."

It is difficult to review the matter, as such, in a compilation of this kind, more particularly when so much of it consists of extracts from other writers. In spite of a large proportion of works by the author—46 out of 158—in the "List of Books," the references are very fairly distributed, and with, on the whole, a very impartial judgment which frequently leads to the juxtaposition of opposite views. It would be strange if there were not details at which to carp. Perhaps the most glaring fault in the text itself is the small space given to the subject headed "Language and Writing." All that we know about the hieroglyphic and cursive writings, and the literature they express, is summarised by Petrie in a single page, and no mention is made of the great Herakleopolitan literary tradition. Such omission, however, is at the worst an error of judgment. There is one point with which criticism must deal far more sternly. It is an old source of bitter complaint amongst Egyptologists, and in a specialist Egyptological journal we should prefer to pass over it. For there, at least, it does no harm, since we are aware of Sir Flinders' idiosyncrasy in the matter. But to those unacquainted with the literature on the subject his introduction to Egyptian chronology will not only be utterly misleading as to the facts themselves, but also prejudicial to the trustworthiness of other writers.

The form of this introduction, consisting of a short list of periods and dates (headed "Periods of Egyptian History"), is familiar to Egyptologists. In these columns are placed respectively a date, the name of the geological period, or later of the dynasty, and the site on which remains of the period have been found. Passing over, as too technical a point for discussion here, the concatenation of two entirely separate flint finds at Badari and in the Fayum Desert under the single description of "Solutrean" (with a correspondingly high date—11000–9500 for both), we come to the crux of the matter in the subdivision of Dynastic dates, headed respectively "By the Egyptians," "By Berlin 1917," and "Berlin 1900." Thus for the 1st Dynasty we get the equation: By the Egyptians, 5500–5300; By Berlin 1917, 4186; Berlin 1900, 3400. If only one Berlin date were given, it might be possible to assume that Sir Flinders Petrie was holding the dating of the Egyptians up to scorn in the light of modern scientific research! As it is, the only conclusion that the uninitiated can draw is that German scholars are so uncertain of their chronological methods that they alter a single date by nearly a millennium in the course of seventeen years' study; hence no reliance is to be placed in them; and that all this is due to the fact that they will not follow the ancient Egyptians' own account of their chronology (as contained in the Palermo Stone, etc.).

This can only be characterised as a very strange presentment indeed of the facts. In the first place, "Berlin 1900" represents the date generally accepted (with very slight variations) by scholars not only on the Continent, but also in Great Britain and in the United States, with only two exceptions, namely, the authors of the systems detailed in Petrie's other two columns, himself and Dr. Borchardt, who is meant by the column "By Berlin 1917," which is still credited by one or two German scholars, in spite of its recent demolition by Prof. Peet. Thus the date proposed by Eduard Meyer (Berlin 1900) has been generally accepted, with but slight modification, ever since. The phrase "By the Egyptians" is equally misleading, suggesting as it does that the German historians must have disregarded the evidence of Egyptian documents. No suggestion could be more inept, for without those documents it would be impossible to produce any chronology at all. We need not go into the technical points for or against the inclusion of the extra Sothic cycle which is responsible for the difference in dating between Petrie and all other scholars; for it should be clear to all fair-minded persons that unless the rest of the Egyptological world is leagued together to put Petrie in the wrong, regardless of truth, the chances are that the majority is right. We do not, of course, take objection to Sir Flinders Petrie's statement of his own opinions, but to this curious presentation of other people's, more particularly in a book which will by its nature be read (if at all) by the layman, who cannot test the matter, rather than by specialists, who discount what Sir Flinders says on the subject of chronology before the time of the XVIIIth Dynasty.

Timber Pests.

Enemies of Timber: Dry Rot and the Death-Watch Beetle, in which the Origin and Life-History of the two worst Enemies of Timber are given, with a Description of the Damage they cause, and the Methods to be adopted for their Examination By Ernest G. Blake Pp. xvii + 206 + 10 plates. (London: Chapman and Hall, Ltd., 1925.) 12*s.* 6*d.* net.

IN these days when there is grave need of sound technical advice designed to decrease private and national waste, and when it is so desirable that the general public shall acquire confidence in the practical value of technological science, it is regrettable that so unsatisfactory a compilation as the book under review should have been published In the text elementary errors on fundamental matters and details abound, while misleading practical conclusions and unsound advice recur at intervals. A few quotations suffice to justify this condemnation.

"The endogens [monocotyledons] are described as inward growers, because the new tissue is formed annually at the centre of the tree instead of at the outside." "In the hardwoods [dicotyledons] the annual rings are nearly always narrow . . ; the colour of the wood is dark . . .": in the softwoods [conifers] "the annual rings are a good deal wider than in the previous class. . . ."

"Dry rot is caused by the extraction of a portion of the mineral contents by the roots of the fungus." "There are four conditions that are necessary for the successful germination and for the development of the fungus [causing dry rot]; these are darkness . . ."; there is "absolute necessity for the complete stagnation of the air before it [the fungus] can develop to its fullest maturity."

Particularly dangerous as regards its practical results are the misstatement that a fungus causing dry rot "is propagated only by means of spores," and the allegation that fungus-infected wood can be sterilised by "subjecting it to heat . . . in a drying kiln that is raised to . . about 110 Fahr." Of the many species of fungi causing dry rot the author deals only with three, all of them growing outside as well as inside wood; he never even mentions those species the vegetative growth of which is confined to the interior of the wood. Despite of repeatedly terming dry rot a disease, he fails to see that the most economic treatment should be that suited to the particular fungus present, and regardless of expense he prescribes the same costly treatment for all.

The part of the book dealing with the only two species of wood-attacking insects considered, *Anobium punctatum* and *Xestobium tesselatum*, is perhaps the least unsatisfactory; for the author appears to have made free use of the writings of Dr. Gahan and Prof. Maxwell Lefroy, and provides some excellent figures of the two species and their work Yet it is truly remarkable that an author setting out to give practical advice on preservation of wood in buildings should be under the impression, and should actually state, that dangerous attacks by Xestobium are more unseen and stealthy than those of termites and fungi causing dry rot. He appears to be unaware that a joist attacked by 'worm' sustains its load years after its surface shows holes made by these insects, whereas a joist hollowed to a mere shell by termites, or thoroughly rotten with internal decay caused by a species of Lenzites, may show no external sign of injury before it crashes

P. G.

British Universities.

The Yearbook of the Universities of the Empire, 1926. Edited by W. H. Dawson. (Published for the Universities Bureau of the British Empire.) Pp. xii + 792. (London: G. Bell and Sons, Ltd., 1926.) 7*s.* 6*d.* net.

THE "Yearbook" was first published in 1914 as a handy substitute for a collection of the calendars of the universities of the British Empire. According to the preface, the aim of the editor was to collect from the calendars information of general interest and value to members of other universities, to public bodies, and to the public generally. This is a task by no means to be underrated, and we may say at once that it has been admirably carried out. The arrangement of the book is conveniently simple and consistent throughout, so that in a few minutes a working knowledge of it can be obtained.

The volume is intended to be used for reference and can scarcely be said generally to be 'readable' in the ordinary sense; nevertheless, the introductions to the sections dealing with the universities of Great Britain and Ireland, of Canada, of Australia, of South Africa and of India, form interesting summaries of the history of university education in the Empire. Under the heading of each university is collected a vast amount of important and useful information as to the institutions, teachers and degrees, together with some account of inter-university co-operation and what may be called extra-mural work, such as public lectures and extension work.

University education is now an integral part of our national life, and the general public can scarcely fail to find interesting the sketch of the work of the universities of the British Empire and the notes showing the developments during the past year.

The appendices, in our opinion, constitute the most valuable part of the work. The sections on individual universities are undoubtedly a great convenience, but would probably be used most extensively by those who already have access to the calendars. The appendices, however, collate information of the utmost value. It is obviously necessary, for parents and teachers especially, to have a concise guide to the professions and careers for which universities can provide preparation, and in this respect the information may be considered adequate. No less valuable is the section dealing with professional schools and subjects of specialised study in the universities of the United Kingdom. Again, information is collected in the appendices as to matriculation examinations and conditions of admission of students from abroad. This alone should assure that the "Yearbook" is ready of access to parents and students, especially to those residing abroad. We have had considerable experience of overseas students, and are certain that much disappointment and expense would be avoided by them if they had a clear idea before they left home as to what the universities require for the purposes of admission. The "Yearbook" information on the subject is by no means exhaustive, but it at least provides an indication as to how to proceed.

Much could be said in commendation of the other appendices, but it will be sufficient in a short notice to express our opinion that the editor has performed a great service by including information about inter-university scholarships and research grants and about foreign universities, since the practice of migrating to other universities at home and abroad for advanced work has now fortunately become well established.

In dealing with a book of this kind it is not unimportant to note that there are complete indexes of names and of colleges as well as a general index. Looking at the "Yearbook" as a whole, it is difficult to see how the material could have been arranged more effectively. It is extraordinary what interest the editor has managed to infuse into a book which, in the manner of directories, must be dull in places. The work, too, must be regarded as one result of the working out of the great aim of the body for whom it is published—the Universities Bureau of the British Empire—namely, to bring into closer touch with each other the universities of the Empire.

S. J. W.

Histogenesis of Human Endocrine Organs.

The Histology of the more Important Human Endocrine Organs at Various Ages. By Dr. Eugenia R. A. Cooper. (Oxford Medical Publications.) Pp. xiii + 119. (London: Oxford University Press, 1925.) 12s. 6d. net.

In this small volume a praiseworthy attempt is made to record the histological appearances of some of the endocrine organs of the human subject at various ages. The author confines her task to the thyroid, parathyroid, pituitary body, suprarenals, and thymus, though recognising that the latter organ has little claim to be considered an internally secreting gland.

For purposes of comparison of the same organ at different ages constant methods of fixation and staining are necessary, and the author has selected the simplest and most commonly employed. Formal infixation has its advantages when the material to be investigated is not available immediately after death; but exact cytology is impossible, and only the grosser changes in structure can be revealed under these conditions. For this reason the work will be of more interest to the pathologist than to the histologist. Another serious difficulty lies in the determination of what is normal and what is pathological in human material. Some of the observations recorded in the book have been made on subjects, presumably healthy, who have died from accidents, but the bulk of human material obtained from the mortuary is more likely to be pathological. The author is aware of this, and quotes Hammar to the effect that "the thymus gland is never found in the normal condition in persons who have died from disease." But bearing this in mind, a real service is undertaken in the description of glands at different ages as revealed by ordinary methods. A knowledge of microscopic structure at various ages in the human subject can only be obtained by the continuous observation of an abundance of carefully selected material. The author has made a good beginning, and it is to be hoped that she will carry on the work.

The pituitary gland is fully described; but it would be better in future to distinguish between the pars intermedia and pars tuberalis, the histological characters of which are quite distinct in the human pituitary. Some interesting observations are made upon the development of the suprarenals, but the employment of special methods is necessary to arrive at their correct interpretation.

The volume would be improved by the addition of the pancreas and gonads to the list of organs described. The condition of the Islets of Langerhans in pathological conditions requires investigation, but more elaborate methods would have to be undertaken if anything is to be made of the 'a' and 'b' cells of these structures.

The photomicrographs are for the most part well chosen and admirably reproduced; an index and useful bibliography are also furnished.

Our Bookshelf.

The Classification of Flowering Plants. By Dr. Alfred Barton Rendle. Vol. 2: Dictoyledons. Pp. xix + 636. (Cambridge: At the University Press, 1925.) 30*s.* net.

After a somewhat long delay, the second and concluding part of this work has appeared, and may be cordially welcomed. Like the first, it follows the system of Engler, but in a general and not in any very close manner, and with considerable alterations in the system that many will think to be great improvements, especially from the point of view of practical usefulness in the study of systematic botany—the purpose for which the work is chiefly designed.

In a large monographic study, like the great work of Engler and Prantl, one must try to represent as closely as possible what one considers to be the most natural phylogenetic arrangement practical with the knowledge then available But in ordinary practice, with a reader who is not highly skilled in taxonomy, one may almost say that the more nearly phylogenetic the arrangement, the more difficult does it become to use the system for the everyday purpose of determining the approximate relationships of plants more or less casually encountered. A departure from this method is desirable in the case of a book designed for students, and that is provided here with the restoration of the old group of the Monochlamydeæ. To be able to place a plant at once in one of three, rather than in one of two, divisions of dicotyledons is a great simplification of the labour; instead of having to wade through thirty orders, one has at most only seventeen. Each of the three groups thus made is then grouped in a phylogenetic arrangement, the Dialypetalæ, for example, beginning with the Ranales (now so commonly accepted as the most primitive of all) and working up to the Umbelliflorae, the Monochlamydeæ running from the Salicales to the Centrospermæ. Various alterations are also made in the arrangement of the orders and families, as compared with that adopted by Engler, and a great improvement is the splitting of some of Engler's unwieldy orders, *e g.* of his Geraniales into Geraniales and Rutales.

Turning to the details of the book, the accounts of the individual families are clear, full, and concise, and at the end of each is given a most useful reference to the two or three most important publications dealing with that family. Finally, a word of praise must be given to the clearly drawn and well-explained figures and diagrams.

Plant and Animal Improvement: a Textbook for Students of Agriculture. By Prof. Elmer Roberts, in consultation with Prof. Eugene Davenport. Pp. xii + 174 + 5 plates. (Boston, New York and London: Ginn and Co., 1925.) 6*s.* net.

This modest volume stands distinct among a rather considerable number of books on genetics and breeding which the past few years have brought us. Its aim is "To give the student an intelligent view of the processes involved in the improvement of plants and animals." A simple primer, with no pretensions to being anything else, in letter and in spirit a 'practical man's' book, it seeks not to prove but to relate. Simple language, with plenty of attractive illustrations and clear diagrams, will undoubtedly appeal to the agricultural reader who interests himself in science solely because it may forward his practice

Although detail is minimised, the exposition of fundamentals appears in general to have that security which brevity may sometimes endanger The field of the book is naturally limited, but seems wisely chosen. Domestication with the elements of cytology and reproduction in animals and plants make a good introduction. Then come the rudiments of heredity and selection and those interesting theories, like telegony and prepotency, with which the breeder appears almost to be born. An inspiring chapter for the breeder is taken up by the ancestry of domestic animals. At the end is the now inevitable chapter on statistics. This is almost too brief and simple to be safe. But it is not in the brief exposition alone that statistical principles are so presented to the agriculturist as to jeopardise biological soundness. That yield trials should find no adequate place is much to be regretted In scope and standard the book falls below the requirements of a normal university course for agriculturists. It offers, however, very profitable reading for the beginner and will certainly attract the practitioner.

Plant Forms and their Evolution in South Africa. By Prof. J. W. Bews. Pp. viii + 199. (London: Longmans, Green and Co, 1925.) 12*s.* 6*d.* net.

In discussing in detail the growth forms of South African species of plants, Prof. Bews has developed in an inspiring way a conception of their ecological evolution. Starting from the idea that a certain number of plant habitats (such as moist tropical forests, stream sides, and swamps) are likely to have persisted little changed for long periods and at least since Cretaceous times, he points out that these primitive types of habitat are on the whole chiefly populated by primitive types of plants. This conclusion holds whether the plants are judged to be primitive either on their reproductive characters or on their vegetative form. It is, therefore, a corollary of this that, on the whole, the more highly developed types of plants will occur chiefly in the more specialised types of habitat.

The South African flora lends itself very readily to interpretation along these lines. A large element of the flora is assumed to have come from the moist tropical forests to the north, and it is, therefore, not unexpected to find that most of the characteristic endemic forms are xerophytic. Further, if, in line with recent discussions, the tree growth form is regarded as primitive, then it automatically follows that the large number of scrub and grassland species in South Africa are, on the whole, of more recent origin, and the general trend of evolution would thus be towards xerophytic types. Prof. Bews notes that in such sub-tropical areas there is a tendency for a larger number of tropical types to appear as a given succession progresses, and he suggests the possibility of making use of this sequence to obtain some idea of the evolutionary groupings. An interesting observation is credited to General Smuts—that as the South African season develops, the tropical elements become more prominent, to the partial exclusion of the specialised South African types.

Blacks and Pitches. By H. M. Langton. (Oil and Colour Chemistry Monographs.) Pp. xi + 179 + 7 plates. (London: Ernest Benn, Ltd., 1925.) 15*s.* net.

This is one of a series of very useful monographs on oil and colour chemistry. The first five chapters deal with the production and properties of black carbonaceous pigments, followed by three chapters on the uses of such pigments in the paint, printing ink, and rubber industries. The following nine chapters deal with pitches, bituminous materials, and so on, the industrial uses in roofing felts, paving materials, paints, japans, etc., being considered in the concluding three chapters. Chapter xviii. is devoted to the weathering and ageing of bituminous materials.

A very wide range has been covered, and it can scarcely be expected that a full treatment of the subject could be condensed into 170 pages. Nevertheless, the volume is very readable and the author is to be congratulated on having done so much in so little space. The general arrangement of the book is good, the chapters following each other in logical sequence. An effort has been made to scan briefly all recent work on the subject, and for the reader seeking more detailed information the references and bibliography will be found very useful.

The author has, of necessity, drawn largely on American sources of information, and it will be clearly apparent to any reader how little favour the subject of blacks and pitches has found with research chemists in Great Britain.

The Table IX. on p. 39, taken from Bulletin 192 U.S. Dept. of the Interior Bureau of Mines, ought to have been reproduced in full scale, since in its present state it needs a lens to read it. Tables X. and XI. suffer from the same defect, and also Fig. 10. In this diagram the explanatory details to which the numbers refer have been omitted.

Visual Education. By F. N. Freeman and others. Pp. viii + 391. (Chicago: University of Chicago Press; London: Cambridge University Press, 1924.) 3.50 dollars.

Many recent books on juvenile delinquency have suggested that 'the pictures' have an educational influence in the undesirable arts of pilfering and truancy. This book, however, is a comparative study of the value of the moving picture and of other visual and oral methods of presenting the more conventional educational information imparted in schools. It summarises the results of a number of investigations made in the United States with a grant from the Commonwealth Fund. Most of the experiments consisted in teaching the same lesson to parallel classes of children by different methods—the motion picture, the lantern, personal demonstration, and oral presentation—and comparing the subsequent knowledge and achievements of the children.

The results so far obtained are not very conclusive, but suggest that up to the present the chief use of the motion picture is in furnishing an introduction to instruction about moving objects, but even then it should be shown in small lengths. For general purposes, demonstrations and oral lessons, with the accompanying personal emphasis of the teacher, give more satisfactory and lasting results.

Much research is needed, the authors contend, to find all the fields of instruction in which the cinema will be useful, and the form of film best adapted to educational purpose. The interest aroused in this new type of teaching for industrial as well as for scholastic education will undoubtedly ensure that such research will be forthcoming. W. J. G. S.

Left-handedness: a New Interpretation. By Beaufort Sims Parson. Pp. ix + 185. (New York: The Macmillan Co., 1924.) 8*s.* 6*d.* net.

The interest that has long been felt in the subject of left-handedness is testified to by the forty-seven pages of bibliography at the end of this book, and by the number and variety of theories described in the first chapter. Hereditary transmission, visceral distribution, anatomical inequalities, have all been advanced as possible explanations of left-handedness, but Mr. Parson finds none of these completely satisfactory and therefore offers a new and plausible theory of ocular dominance. His tenet, for which he gives experimental proof, is that man has progressed from pure binocular vision, and now has developed unilateral sighting facility which furnishes clearer vision. From this 'one-eyedness,' 'one handedness' (as opposed to ambidexterity) naturally follows, for the hand on the side of the functioning eye is more convenient for aiming. Habit ensures that this same hand is used for the manufacture and use of all instruments.

Mr. Parson suggests that the right, rather than the left, eye and hand have biological ascendancy from natural selection due to the increased chances of survival of those who used their left hands to protect their hearts, while their right hands were controlling their weapons.

Mr. Parson has devised a manuscope—an instrument for determining the dominant eye, and hence the probable handedness He has used it with interesting results with a large group of school children. The theory needs more evidence before it can be accepted, but it is decidedly suggestive and well worthy of future research. W. J. G. S.

Trattato di chimica generale ed applicata all' industria. Per Prof. Dott. Ettore Molinari. Vol 1: *Chimica inorganica* Parte Seconda. Quinta edizione riveduta ed ampliata Pp. viii+681-1351. (Milano: Ulrico Hoepli, 1925) 45 lire.

The publication of five editions of a treatise on chemistry of the magnitude of 'Molinari' within the space of twenty years furnishes irrefutable evidence of the cordiality with which the book has been received by Italian chemists. The present volume follows the same general lines as its predecessors and completes volume 1, dealing with inorganic chemistry. Although the bulk of this second part exhibits no great advance beyond that of the corresponding portion of the fourth edition, descriptions of most recent developments of value have been added. Moreover, a number of entirely new sections are included, the most noteworthy being those on the low-temperature carbonisation of coal, decolorising vegetable carbons, pulverised coal, titanium pigments, and the borax industry of Tuscany. The important subjects of electrolytic soda and cement are accorded even more detailed treatment than formerly.

In general, the statistical data which form such a marked feature of the book are brought up-to-date, but in many cases the prices of products are still qualified by the description 'pre-War.' The numerous figures are mostly well reproduced and the printing is good, the rather smaller type, of which considerable use is made—evidently with the object of reducing the proportions of the volume—being not at all irksome to read. The price is fixed at what in Great Britain and nowadays would be a ridiculously low amount, and any chemist with a knowledge of the Italian language would find the book a profitable investment. T. H. P.

The Professor on the Golf Links: some Sidelights on Golf from Modern Science. By Charles W. Bailey. Pp. 91. (London: Silas Birch, Ltd., n.d.) 2*s*. 6*d*. net.

This book is by the same author as "The Brain and Golf," which was reviewed in these columns (August 23, 1924, p. 271). It consists of a light-hearted report of the casual conversations of some members of a golf club. The chief talker is known as 'The Professor,' whose topics range from the effect of jazz jumpers for men on their interest in colour and relation to women, to psychological types as reflected on the golf course and even in the owners' golf sticks as well. The author aims at linking golf with mental and physical science in order to interest the average golfer and lower his handicap. It is in lighter vein than the preceding volume, but contains much sound psychology embodied in anecdotal form. He describes golf as the safest safety-valve, because in it the unconscious gets an opportunity for expression in a way socially safe and personally satisfying. One would like to know the incidence of psychoneurosis in golfers: Are the irascible people who let off their irascibility on the links thereby rendered comparatively innocuous and able to bear with equanimity the stresses of ordinary life? The author has yet to give us a more subtle analysis of behaviour on the golf links in terms of modern psychology.

Simen, its Heights and Abysses: a Record of Travel and Sport in Abyssinia, with some Account of the Sacred City of Aksum and the Ruins of Gondar. By Major H C Maydon. Pp. 244+12 plates. (London: H. F. and G. Witherby, 1925.) 16*s*. net.

In setting out on the journey which is described in this book, Major Maydon and his companion, Capt. Blain, had as their objective the barrier of mountains which forms the north-western edge of the great Abyssinian plateau. A preliminary journey of reconnaisance in 1922–23 was followed by a second expedition in 1923–24 in quest of the Walia ibex (*Capra Walie*), the home of which is in Simen, although its existence, as the author says, "was a question of uncertainty." From Simen they went on to Addis Ababa and into the Arusi country in search of mountain inyala. Major Maydon's descriptions of the wonderful hill country of Abyssinia, slashed by precipitous ravines and abysses, conveys a vivid impression to the reader, which is enhanced by some excellent photographs; but he seems to have found, with reason, the natives less attractive than their country. The appendices, in addition to descriptions of the Walia ibex and the inyala, and their habits, give information relating to prices and outfit which will be useful to those who may be inspired by the author to follow in his footsteps.

Practical Pharmacognosy. By T. E. Wallis. Pp. x+115. (London: J. and A. Churchill, 1925.) 7*s*. 6*d*. net.

This excellent little book will be of great value to teachers and students requiring an elementary guide to laboratory work in pharmacognosy. The standing of the author, who is lecturer in botany to the Pharmaceutical Society, and the recommendation implied by the contribution of a foreword by Prof. Greenish, are sufficient guarantees of the accuracy of the text, which is arranged in a very clear and practical manner. The ground covered is necessarily familiar, but the chief value of the book lies in the fact that it is essentially a statement of the laboratory work in this subject given at Bloomsbury Square. Part 1 consists of schedules of instructions for the examination of the drugs, each schedule being accompanied by a most useful complement in the form of short notes. Part 2 comprises a description of forty-five medicinal plants and concludes with a scheme for the description of drugs. The book is abundantly illustrated, and special reference must be made to the many skilful line drawings prepared by the author and his wife.

The Pocket Book of British Birds. By Richard Kearton and Howard Bentham. Pp. ix+389. (London, New York, Toronto and Melbourne: Cassell and Co., Ltd., 1925.) 6*s*. net.

Mr. Kearton and Mr. Bentham have produced a pocket guide to British birds. The letterpress consists of a condensed summary of the usual text-book information about each species. The very small reproductions of photographs seem unlikely to be so useful for purposes of identification as the authors suggest.

Letters to the Editor.

The Fine Structure of the X-ray Absorption Edge in the *K*-Series of Argon and its Possible Interpretation.

As is well known, X-ray absorption phenomena may be characterised in the following manner: In general the absorption decreases with decreasing wave-length of the X-rays. A sudden increase of absorption, however, takes place at some definite wave-lengths ('absorption edges') characteristic for the absorbing element in question. Each of those absorption edges is connected with the removal of an electron from a corresponding sub-group of electrons in the atom. As for the heavier elements there are one sub-group of electrons in the *K*-shell, three in the *L*-shell, five in *M*-shell, we might expect the existence of one *K*-absorption edge, three *L*-edges, five *M*-edges. Such edges have really been found for several elements by different workers.

More accurate measurements, especially of the workers in Siegbahn's laboratory, have brought to light that the wave-lengths of the absorption edges to a rather small amount still depend on the chemical or physical state of the absorbing element. Besides, in some careful investigations it has been shown that the main absorption edge very often is accompanied by one or two other rather faint edges lying immediately in the neighbourhood and usually to the short wave-length side of the main edge. As has been shown by Miss Chamberlain,[1] at any rate part of this 'fine structure' of the absorption edges must be ascribed to the presence of different chemical compounds in the absorbing screen used in the investigations. As in the case of photographic registration, the time of exposure has to be rather long, it is reasonable to assume that an appreciable amount of the absorbing substance may be decomposed during the exposure by the action of the X-rays. We have, however, several reasons for believing that not all of the fine structure of absorption edges hitherto observed can be explained in the above simple way.

In order to obtain some more conclusive data regarding the fine structure of absorption edges, we have investigated the *K*-absorption spectrum of argon. The use of this substance has several important advantages. The well-known Siegbahn vacuum-spectrograph could be filled with the gas. By varying the pressure of the gas the most favourable condition for getting a sharp absorption edge was easily obtained. Complications due to chemical changes of the absorbing substance as observed by Miss Chamberlain are excluded. Besides, we should expect that an eventual fine structure in the case of a mono-atomic gas would afford less difficulties for a theoretical interpretation.

One of the present writers,[2] and independently Wentzel,[3] have suggested the following explanation of the fine structure of X-ray absorption edges. The main edge in the case of the *K*-absorption corresponds to the transition of one *K*-electron just to the outside of the atom; the other edge or edges lying to the short wave-length side of the main edge should correspond to a simultaneous transition of two electrons connected with one single absorption act. If one of these electrons is the *K*-electron and the other an electron of the outmost sub-group, we should expect the order of magnitude of the energy difference of the main edge and the secondary edge to correspond to about 10 volts, which is just the order of magnitude usually found by experiment.

The absorption edge of argon was exposed with gypsum as the analysing crystal. Though several exposures were tried with argon pressures ranging from 3 mm. to 80 mm., no fine structure at all could be detected on the plates, the edge itself being very sharp and prominent. Using the same gypsum as analysing crystal for the elements chlorine and potassium as absorbers, however, in the same time of exposure (from one to six hours) a very good fine structure was easily obtained. The same thing was tried for other regions of the spectrum where we should expect secondary edges connected with a simultaneous transition to the outside of the atom of a *K*-electron and an electron of one of the other sub-groups of the *M*-shell, or a transition of a *K*-electron and an *L*-electron, or of two *K*-electrons. No such edge could be detected, though in our experiments a sudden change of the total absorption of 1 per cent should have been easily detected (the total absorption being 95 per cent. of the intensity of the incident rays). From these experiments we may conclude that absorption processes connected with transitions of more than one electron do not contribute to the absorption of X-rays to any appreciable amount, and that such transitions at any rate cannot explain the occurrence of the fine structure of absorption edges.

We may also assume that the fine structure of absorption edges might correspond to transitions to the different optical orbits available for the electron removed from the inside of the atom by an absorption process.[4] Now in the case of a mono-atomic gas such as argon, the fine structure connected with those optical orbits may be easily estimated. If an electron has been transferred from the *K*-shell of argon to an optical orbit of the same atom, this electron moves in a field of force which to a high approximation must be the same as the field of force of the valency electron in the ordinary potassium atom, the difference in nuclear charge of one unit being compensated by the absence of one *K*-electron. If the same selection rules which are applied in the field of optical spectra and of ordinary X-ray spectra also hold for a transition of an electron from an X-ray orbit to an optical orbit, the only optical orbits which in the present case come into consideration are *p*-orbits, as the orbit of the *K*-electron may be compared with an optical *s*-orbit. The largest energy difference between *p*-orbits, *i.e.* the difference between $2p$ and $3p$, corresponds to about 1·4 volts, which is far too small a difference to be separated in our experiments referred to above.

We therefore repeated the experiments with calcite as the analysing crystal and a very narrow slit (0·025 mm.). We really succeeded in obtaining two different absorption edges at about 0·1 mm apart, separated by a rather sharp black line. Control plates were taken to make sure that the observed structure could not be ascribed to any other cause but the presence of argon in the spectrograph. Measurements of our plates gave for the difference of the observed edges about 1·7 X.U. corresponding to 1·7 volts (with an accuracy of about 20 per cent.). Thus we may state that the difference measured is certainly of the order of magnitude theoretically expected.

[3] G. Wentzel; see Sommerfeld's book, fourth German edition, p. 326.

[4] An analogous suggestion was made for the first time by Kossel, in his earlier work on the classification of X-ray spectra.

With the accuracy hitherto obtained it is, however, impossible to decide with certainty if this difference really must be ascribed to a $2p$ and a $3p$ orbit (the only other energy difference of the potassium spectrum which might come into consideration as being of about the same magnitude is $1s$-$2p$ corresponding to 1·6 volts). Other eventual edges corresponding to higher p-orbits lie too close together to be separated even with calcite.

Experiments are being started with the X-ray absorption spectrum of neon, for which fine structures are expected corresponding to energy differences in the optical spectrum of sodium. As in this case the separation is expected to be much larger than in the case of argon, we hope to be able to decide some questions which still remained unsettled in our experiments with argon.

Spinning Electrons and the Structure of Spectra.

GOUDSMIT and Uhlenbeck have suggested that the structure of multiple lines in spectra can be made much more comprehensible if it is assumed that the electron itself has a magnetic moment of one Bohr magneton ($eh/4\pi mc$) and an angular momentum of one-half unit ($h/4\pi$), which can orient itself in various ways with respect to the normal to the electron orbits Goudsmit and Uhlenbeck point out (*Naturwissenschaften*, Nov 20, 1925) that to obtain such a magnetic moment from the rotation of a Lorentz electron about its axis, there would have to be a peripheral velocity greatly exceeding the speed of light. It can also be easily seen that the magnetic energy with its resulting mass would be much greater than the electrical energy. These difficulties do not seem to be easy to overcome by any small modification of the classical model of the electron. It appears, however, that an entirely different picture of electronic structure, based on the idea of light quanta, is capable of giving a consistent explanation of the energy of the electron, and also of predicting the values of some of the electronic constants

The author has suggested that the energy in light waves consists of corpuscular quanta which are guided by a virtual field, along Poynting's vector or some similar direction. In general, the direction could not be just that of Poynting's vector, for that does not transform as a velocity under the Lorentz transformation. In the particular case where E and H are equal and at right angles, however, as for a wave in free space, a vector of magnitude c along Poynting's vector may be proved to transform as a velocity, so that for this case it can be taken as the velocity vector of the quanta. A defect in such a scheme was the existence of the constitutive energy of the electrons, which presumably is energy in the field, although otherwise the field was not supposed to carry energy. The present suggestion is that the electron's field itself is virtual, and that its energy consists of a quantum, which is permanently attached to it, revolving about it To make this consistent with the radiation theory, the path of the electronic quantum should be determined in the same way as the path of a quantum in a radiation field. This can be done; for if we imagine a virtual field, consisting of an electrical point singularity e, and a magnetic doublet singularity $eh/4\pi mc$, there is a circle in the equatorial plane at every point of which Poynting's vector is tangential to the circle and satisfies the particular conditions given above, so that this orbit can be the path of a quantum The circle has a radius r_0 satisfying the condition that the electric field at this distance, e/r_0^2, should equal in magnitude the magnetic field, $eh/4\pi mcr_0^3$, which gives $r_0 = h/4\pi mc = 1{\cdot}93 \times 10^{-11}$ cm. Evidently at points of this circle the fields are perpendicular to each other, and Poynting's vector is tangential. The picture of the electron is then an energyless field from a point charge and doublet, with the energy and angular momentum located in the quantum travelling with the speed of light in a circle of radius r_0.

We assume the energy of the quantum to be given by the quantum condition for a rotator in its first state, $E = h\nu/2$, where ν is the frequency of rotation. Since the quantum travels with the velocity of light, this frequency is $c/2\pi r_0$. Substituting for r_0, this is $\nu = 2mc^2/h$, giving from the quantum condition $E = h\nu/2 = mc^2$. The mass of this energy is $E/c^2 = m$, so that the quantum carries just the mass of the electron. The angular momentum is equal to mr_0c; again substituting for r_0, this equals $h/4\pi$ Thus we obtain a rational explanation of the half-quantum value of the angular momentum, and of its anomalous ratio to the magnetic moment.

In attempting to work out the dynamics of the paths of quanta, many interesting questions present themselves. It is necessary to consider that there are forces acting on quanta which must operate when the quanta change their direction and hence their momentum The reactions of these forces on atoms may in some cases be the "quantum forces" which the author has suggested for changing the atom from one stationary state to another in a quantum transition. It is hoped that a further study of these forces will provide more definite information about the dynamics of an electron such as has been here suggested.

Mercury Helides.

IN a first note (NATURE, December 13, 1924, p. 861) I announced the synthesis of mercury helide. In a second note (NATURE, March 7, 1925) the empirical formula of the compound was given as HgHe, and afterwards (NATURE, June 20, 1925, p. 947) the formula $HgHe_{10}$ was substituted for the earlier one. Details of the methods and apparatus used for synthesizing the compound were given in a paper communicated to the Royal Society last July. The chief points of interest with which that paper dealt may be conveniently enumerated as follows:

1. The formation of the helide is accompanied by a decrease in the pressure of the helium.

2. The maximum decrease in pressure during any synthesis was never greater than 3·3 per cent. of the initial pressure of 6 mm.

3 At ordinary temperatures the helide possesses stability, but on passing the gas over a red-hot platinum spiral it is completely resolved into its components; and as a result of the decomposition the helium is restored to its original volume and pressure.

4 The compound is neither liquefied nor absorbed by charcoal at the temperature of liquid air.

5. In a quantitative analysis of the helide, the total weight of the mercury obtained was 0·00021079 gm.

6. Experiment proved that the helide is most readily formed when the pressure of the helium approximates 6 mm. of mercury

7. Qualitative experiments made with a Jamin

interferometer having tubes 25 cm. long showed that, as the synthesis progressed, the refractive index of the mixture became somewhat greater than that of the helium alone.

During the past seven or eight months the plans for synthesizing the helide have been modified and the apparatus enlarged. All qualitative experiments made with the new apparatus have clearly indicated the formation of the helide $HgHe_{10}$ and have thus tended to confirm the accuracy of my earlier work. The new apparatus produces a larger quantity of helide, but the maximum percentage found mixed with the helium has never exceeded that obtained in my first experiments.

Using three differently formed synthesizers in series, I have now succeeded in obtaining a second helide of mercury. This also remains gaseous at the temperature of liquid air, and charcoal fails to absorb it.

During the synthesis of the second helide the pressure of the helium was unaffected. Taking the density of helium as 1, that of the mixture of helium and helide, when measured with an Aston microbalance, was found to be 1·150. The helide was decomposed by passing it over a red-hot platinum spiral and the mercury collected. Its weight was 0·0002714 gm. Assuming the formula of the helide to be HgHe, the calculated density of the mixture is 1·148. The close agreement between the measured and calculated values leaves no doubt as to the formula for the helide.

To account for the non-liquefaction of the helides at the temperature of liquid air, I was inclined to regard them as clouds of charged particles. On this point Prof. Soddy has been kind enough to give me his own views. He writes, "I do not think it likely that you have a cloud of solid or liquid particles passing through the liquid air, though it is perhaps a possibility to be borne in mind. . . . My own view is rather that a compound of helium is of a different category from any known chemical compound, as the completed ring of electrons which never act as valency electrons, must be so acting in this case. If so its properties cannot be inferred from those of known gases, and there is therefore no *a priori* reason to expect that it would be condensed by liquid air and charcoal. Its properties must be ascertained *de novo*, and none of them can be inferred from known chemical data." Prof. Soddy regards his views as speculative.

In conclusion, it may be added that experiments made with pure argon yielded results entirely negative. Prof. Soddy has suggested that it would be of interest to repeat the experiments with neon substituted for helium. This I propose doing as soon as I can either purchase or obtain the loan of some 20 c.c. of the pure gas. The presence of helium would obviously be detrimental.

Ecotypes of Plants.

IN *Hereditas*, Bd. vi (1925), which has just come to hand, there is an extremely interesting paper by Gote Turesson on "Plant Species in Relation to Habitat and Climate" This author has grown in Sweden upwards of 10,000 cultures of various types and races of certain widely distributed plants, in order to ascertain the precise nature of the forms inhabiting different environments. Particulars are given concerning about fifteen species, with numerous illustrations

It is found that the species exhibit parallel "ecotypes," which it is proposed to designate by the names campestris, arenarius, salinus, subalpinus, and alpinus. These names are by themselves sufficient to indicate the nature of the habitat, and an experienced botanist will be able to imagine the character of the adaptive modification. However, these ecotypes are to be understood to include only hereditarily modified forms, and the immediate effects of the environment are placed in another category. It is shown that the several ecotypes are not produced whenever the conditions seem to call for them. They are sorted out from the genotypes which the plant is able to produce. Thus there are four species (of the genera Melandrium, Ranunculus, Rumex, and Geum) which produce "alpinus" ecotypes in Scandinavia, but not in the Swiss Alps, although the very same species exist in Switzerland. It is as if the plant produced the hand of cards, and the environment played the game. The five parallel sorts of ecotypes correspond with five common types of environments into which suitable varieties might enter and in which they prospered.

The author has done his best to correlate the several ecotypes with names already bestowed by botanists. In this he has not been altogether successful, the numerous available varietal names, based on herbarium specimens, being often not precisely applicable in the sense desired. Thus in *Spiræa ulmaria* the "variety denudata" is present in all three ecotypes studied, and although the type specimen of Presl probably belongs to one of them, the restriction of the name to this ecotype would quite contradict the original intention and general usage. It is therefore proposed that previous names shall be discarded in the type of work represented by the paper, and the ecotype names *campestris*, *arenarius*, etc., substituted, no matter what species is concerned. There are, however, numerous minor biotypes not covered in this way, and the author remarks in reference to *Leontodon autumnalis*: "To those, however, for whom the increase and the naming of 'new' biotypes is a particular pleasure, as well as to other intending bidders, I am willing to offer a couple of hundreds hitherto undescribed in a living and exquisite condition."

At this point it may be possible to question the adequacy of the author's methods. The ecotype names certainly have the very great advantage of being intelligible in a general sense, without further explanation. But ought we to be satisfied with this "general sense"? Mr. Turesson himself brings out very clearly the fact that parallel ecotypes of the same species in different regions may not be just alike. Thus, while the ecotype system is highly illuminating, it should not take the place of definite names accompanied by precise descriptions, and supported by type specimens in the herbaria. Also, it is not clear that the most minute analysis of the various biotypes will not after all furnish the necessary materials for an adequate synthesis. Probably the fault to be found with taxonomists is not connected with the minuteness of their analysis, but with the mechanical way in which much of the work has been done, in the absence of guidance from biological theory. We may even believe that the coming years will see the study of biotypes and phenotypes carried to extremes now undreamed of. The work will represent a fascinating game, out of which will emerge from time to time results of high practical and scientific value.

The Boskop Skull.

In criticising Pycraft's paper on the Boskop skull, my whole object was to get a fuller consideration of what I believe to be an extremely important early human skull. Opinions will differ so to the restoration of all imperfect human crania. We have seen how greatly anthropologists have differed in the restoration of the Piltdown man, and it is not surprising that there should be differences about the Boskop man.

Pycraft agrees with Haughton in giving the greatest length as 205 mm. Now the calvaria as preserved certainly measures 205 mm., but much of the lower part of the frontal is lost, and though there was certainly no large supra-orbital eminence, there must have been, from the curve of the anterior part of the frontal preserved, at least a small one, and even Pycraft in his restoration shows a small one. By no possibility can the antero-posterior measurement have been less than 208 mm.: it may have been 212 mm. Dart gives it as 210 mm., and this must be very near to the actual measurement.

Pycraft doubts whether any anthropologist would 'restore' the skull as I have done. Perhaps he is right. His own restoration does not differ very greatly from mine. He puts the temporal fragment a little lower than I do, and he has failed to observe the small portion of parietal attached to the temporal. By lowering the temporal fragment he would make the brain still larger than I would. He objects strongly, however, to a brain of 1900 c.c. or more. Elliot Smith, Dart, and Drennen all agree to a brain of 1900 c.c., so that whatever errors I may have made in the restoration I am certainly in as good company as I could desire as to the result.

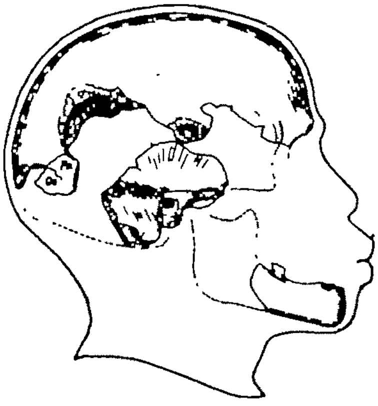

Fig. 1.—Restoration of the Boskop skull, with outline of soft parts as they may have been before the teeth were lost.

With regard to the jaw, concerning which Pycraft has nothing to say in his paper, he makes in his letter (Nature, February 6, p. 196) the following remarkable statement: "All of us who examined this fragment while it was at the British Museum regarded it as of no importance at all!" When I examined the jaw ten years ago, and I have never seen it since, I came to the conclusion, after very careful consideration, that the enlarged socket had held the root of the canine and not the first premolar. I made many drawings of the jaw, which I still have, and even had it X-rayed. Part of the socket, but not all of it, has been eroded by an abscess, but whether this is the socket of the first premolar or of the canine the jaw is still a remarkable one, and it will certainly come as a very great shock to many that a large fragment of the jaw of an extremely ancient and completely fossilised human being—possibly the oldest known 'Neanthropic' type—is regarded by all those who have examined it at the British Museum "as of no importance at all."

Fig. 1 is from a restoration I made ten years ago, and may convince those who are not anthropologists that the skull and even the jaw are of some interest.

The Stone Age in Ceylon.

In *L'Anthropologie* (Nos. 1 and 2, vol. 36) Dr. Fritz Sarasin discusses in a valuable paper (pp. 75-115) the pros and cons of this question. He concludes that there existed a pre-Veddah population in Ceylon—to which the "Cambridge History of India" does not refer—whose culture was analogous to the Aurignacean of Europe.

Dr. Sarasin, however, makes the arresting statements that it is difficult to imagine how men, possessed of only small stone implements incapable of cutting down trees, could exist in forests so humid and full of leeches as those of the Ceylon mountains, and in which they could not find the necessary subsistence, unless, through climateric oscillations, there occurred steppe periods; and that it seems impossible, with the present climate, for these human stations (which he discusses) to have existed in the forests.

May I recall to Dr. Sarasin's memory the conditions under which the Koeboes of Sumatra exist? These people, perhaps the most primitive on the globe and supposedly the most ancient inhabitants of Sumatra, live in isolated communities in several regions of that island. Their abode from time immemorial has been in the vast, sunless, pathless, tiger- and leech-infested and moisture-laden virgin forests, out of which they rarely emerge of their own accord, but through which their sense of direction is 'uncanny.' They make no clearances, having no implements capable of the work, nor do they cultivate a single comestible. They subsist entirely on the inexhaustible products of the woods, especially on durians, jack-fruits, figs, tubers of sorts, wild honey, and even the putrid carcasses they may discover. From time to time, when successful in killing a rhinoceros or a tapir, they gorge themselves until only the bare bones of their feast remain, alongside which are left no signs of human activity. They live as do the beasts, ever in search of the wherewithal to appease their insatiable appetite. Until the intervention of the Dutch authorities, the Koeboes were hunted by Sumatran 'radjahs' and chiefs for enslavement as if they were really wild animals. The Malay so esteemed them when I made acquaintance with these nomads forty-five years ago. They have no true abiding place; they erect temporary wind-screens with palm leaves and branches, more primitive even than the Australian's humpy. Their weapons, all of wood, are pointed, fire-hardened bamboo spears and the deadly accurate blow-pipe. A few among them now possess knives obtained from the Malays by the curious method of silent exchange. Their dead are thrown into some dense thicket, which is ofttimes set on fire, but the body is generally left for any prowling carnivore. This custom accounts for the rarity of their osseous remains—as probably for that of the bones of the Chelleans and Acheuleans—except of those sedentary few groups, partly 'tamed' and half converted to Moslemism, who practise sepulture.

If these a-lithic nomads had discovered stone artifacture, their handiwork would have strewn the forest floor and been found abundantly in the alluvium of the rivers, without any marked climatic oscillations. Their discarded belongings, which in a few months turn to dust, leave no record of an age-long persistence under their verdant sanctuary. Their life-story, however, affords a highly instructive picture of how generations knowing only wood, of whom no evidence survives, may have succeeded in handing on their race from one millennium to another.

The Hydrogen Doublet.

IN measuring doublet separations, the Fabry-Perot interferometer can be so adjusted that the fringes of one component fall half-way between those of the other. This eliminates most of the distortion present in other instruments. Using this method, the doublet separations at a pressure of 0·5 mm. and a current density of 0·25 amp. per sq. cm. have been found to be 0·316 ± 0·002 for Hα, 0·329 ± 0·005 for Hβ, and 0·353 ± 0·007 for Hγ. The wave-lengths of each component have also been determined and indicate that $R = 109677{\cdot}70 \pm 0{\cdot}04$, with the use of Sommerfeld's formula.

The doublet separations, however, do not fit Sommerfeld's simple theory with the ordinary principle of choice. They can be explained by assuming that the forbidden components for which $\Delta k = 0$ are present, increase in intensity with an increase in current, and are polarised with the electric vector parallel to the current. These components have always been found in the work on He⁺, so that they would naturally be expected in hydrogen. The presence in Hα of the component designated by Sommerfeld as IIc, will reduce the theoretical separation to the observed value, while the presence of Ib will not affect it very much. The polarisation of IIc will produce a smaller doublet separation in the light from the side of the tube than in that from the end. This is found to be the case when the current is heavy enough partly to orient the atoms. The corresponding polarisation of the light from the side is found also at current densities in the neighbourhood of 1·5 amp. per sq. cm. The increase in intensity of these components with an increase in current will produce a greater relative increase in the short wave-length component than in the other. This is found experimentally to be the case.

The intensities predicted by Kramers, upon the assumption of a disturbing field, are much too small to explain the observations if fields small enough to be compatible with the observed width of the lines are used. The results tend to support the suggestions of Uhlenbeck and Goudsmit (NATURE, February 20, p. 264), which in effect replace the principle of choice for azimuthal quantum numbers with the one for inner quantum numbers.

Domestic Heating.

LETTERS to NATURE have to be short, so every word should carry its full significance. I said in my letter in the issue of March 6 that the peculiar value in glowing coal fires "is either absent or very weak in radiation from anthracite stoves or gas and electric fires." To a careful reader it would be obvious that I had tried the effects of radiation from a gas fire Prof. Hill (April 3, p. 487) is incorrect in his assumption that I would have got "equally good effects from a *glowing* gas fire." I did *not* get equally good effects from a glowing gas fire On the contrary, I got markedly inferior effects. Even the best form of gas fire is positively irritating rather than healing to surfaces exposed to it.

Of course, I allow that the bright light of a good electric lamp has some slight beneficial effect, and is better than nothing. Prof. Hill quotes its effect on the iguana. Human physiology, however, is very different from that of an iguana, and however useful evidence may be from animals, first-hand evidence from a sensitive human subject is much more valuable.

Prof. Hill speaks of the coal fire polluting the atmosphere and screening off the sunshine. May I ask him to examine the returns of the tonnage used in domestic fires and note how small it is compared with the millions of tons used by commercial fires? I am entirely with him in claiming that electricity and gas should be used in all factories and for cooking and heating water. Moreover, before condemning the domestic coal fire, Prof Hill should take into consideration the possibility of its improvement (which I urged upon our Government in 1914) The valuable domestic qualities of coal could be retained and the smokiness and economic loss of by-products be eliminated by the use of partial coking at low temperature.

The Oxidation of Ammonia.

L. ANDRUSSOW (*Ber.* 59, 458, 1926) has suggested a scheme of reaction for the oxidation of ammonia in which nitroxyl, NOH, is an intermediate product. The scheme put forward by Andrussow, together with many others, were derived by the present writer some years ago when engaged in experimental work on ammonia oxidation, but none of these has been published. It seems desirable, however, to point out that the scheme put forward by Andrussow suffers from the defect that nitroxyl, NOH, if formed as an intermediate product, might be expected to break down to a considerable extent into nitrous oxide, a substance which, so far as the writer is aware, has never been detected among the products of the oxidation of ammonia. A more likely intermediate product would be nitrohydroxylamic acid, which is known to break down with formation of nitric oxide It is suggested that the oxidation may occur in the following stages, each reaction in which is bimolecular or unimolecular:

(i) $NH_3 + O_2 = NH_3O_2$.
(ii) $2NH_3O_2 = 2NH_3(OH)_2$.
(iii) $2NH_2(OH)_2 = N_2H_2(OH)_2 + 2H_2O$
(iv) $N_2H_2(OH)_2 + O_2 = N_2H_2O_3 + H_2O$
(v) $N_2H_2O_3 = 2NO + H_2O$

The writer had intended to make further experiments on the mechanism of the oxidation of ammonia but has not been able to carry these out. He therefore puts forward the above hypothesis as an alternative to that of Andrussow, since it does not seem open to the objection mentioned above.

What We Know.

LET this, from Meredith, be my reply to the electrician in my composite friend Sir Oliver Lodge (NATURE, March 27, p. 453).

O sir, the truth, the truth! is't in the skies
Or in the grass or in this heart of ours?
But O the truth, the truth! the many eyes
That look on it! the diverse things they see,
According to their thirst for fruit or flowers!
Pass on. it is the truth seek we.

HENRY E. ARMSTRONG.

Odours and the Sense of Smell.

By Dr. J. H. KENNETH.

FROM year to year the number and extent of specialised investigations of the organs and sense of smell and of odorous substances is steadily increasing. There are few treatises which deal with the subject in a comprehensive manner, and none which could be termed exhaustive. The reasons for this deficiency in scientific literature are many, the main reason being the difficulty of combining, except by means of a symposium, expert knowledge of each of the many different subjects which coalesce in the science of smell. Boyle's "Exercitationes" (1672), Cloquet's "Osphrésiologie" (1821), Zwaardemaker's "Physiologie des Geruchs" (1895), and "L'Odorat" (1925), the presidential address to Section A of the British Association (1898), by Prof. Ayrton; Haycraft on "The Sense of Smell" (1900), Henning's "Der Geruch" (1916), the "Essai d'olfactique physiologique," by Heyninx (1919), and "Smell, Taste, and Allied Senses in the Vertebrates," by G. H. Parker (1922), are some of the outstanding efforts towards an integration of the heterogeneous elements composing the science of smell. This co-ordination of special knowledge comprised in the science of smell (olfactology, *osphrésiologie, Geruchslehre*) in its widest interpretation may conveniently be termed 'osmics' (*l'osmique, osmica, Osmik*).

The subject may be divided into three main and interdependent aspects or foci; morphological, psychophysiological, and physico-chemical. In addition there would be included all the numerous applications engendered by the science in its different aspects.

The morphological division, again, may be divided into two parts—one dealing with the structure and development of the peripheral and central olfactory apparatus (osphrenes), and the other with the structure of odorous apparatus (osmenes), both in health and disease. There are many anatomical, histological, and embryological data available; for example, accounts of the olfactory mucous membrane of the frog, the olfactory nerve of the goose, the absence of olfactory pigment in albinos, hippocampal abnormalities in epileptics, scent organs of butterflies, and the odorous gland of the chamois, to mention some at random. All these many isolated observations require some sorting out and co-ordination, not merely in order to facilitate knowledge of morphological work already done, but also to stimulate and direct further research and integration of knowledge. Even the comparative histology of the olfactory mucous membrane, or that of the vomero-nasal organ, has yet to be completed, let alone the comparative morphology of osphrenes and osmenes as a whole. Consideration is also due to the connexions between the olfactory apparatus and other parts of the body, such as endocrines and the sexual apparatus. Osmics thus provides a most extensive field of research, not only for the individual morphologist, but for team work.

While noses have an interest all of their own, it is their performances which make a wider and more intensive appeal. From the mysteries of good and evil as represented by fragrances and stinks, to the examination of the psycho-galvanic response to the action of hydrogen sulphide and amyl acetate on the lipoids in the hairs of the olfactory cells, is a far cry, a cry dimly perceived by the osmic as well as by the cosmic philosopher. The general study of reactions to olfactory stimuli is not easily systematised, partly owing to the prolonged courtship between physiology and psychology. However, a discussion of some of the problems requiring elaboration will indicate the scope of the physiological and psychological aspects.

To begin with, the nature of olfactory stimulation is not yet satisfactorily understood. The general opinion would favour the theory that it is induced by some form of solution of the odorous molecule (odorivector, *Geruchstrager*). The minimum number of such odoriferous molecules necessary to produce an olfactory sensation is estimated by Prof. Zwaardemaker to be 20×10^8 in one nasal fossa. The intensity of the sensation would appear to depend on the number of molecules impinging on the olfactory mucous membrane, while the quality of the sensation depends on the molecular structure of the odorivector. According to Heyninx, the quality of the olfactory sensation depends on the wave-length of the molecular vibration, only such wave-lengths being sensed as lie between 0·35μ and 0·20μ. He does not record the inference that this theory would account for the greater liminal range in many animals. Further, following conclusions by Parks which have been quoted by Chwolson, the molecules would form a layer of 0·13μ in thickness on the surface of the olfactory membrane. Their vibration would be transmitted to the olfactory hairs and cells Heyninx suggests that the olfactory pigment functions so as to provide something like resonance. It has occurred to the writer that such 'resonance' may be due to one of the primary functions of the pigment being possibly that of a protective screen against overstimulation of structures in the corium of the olfactory mucous membrane, by ultra-violet activity.

A considerable amount of work has been done by various observers, chiefly by Zwaardemaker, on the measurement of olfactory acuity (olfactometry) in health and disease. Observations on the senses of the Todas, by Rivers, and experiments on Javanese and Europeans, by Grijns, adumbrate a more extensive investigation of olfactory acuity in the different races of mankind. More quantitative data than are now available on the olfactory acuity of animals are also desirable. Of interest here, too, is the measurement of simple reaction time, which has been carried out by Buccola, Moldenhauer, Vaschide, and requires amplification and comparison with association time. Crude stop-watch experiments tend to show that in a given individual the time required for smell-word association does not seem to differ from that for word-word association; but there is a difference which requires demonstration by more exact methods of experimentation.

Another interesting field for research is the investigation of olfactory reflexes and odour preferences. There are inborn and acquired likes and dislikes, which form a kind of olfactory syndrome or diathesis characteristic of the individual. Owing to fluctuations in the affective judgment of odours due to changes in metabolic conditions, it would seem probable that an olfactory diathesis would have some diagnostic value, especially if linked with an examination of colour preferences.

Although the history of perfumery gives much information with regard to odour preferences among different peoples, experiments on a large scale are desirable in order to correlate affective judgments with other factors, such as pigmentation, endocrine balance, etc. Quite an appreciable amount of work has been done on the question of smell and sex, but there is room for further investigation. The problem of preferences is intimately related to the examination of olfactory associations. When dealing with familiar odours, the percentage of failures to form ascertainable associations is relatively small, according to recent (1924) experiments only about 15 per cent. The fact that olfactory associations are very largely formed unawares, makes their investigation of some practical importance, especially when linked up with olfactory associations occasionally occurring in dreams. An odour constitutes a more effective characterisation of persons, objects, and places than a verbal description, and the absence of a direct vocabulary of olfactory sensations raises difficulties. However, the images called up by odours are so vivid that there would seem to be a case for their occasional employment in the practice of psycho-analysis. Another suggestion is to employ odours to induce certain ‘ moods ’ for therapeutic purposes, and perhaps, in time, the ancient use of burned feathers may develop into a system of osmotherapy based on a wide knowledge of olfactory reactions.

Olfactory fatigue has not been mentioned, nor the problem of a classification of odours, nor methods of educating the sense of smell, nor a tithe of the many problems awaiting co-ordination and further research by the physiologist and psychologist. The plethora of osmics is further indicated by the multitude of problems arising from a consideration of the nature of odorous substances (osmyls).

The relations between odour and chemical constitution, emphasised by Haycraft, Cohn, Durrans, and others, by the increasing number of investigations carried out in the industry of perfumery and flavouring materials, has been further extended by recent research on phenomena connected with odorous particles. Tyndall’s discovery of the absorption of radiant heat has led to the examination of infra-red absorption by Grijns and the ultra-violet absorption bands by Heyninx, and of correlated phenomena. It is not yet possible to draw satisfactory physiological conclusions from these investigations (the interpretations of which are open to criticism), but it can be stated that potential molecular energy may act on the olfactory cells. Zwaardemaker and Hogewind (1920) have pointed out that in homologous series there is an increase in diamagnetism exactly proportional to the number of atoms in the molecule. However, even Zwaardemaker (1925) is obliged to acknowledge that the precise nature of the olfactory stimulus has not yet been satisfactorily explained, but that “ il y a de nombreuses perspectives pleines de promesses, qui pourront être dévoilées en continuant la recherche physique.” Even this most cursory and incomplete account of some of the innumerable problems tends to show the need for co-ordination and direction of research, not merely in the interests of pure science, but also on account of the numerous applications in everyday life, in industry, and in medicine. There is ample justification for the organisation of the science of smell as a whole, in order that existing data may be integrated and further research may be organised and directed.

The Geological Age of the Earth.[1]

IN delivering the twenty-seventh Robert Boyle lecture last year, Prof. J. Joly returned to his attack on the higher estimates of geological time which have been based on the lead-ratios of uranium-bearing minerals. He favours an estimate of 160 to 240 millions of years for the period that has elapsed since the Archæan, and refers to the lead-ratios of certain thorium minerals and to the sodium method of arriving at the age of the oceans as providing confirmatory evidence. It can, I think, be shown that in both cases the data used are misleading, and that the results from both methods can be readily interpreted to support the very estimates to which Prof. Joly considers they are opposed.

On the assumption of uniformitarianism, the salinity of the ocean points to an age of about 80 to 100 million years. The amount of sodium in the oceans has been determined with sufficient accuracy to justify the method, but this cannot be said of the annual increment of sodium brought down to the sea by the rivers. Denudational statistics show that for all the open drainage areas of the world, the total amount of sodium removed in solution is more than 2·1 per cent of the material mechanically and chemically removed from the lands. On the other hand, the rocks actually exposed to denudation contain on an average only 1·3 per cent. of sodium. Thus it appears that the rocks would have to lose more sodium than they had ever contained in order to supply the amounts alleged to have been added annually to the oceans.

Four partial and independent explanations of this remarkable discrepancy can be suggested. (*a*) To a slight extent the discrepancy is mitigated by the fact that part of the material liberated by denudation remains on the lands and is largely left out of account in the above calculations. (*b*) Many of the analyses of river-waters for sodium have probably been inaccurate, for unless extraordinary precautions had been taken to overcome the difficulties inherent in such analyses the results would usually be too high. (*c*) It is also probable that part of the sodium carried by the rivers is cyclic, and the invariable presence of chlorine in river-waters supports this contention. The amount of chlorine in igneous and other rocks is hopelessly inadequate to provide the quantities found in rivers. Volcanic and other juvenile sources have doubtless served to supply most of the chlorine now accumulated in the oceans, but analyses of rain-water show that volcanic sources cannot be of appreciable importance at the present day. The high relief of the existing lands provides the necessary head for a vigorous circulation of groundwaters. This is an important factor in chemical denudation, and is likely to be responsible for part of the mysterious sodium chloride that finds its way into the rivers. (*d*) Another geologically unusual source of sodium supply is found in the easily eroded glacial deposits with which wide areas are now covered.

---

[1] Oxford University Press, 1926, pp. 18. 1s.

Neither of the factors (*c*) and (*d*) can have been operative throughout geological time, and if it be claimed that they suffice to explain away the discrepancy, then it is only at the cost of admitting that present rates of supply are, for the same reasons, abnormally high.

This raises for discussion the fundamental assumption of uniformity of rate. In recent years the assumption has been widely criticised on the following grounds, all converging to show that present rates of denudation are far higher than those that have prevailed during the average conditions of geological time. (*a*) The continents are now more elevated and the lands more extensive than they have generally been, since we are now near the close, or just emerging from, a period of great mountain building and uplift (*b*) In the past denudation must have repeatedly fallen to an almost negligible value during long periods of quiet peneplanation, and underground waters which are now relatively vigorous must then have become sluggish and relatively ineffective. (*c*) At least since Cambrian times the greater part of the existing lands have, on balance, received sediments rather than supplied them, whereas at present enormous areas are undergoing rapid denudation. (*d*) The presence of widespread glacial deposits facilitates rapid local denudation. (*e*) Finally, human activities have increased the rate by the removal of forests; the tilling of soils; excavations for transport and other purposes; and the addition to the atmosphere of unnatural quantities of acid gases.

A number of geologists have suggested that present rates may easily be from five to fifteen times as high as the average rate for geological time. Moreover, since river analyses for sodium are open to grave suspicion, and the geochemistry of chlorine is still far from being understood, the real income of the oceans in sodium may be less than a third of the amount alleged to be income, which amount is probably partly fictitious, partly capital restored to circulation. It is not unreasonable to combine these sources of underlying error, and to conclude that the age of the oceans may well be twenty times the 80 or 100 million years commonly assigned to it. At least it is certain that the sodium method cannot at present be considered as making any serious contribution to the problem. On its merits the method can be interpreted as pointing to too high an age, and this is a distinct advantage, since it becomes possible, in a way not hitherto allowed for, to admit the probability that the oceans were originally salt, and that additional supplies have since been furnished to them at intervals by juvenile or magmatic waters.

Turning next to the vexed question of the accumulation of lead in thorium minerals, there is no difficulty in demonstrating that the lead-ratios of such minerals are far from leading to concordant or trustworthy results. Thorium minerals of the same geological age give lead-ratios that vary widely among themselves, generally in the direction of lower values than those afforded by uranium minerals. As a type example of this discrepancy, Prof. Joly takes a pitchblende and a thorite from Ceylon. He says, "whereas the uranium-lead ratio indicated 512 millions of years, the thorium-lead ratio gave 130 millions of years." The actual data for these minerals and other analysed thorites from Ceylon are as follows:

Ref No.	Minerals from Ceylon	Percentages of			Lead-ratios Pb/(U+0·37 Th)	Millions of years
		U.	Th	Pb		
1	Pitchblende	71·40	7·86	4·75	0·066	436
2	Thorite	4·57	62·8	1·28	0·046	304
3	Thorite	3·50	59·2	0·78	0·030	198
4	Thorite	1·62	54·4	0·36	0·017	112
5	Thorite	1·88	65·4	1·71	0·065	429

1. Colonial Reports, Misc No 37, Ceylon Cd. 3190, 1906.
2 and 3 Colonial Reports, Misc No 87, Ceylon Cd 7175, 1914
4 Soddy and Hyman *Trans Chem Soc*, vol. 105, p 1404, 1914
5. Colonial Reports, Misc No 74, Ceylon Cd 5390, 1910.

The ages calculated from Nos. 1 and 4 are lower than those obtained by Prof. Joly because of the adoption of more recent values for the half-periods of uranium and thorium. There is clearly no reason whatsoever for picking out the minimum result given by No. 4 as being in any way more correct than that of the still richer thorium mineral No. 5. The latter gives a ratio practically identical with that of the pitchblende; and when the analyses of the associated thorianites are examined they are found to give ratios varying from 0·048 to 0·075, the average of fourteen ratios being 0·063. The conclusion drawn by Prof. Joly from his comparison of the pitchblende and the thorite No. 4 is based on very limited evidence and is seen to be quite unjustified in the light of the remaining evidence.

The variability of the lead-ratios of thorium minerals suggests that the latter tend to lose lead by the solvent action of percolating waters; and further, that thorium-lead is extracted in preference to uranium-lead. If the lead generated within a uranium mineral forms a highly insoluble uranate, then it is not likely to be easily removed. The lead generated from thorium, however, cannot form a thorate, and within a mineral it is probably present as a comparatively soluble oxide or silicate. Thus there are chemical reasons why one isotope of lead should generally be left while the other is liable to be taken. Atomic weight evidence adds consistent support to this new hypothesis, and for the first time a workable explanation of the long-puzzling discrepancies between uranium and thorium minerals is provided.

If this hypothesis be correct, then the higher lead-ratios of thorium minerals are, like the higher helium-ratios, most likely to approach the true index to age. Thorite No. 5 from Ceylon is likely to give a much more accurate result than No. 4, and, admitting this, there remains no convincing reason for supposing that uranium may have disintegrated more rapidly in the past than we observe it to do to-day. The evidence from pleochroic haloes cannot be accepted as pointing to a declining rate of activity of uranium through geological time, because the part played by the actinium series of elements has not yet been taken into consideration Thorium haloes reveal no variation of radius with age, thus proving in the most conclusive way possible that the rate of disintegration of thorium has not varied appreciably in the past. Since the lead-ratios of some thorium minerals are of the same order as those of uranium minerals of the same geological age, it follows equally that the rate of disintegration of uranium must have remained practically constant. It is quite possible that the ages indicated by the lead-ratios of uranium minerals may be a few per cent. too high, but the evidence is overwhelming against Prof. Joly's contention that they may be so much as four times too high. In the state of our existing knowledge and using the most probable modern data, we may safely say that the age of an unaltered primary mineral is given to a first approximation in millions of years by the formula $6600\ \mathrm{Pb}/(\mathrm{U}+0{\cdot}37\ \mathrm{Th})$. With Prof. Joly's conclusion we shall all agree: "Kelvin's well-known limitation '20 to 40 millions of years' is gone for ever."

ARTHUR HOLMES.

Fuel Research.[1]

FROM time to time the Fuel Research Board, under the chairmanship of Sir Richard Thelfall, and with Dr. C. H. Lander as director, issues technical reports which have received individual notice in NATURE. It has recently issued a general report on its activities, and this is of great interest, because the whole range of the work engaged upon is traversed, and the progress along the lines laid down at the outset can be gauged therefrom. It is fitting to recall the circumstances of the initiation and development of the Board as recorded in the report.

The decision to establish a Board of Fuel Research was taken on February 6, 1917, presumably because the grave difficulties of that time were found to be accentuated by the inadequacy and want of balance in resources of fuels of different types in Great Britain. It was deemed prudent to embark on an intensified scientific study with the resources of the State so as to diminish, if possible, these difficulties and along two main lines of inquiry. The first was to make a physical and chemical survey of the coal seams of Great Britain and a study of the fundamentals of coal. The second line was to make an effort to meet one of the most clamant needs of the times—a supply of liquid fuel home-produced—and simultaneously to provide a smokeless fuel for domestic and other purposes.

Doubtless with the idea that some result of immediate practical value might thereby be obtained, the second of these lines was given precedence, and for this purpose the Fuel Research Station was erected at Greenwich, where the late Sir George Beilby—the first director, and one might almost say the founder—was able to put to a critical test ideas on smokeless fuel production which he had held for many years. This extensive experimental station, which is elaborately equipped for the handling and treatment of fuels by various processes of industrial importance, is described with plans and illustrations in the report now issued.

The report gives an account of the work done there on carbonisation at low temperatures. It must be confessed that the early hopes placed in coal carbonisation at low temperatures have not yet been realised at Greenwich, but let no one conclude that the effort has been in vain. The difficulties are as much economic as technical. The intensive study of carbonisation at low temperatures, which has been a world movement, has clarified our notions on the carbonisation process in general, and the publication of authentic results has equipped with technical data those attacking the problems to-day immeasurably better than the pioneers of twenty years ago. At the Research Station high hopes are now placed in the use of a suitable vertical retort of metal which has been in operation for some time, but patience will be necessary before assessing its commercial applicability.

Apart from war-time necessities, the return of peace is only serving to emphasise the importance of coal carbonisation, which is very generally regarded as a possible means of increasing the value of coal by exploiting all its potentialities—both thermal and chemical. In order that no obstacle shall prevent the merits of any low-temperature process wherever discovered from receiving recognition, the Fuel Research Station is now empowered to test and report on processes without fee. This service already rendered in two cases (NATURE, February 14, 1925, p. 246, and November 14, 1925, p. 728) is of great public value, for the lack of such impartial tests has led to the dissemination of exaggerated ideas and hopes.

The other main line of work contemplated at the start of the Fuel Research Board was the chemical and physical survey of the coal resources of Great Britain. Now, although much information is in the possession of some consumers as to the relative properties of coals of different origin, there is still a great need for published data of the right kind and extent. It is significant that the only published systematic tests of British gas-making coals are to be found in German technical literature. The tendency of fuel technology is towards increasing refinement of method, and this implies increasing discrimination in the choice of raw material. This tendency is well exemplified by the selection which has to be made in coals for carbonisation in the continuous vertical gas retort. The methods, such as grinding and blending of coals, which are now under experiment and discussion for the production of smokeless domestic fuel, will certainly involve a closer technical control, and therefore a more precise knowledge of the original coals. Such a control may well extend to the composition and character of the ash, which is not without influence on the processes of carbonisation and gasification, and on the behaviour in the boiler furnace. The task of such a survey is a great and protracted one, and eminently suitable for the broad shoulders of a State department. A useful and necessary preliminary step has been to arrange a convention of analytical procedure so that results shall be comparable wherever obtained, and this is already well in hand through the Sampling and Analysis Committee of the Board, which includes members well qualified to speak on such matters. The survey, to be satisfactory, needs to be made with reference to geological and mining conditions, and hence a considerable amount of decentralisation has been found advisable. Local committees of coal owners and others have been established in those areas where the Survey is already in operation.

---

[1] Department of Scientific and Industrial Research. Report of the Fuel Research Board for the period ended 31st December 1924; with Report of the Director of Fuel Research. Pp. vi+78+8 plates. (London: H.M. Stationery Office, 1925.) 1s. 6d. net.

The Fuel Research Board was called upon to render an important service in its early years, namely, to advise the Government of the day on the action to be taken in re-establishing the standards for the sale of gas, which had been suspended during the War. It was able, however, to avail itself of the comprehensive experimental study of the efficiency of different grades of gas in use, which had been carried out by the Joint Committee of the Institution of Gas Engineers and the University of Leeds. The recommendations it was finally able to make to the Board of Trade were embodied in the Gas Regulation Act of 1920, establishing the "therm" system of charging, which will undoubtedly in time be regarded as a landmark in the history of fuel industries in Great Britain. It has already had a great influence on the outlook of the British gas industry. The process of "steaming" the charge of vertical retorts came into prominence during the War years as a means of expanding the output of existing gas works plant, and led to much discussion in the gas industry. Eventually the Joint Committee mentioned above investigated the claims made for this process in a series of tests at Uddingston, which showed the uses and limitations of steaming. The Fuel Research Board has since then not only confirmed but also added to these results by the carbonisation with steaming of a variety of coals from different areas—a material contribution to the survey of carbonising coals. Work on the water-gas process has also been carried out at the Fuel Research Station.

The utilisation of fuel in domestic grates is so commonplace a matter that many will learn with surprise that until recently little precise scientific information was available, and some ideas popularly held are fallacious. Much of our quantitative knowledge is based on the experimental work initiated in 1912 by the Manchester Air Pollution Board and carried on under its auspices for ten years—latterly with financial assistance from the Department of Scientific and Industrial Research. In 1922 the work was taken over by the Fuel Research Board, and the reports already issued have thrown much light on this important question.

Peat, steam-raising problems, internal combustion engines, alcohol, oil fuel, have all been the subjects of investigations by the Board. There is scarcely a branch of fuel utilisation which has not received some attention; and, indeed, a good idea of the "present state of the art" and the problems awaiting solution may be gained from a perusal of this report. The field of work is so wide that it is impossible for the research staff even of a national board to cover it in more than a fractional measure. It is gratifying to observe recognition of this in the allocation of financial assistance by the Board to independent workers in the universities and other centres of experiment. H. J. HODSMAN.

Obituary.

DR. W. E. HAWORTH.

DR. WALLACE ELLWOOD HAWORTH, who, as a result of a collision between the motor cycle he was riding and a motor car, sustained fatal injuries at Salisbury, Southern Rhodesia, and died on March 13, furnished an example of a man who, possessing naturally a scientific bent, was able to devote himself wholly to scientific pursuits only somewhat late in life. He was sixty years of age at the time of his death and held the post of a Milner Research Fellow in entomology of the London School of Hygiene and Tropical Medicine, having, in accordance with the arrangement made between the School and the Government of Southern Rhodesia, been sent out to work in collaboration with Dr. G. R. Ross, who is engaged upon an inquiry into the etiology of blackwater fever. Dr. Haworth was responsible for the collection and identification of mosquitoes, and was gathering data showing how the distribution of anophelines coincided with the presence of cases of blackwater.

Dr. Haworth, who was born in New Zealand, had always been interested in zoology, a subject to which he devoted himself when at Canterbury College, Christchurch, from 1882 until 1885. He commenced the study of medicine at the University of Edinburgh in 1886, graduated M.B., Ch.B. in 1892, and then turned his attention to public health, taking his B.Sc. in that subject in 1893. In the same year he was appointed examining officer for ships at Leith during an outbreak of cholera on the Continent. After two voyages to India as a ship's surgeon, he settled in private practice in Southern Rhodesia and was there from 1896 until 1917. Throughout this period his interest in zoology was maintained and he was, to use his own words, constantly observing the life-histories of various insect pests.

From 1917 until 1919, Haworth was on active service with the Rhodesian Native Regiment in Nyasaland, German East Africa, and Portuguese East Africa, and thereafter was employed temporarily in Government service, holding the posts of M.O.H. Tanga, acting director of the Bacteriological Laboratory, Dar-es-Salaam, and Medical Officer of Health at Lindi. Both at Tanga and Lindi his duties included those of Port Health Officer. It was especially at Dar-es-Salaam that he made his interesting and important researches on the breeding of mosquitoes in the tops of coconut palms. The results of his investigations were embodied in a carefully written paper which appeared in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* in October 1924. It is noteworthy that, despite his age, Dr. Haworth himself scaled coconut palms during the course of his observations. These have been the subject of some criticism, but are admittedly of a pioneer nature and were the means of bringing three new species of Aëdes to light.

Dr. Haworth returned to Great Britain in 1924 and then, full of energy and enthusiasm, took a course on systematic entomology under Prof. Ashworth. Thereafter, as has been recorded, he received an appointment at the London School of Hygiene and Tropical Medicine. During the few months he was in Salisbury he worked with ardour at his special subject, made arrangements for extensive mosquito surveys, and collected a large amount of material. His tragic and untimely death has robbed the School of a zealous and well-trained research worker, and is greatly deplored by all who knew him.

Mr. A. R. McCulloch.

By the death of Allan Riverstone McCulloch, which took place at Honolulu on September 1, 1925, systematic ichthyology lost one of its foremost exponents. He was born at Sydney, New South Wales, on June 20, 1885, and at the early age of thirteen he commenced work at the Australian Museum, Sydney, as an unpaid assistant. Even in those early days young McCulloch was distinguished by his enthusiasm, his ability, and his determination to succeed. Assisted and encouraged by Mr. Edgar R. Waite, then in charge of the vertebrate section of the Australian Museum, he made rapid progress both in the study of zoology and in drawing, and when, in 1906, Waite became Curator of the Canterbury Museum, New Zealand, McCulloch succeeded him, though he was then not quite twenty-one years old. By that time he had definitely resolved to devote himself to the study of fishes, and that became his life-work, though he was skilled in all branches of zoology, and was a recognised authority on decapod crustacea.

Exceedingly versatile, McCulloch was never satisfied with the second best, and became an expert photographer and kinematographer, an accomplished artist and musician, and a delightful lecturer. Although not of robust physique he was active and full of courage, and had made several adventurous trips to the Great Barrier Reef and various Pacific Islands. In 1922, in company with Captain Frank Hurley, he traversed part of Papua, and returned with many valuable specimens and a wealth of observations on the natives and the animals of the island.

At the time of his death, McCulloch was on long leave granted him by the Trustees of the Australian Museum in the hope that his bodily and mental vigour would be restored. He left Australia to attend the Pan-Pacific Fisheries Conference at Honolulu, and, with his accustomed ardour, he took a leading part in the work; but he overworked himself and paid the penalty of enthusiasm in his chosen field of research.

When McCulloch died at the early age of forty years, he left behind a record of accomplishment rarely equalled in the full span of a human life. His work was marked by thoroughness and accuracy. Largely as a result of his numerous contributions, the taxonomy of Australian fishes has been placed on a secure foundation. Most of his work appeared in the *Records of the Australian Museum* or in the official publications of other State Museums in Australia. His most important work, which embodied the results of many years' toil and research, was his "Check List of the Fishes and Fish-like Animals of New South Wales," published by the Royal Zoological Society of New South Wales (*Australian Zoologist*, vol. 1, 1919, pp. 217-227; vol. 2, 1921, pp. 24-68; 1922, pp. 86-130). This fine piece of work was in 1922 issued separately as "Australian Zoological Handbook, No. 1," and forms an enduring monument to the industry and ability of the author.

McCulloch had a most pleasing personality, and was ever ready to assist his colleagues. Many scientific workers, both in Australia and abroad, owed much to his helpful advice and criticism.

C. A.

Mr. E. K. Jordan.

Eric Knight Jordan, one of the most active and promising among the younger geologists of America, was killed in an automobile accident on March 10. Born in San Francisco on September 27, 1903, the son of David Starr Jordan and Jessie Knight Jordan, he had shown in early boyhood unusual interest in scientific research. Before he entered the university he had made a collection and prepared a manual of the molluscs of California. This MSS., still unpublished, contains much original work, especially on the chitons and the minute snails, Odostomia. His study of the molluscan fauna of Trinidad Head (Calif.) was written when he was fifteen years old, and was published by the U.S. National Museum.

Graduating from Stanford in 1923, with geology as his major subject and zoology as a minor, Jordan made in 1924, under the auspices of Cornell University, a large collection of fishes from Hawaii. Under the direction of the California Academy of Sciences, he took part in a biological and geological survey of the middle portion of Lower California. The reports on the last two expeditions are still unpublished.

A unique combination of heredity and environment made Eric Jordan a perfect specimen of young manhood. Handsome, vigorous, earnest, with a love for his chosen field of science which might be said to approach genius, he was heir also to the personal charm which has endeared his parents to numberless Stanford men and women. But a short month before his death he was married to an accomplished class-mate of his, Elizabeth Roper. The scientific world can but tender its respectful sympathy to one of its masters, so tragically bereaved, and mourn for so fair a promise, never to be fulfilled.

Albert Guérard.

We regret to announce the following deaths:

Dr. S. M. Barton, professor of pure mathematics in the University of the South, and a charter member and past president of the Tennessee Academy of Sciences, on January 5, aged sixty-six years.

Prof. L. G. Gouy, of the University of Lyons, distinguished for his contributions to the theory of the propagation of spherical waves, the velocity of light and Brownian movements, on January 27, aged seventy-two years.

Prof. W. J. Lewis, F.R.S., senior Fellow of Oriel College, Oxford, and professor of mineralogy in the University of Cambridge, on April 16, aged seventy-nine years.

Dr. Carlo de Marchésetti, honorary director of the Museo Civico de Storia Naturale and director of the botanic garden, Trieste, on April 2.

Mr. H. Kirke Swann, author of a number of important ornithological works, including a "Monograph of British Accipitres," now in course of publication, on April 14.

News and Views.

ON April 14 Sir James G. Frazer, O.M., was officially invested by M. de Fleurian at the French Embassy in London with the most distinguished title of Commandeur de la Légion d'Honneur, which had recently been conferred on him by the French Government. This rank in the Legion of Honour is, we believe, the highest which is conferred upon a private individual, and is a fitting recognition of one who for many years has held an outstanding position in the field of thought and scientific investigation. It is a little more than a year ago that Sir James Frazer's contributions to the study of the development of human consciousness as manifested in the religious beliefs and social organisation of primitive and early man received the signal recognition of the Order of Merit. This testimony to his pre-eminence among scientific workers in Great Britain is now supplemented by an honour which will serve to remind his fellow-countrymen, should such reminder be needed, that his reputation stands equally high on the Continent, and that his lectures in France and translations of his works have made the name of the author of "The Golden Bough" almost equally familiar on both sides of the Channel. We offer Sir James Frazer our sincere congratulations on this latest honour.

IN our issue of November 21, p. 758, in commenting upon the recent very successful visit of Sir Ernest Rutherford to the capital cities of Australia, we expressed a desire to know whether the Australian universities which arranged this visit meditated plans for making such invitations at regular intervals. A correspondent informs us that in 1922, at the Australian Universities' Conference in Melbourne, Prof. Darnley Naylor, of Adelaide, suggested that Prof. John Mackail, the well-known classical scholar, should be invited to deliver lectures in certain of the cities in 1923. The interest taken by the public in these lectures led to the appointment in the University of Melbourne of a small body, known as the Overseas Lecturers' Committee, to make arrangements each year, in consultation with the sister universities, for the visit of a distinguished authority from overseas. No restrictions as to subject were laid down. In 1924 Prof. John Adams accepted an invitation, and his addresses on educational theory and practice were greatly appreciated. Last year Sir Ernest Rutherford visited nearly all the States. The lectures are usually given late in August or in September, and a lecturer is able to return to England a few weeks after the commencement of the Michaelmas term. Unfortunately, Australia cannot offer the financial inducements which attract many British leaders to the United States on similar missions. Moreover, the physical strain of a tour extending from Perth to Brisbane may be considerable. But perhaps the exceedingly hearty appreciation of Australian universities and public audiences, and the sense of most valuable work accomplished in forming "a real net-work of thought and action among British universities," may serve to make it easy for Australia each year to obtain the services of an outstanding scholar from the mother country.

AT the present time the changing of generating stations into substations is one which interests electrical engineers. The working, therefore, of the new substations at Ilford is being watched by all those interested in supply. The authorities at Ilford were informed by the Electricity Commissioners so far back as 1920 that no further extensions of their generating plant would be permitted. If they required extra current they would have to take it from a neighbouring generating station. At that time the only suitable station which could supply them was at West Ham, and it is from this station that the supply for the substations at Ilford is obtained. In the future, it is probable that West Ham itself will be a substation, as it is not on the list of the 'selected stations.' This, however, will not affect the supply. These substations, especially when fully automatic, will want regular inspection by a competent staff. Although automatic devices can be looked after by a much smaller staff, yet they must be highly technical. The rapid growth of the supply when the price is reduced will increase the demand for technical inspectors, and we do not think that electricians need fear loss of work or loss of status. The introduction of machinery greatly increases the output, but it does not decrease the number of workers required. One of the substations at Ilford only operates when the load reaches a certain value. Automatic switches actuated by relays then start a rotary converter. Another substation is simply a kiosk built of steel containing high-tension switches which operate a transformer. The rapid extension of fully automatic machinery in substations, both for electric power supply and in telephony, will probably soon be accelerated.

FOR his Friday evening discourse at the Royal Institution, delivered on April 16, Dr. A. W. Hill took as his title "The Quest for Economic Plants." The quest for spices, drugs and herbs has caused men from the days of the remote past to wander far and wide. In Dr. Hill's opinion the available evidence points to South America as the original home of the banana, coconut, and of the ground nut, and possibly of the oil palm, but when and how they were first transported is and will ever be something of a mystery. Turning to the more recent history of plant introductions, the ill-fated voyage of the *Bounty* may first claim attention. This voyage, undertaken in 1787–1789 for the purpose of conveying the bread fruit—Artocarpus—from the South Sea Islands to the West Indies, is of interest not only because of the mutiny and from the fact that David Nelson, a Kew gardener, was appointed by Sir Joseph Banks to look after the plants, but also because a plan of the ship showing the arrangement for the storing and packing of the pots of plants is given. This may be regarded as the first definite attempt in historic times at plant introduction, on a large scale, of an economic product from one part of the world to another.

THE invention by Nathaniel Bagshaw Ward, examiner to the Society of Apothecaries from 1836 until 1854, of Wardian cases, which are in effect miniature green-houses, made possible the introduction of tea from China to India in 1848 by Robert Fortune, curator of the Chelsea Physic Garden. This was followed by the introduction of Cinchona, the source of quinine, from the Andes of northern South America to Kew by Sir Clements Markham in 1861, and thence to India; and by the introduction of Para rubber, *Hevea brasiliensis*, in 1876, by Sir Henry Wickham and others from Brazil through Kew to the East. The quest for economic plants has since assumed a new aspect. It is now very largely one of finding plants resistant to the diseases which everywhere are manifest, such as the Panama disease of bananas, the withertip of limes, the leaf disease of Para rubber which is causing so much trouble in South America, and so on There are also modern problems of great complexity relating to the yield of latex from Para rubber, the improvement in type of the oil palm and genetical work in connexion with cotton, rice, sugar and bananas, besides problems relating to soil and climatic conditions which tend to keep alive the romance of economic botany.

THE report of the Council of the Linen Industry Research Association for the year ended September 30, 1925, was presented to the members, on March 23, at a meeting at the Research Institute, at Lambeg, close to Belfast. The Association has been six years in existence, under the direction of Dr. J. Vargas Eyre, who has been most successful in discovering the problems and meeting the needs of the industry—so much so, that those who at the beginning had little use for science are now not merely warm admirers of the work the staff has done for the industry, but persuaded that such a Research Institute is an indispensable accessory. Success is due to the fact that the director has kept practical requirements always to the fore. Commencing with the seed, a large amount has now been raised (more than a ton from a single seed of Russian origin he selected fifteen years ago), which is calculated to yield a plant of even growth, affording a flax of superior quality. The development of the seed has been most carefully studied, not forgetting its value as a source of oil. The retting process has been so thoroughly investigated that a "controlled process" appears to be well within sight. The preparation of flax for spinning has been a subject of the most searching inquiry, and there would seem to be promise of no slight simplification of spinning operations. The very difficult problems of bleaching and dyeing have also received much attention, with a view to diminishing the excessive loss in weight and alterations which affect dyeing properties.

THESE are but some of the co-ordinated activities of the research staff of the Linen Industry Research Association, which has loyally co-operated to a common purpose, with unusual regard of a practical end. The example set should be of no slight value. It is matter for congratulation, that the Council is able to report that the efforts to finance the Association for a second period of five years have, to a large extent, been successful. Congratulations are due to the chairman, Mr. J. G. Crawford, upon the work he and his Council have done in promoting the introduction of the scientific spirit into their industry. It is age-old and at a critical stage but courageous and clearly marked out for a new and invigorated life of usefulness and prosperity. The feature of the meeting at Lambeg was a most feeling account given by Dr. Eyre of his stewardship To his and the Council's great regret, he is severing his connexion with the Institute. The Association, therefore, is in need of a suitable successor. The post is one of no slight difficulty, as a man is required who has not only sufficient knowledge to have feeling for chemical, botanical, physical and engineering problems, but is also practical in outlook and gifted with tact and organising ability.

THE explorations in Derbyshire caves carried out by Mr. E. C. R. Armstrong, under the auspices of a joint committee of the British Association and the Royal Anthropological Institute during the last two or three years, have produced, and may be expected to continue to produce, important evidence bearing upon the extent and epoch of early man's occupation of the northern Derbyshire area. What may prove an important addition to our knowledge of the archæology of the Peak district, should subsequent investigation confirm and extend present conclusions, has been made by a discovery in a previously unknown cave in the Manifold Valley The cave was found by the Rev. G. H. Wilson of Bakewell, a well-known local archæologist. According to a statement in the *Times* of April 15 he has found in a stalagmite matrix which lies below limestone boulders at the end of the cave a skull and skeletal remains of the rare pleistocene lynx *Felis borealis*. Remains of wolf, polecat, small ox, red deer and reindeer were also found in a lower chamber of the cave. Beneath the stratum containing reindeer was a layer of charcoal, which Mr. Wilson believes to point to the presence of man.

THE April issue of the *Fortnightly Review* contains an article by Mr. Lancelot Lawton entitled "The Coal Report: No Solution." The title is interesting because it would seem to imply that Mr. Lawton thought that the Royal Commission would be able to find a solution for the difficulties of the industry. If that really was his belief, it need only be said that his optimism was not shared by any one familiar with the position of the industry, because it has long been evident to those acquainted with the facts that the solution must come from within the industry itself, and can be reached only slowly by hard work, sacrifices, and an earnest determination to co-operate for the welfare of the industry on the part of all concerned therein. Few will agree with Mr. Lawton "that the Coal Commission has been a lamentable waste of time and an altogether needless proceeding"; the Coal Commission has done admirable service in putting together the facts of the industry clearly and authoritatively, so that all interested can make themselves definitely acquainted therewith, and that there is no longer any excuse for the public ignorance that prevails as to many of the conditions under which coal mining is carried on. The Coal Commission's report shows unmistakably that the trouble with the British coal industry is that the coal costs too much when it reaches the consumer. If Mr. Lawton had grasped this fact, he would scarcely have put forward the solution of the difficulty, which he finds in low temperature carbonisation! It is obvious to any one, even without expert knowledge, that the use which the consumer makes of the coal after he has received it is no remedy for the fact that the cost of British coal to him is too high.

SIR WILLIAM BRAGG is to deliver three lectures at the Royal Institution on April 29, May 6 and 13, at 5.15 P.M., on "The Imperfect Crystallisation of Common Things." Whereas some solid bodies are single crystals, and some are not crystalline at all, a large number consist of aggregates of small crystals, and their properties are dependent both upon the nature of the crystals and the nature of their aggregation. In metals that have been drawn, rolled, or worked in any way, the crystals tend to orientate in special directions, and a large amount of work has been done in recent years on the connexion between these peculiarities of crystalline arrangement, the treatment to which the metal has been subjected, and the consequent changes in physical properties. So also in natural structures, such as wool, cotton, and other fibres, in animal growths such as spines, bones, and teeth, there are peculiarities in the arrangement of their minute crystalline contents, which are often associated with the manner of their growth. The methods of X-ray analysis have been lately applied to the study of such cases, and a new field has been opened up which may well prove to be of great importance in the study of the properties of all rigid structures, both natural and artificial. Sir William Bragg's three lectures will deal with the methods which have been employed in this field, and examples will be given of the results already achieved.

PROF. H. NAGAOKA has now occupied the chair of physics in the Tokyo Imperial University for close on thirty years. In 1921 a committee of his friends and former students undertook the compilation of a volume of original papers in celebration of the twenty-fifth anniversary of his appointment (Tokyo: Publishing Committee of the Nagaoka Anniversary Volume, Tokyo Imperial University, 1925). This has recently been published, and seven hundred and fifty copies have been distributed to physicists and institutions all over the world. The delay is mainly attributable to the great earthquake of 1923, in which at least one of the contributors lost his life. It is a handsome volume of more than four hundred pages, including some forty papers relating to a great variety of problems in physics, mathematics, meteorology and astronomy. The very wide field covered precludes any attempt to review the subject-matter; at the same time it is an appropriate reminder of the remarkable range of Prof. Nagaoka's own interests and researches. The committee is to be congratulated on the production of a notable *Festschrift*.

THE issue of the *Journal of the British Science Guild* for March contains some valuable suggestions for the method of procedure at conferences called to settle important questions on which action by the State is necessary or desirable. The Ministry concerned should first constitute an agenda committee, on which each interest should be represented, to draw up a statement of the points at issue. This should be circulated to each of the interested parties, and each is to make a preliminary reply to all the points at issue. The preliminary replies are to be circulated to all the parties, which are then to send in final replies to replace the preliminary ones. The Ministry then collates statements and replies and shows the points of agreement, if such exist, and the real differences. The actual conference is then constituted by the Minister to discuss the issues as summarised and to make recommendations. This procedure is so scientific and orderly that it might with advantage be adopted at all conferences whether under the auspices of the State or not, and much time and temper saved.

THE Report of the Clifton College Scientific Society, for the years 1924–25, is a record of much useful work and many-sided activities on the part of its members. The weather report for the two years under review is summarised by means of three interesting graphs in which the records are compared with those for the period 1881–1915. Among the natural history notes mention must be made of the record of a nesting Great Grey Shrike, which is of special interest in view of Coward's remarks on this species, in his "Birds of the British Isles." The exact locality is, wisely, not mentioned, though doubtless adequate account of it has been preserved in the School records. As is usually the case with school societies, the Lepidoptera command the larger share of attention among the insect groups, but we are glad to note the plea made that other orders of insects should not be neglected. A start has been made with the Coleoptera, and this excellent example will doubtless be extended to other groups. We cordially endorse the advice given to members of this Society—to study the living insect and its habits, and to collect as sparingly as possible. This is in the best traditions of the naturalist and of the very essence of field work. The members of the Society who are interested in entomology may be advised to explore the possibilities of the Bristol Museum as an aid to the classification of their captures.

WE have received the first number of a new quarterly publication entitled *Health and Empire*, the official journal of the British Social Hygiene Council (London: Constable and Co., Ltd., 10*s*. per annum). The subject-matter consists of editorial comments, articles, reviews of books, summaries of official publications, and notes on the Council's activities. Among the articles, Prof. Cyril Burt writes on the "Contribution of Psychology to Social Hygiene." He has much to say on sex delinquency, and his conclusions are hopeful for the future. He believes that many of the amorous adventures of youth of either sex in civilised life are attributable, not solely to the sex instinct, but also in part to the hunting instinct: the youth prowling after the girl, the girl promenading after an attractive youth, are simply stalking each other, because the streets of the modern city provide no other animal to chase. Much misbehaviour, too, is really based upon the so-called maternal or protective instinct. Prostitution, he believes, will slowly vanish, just as the organised robberies, fighting, and duelling of former times have been mastered. "The main force of the sexual instinct will in the near future be controlled, ennobled and refined." Altogether, a critical and illuminating article! Prof. Percy Nunn contributes an article on the "Influence of Education and Tradition in Social Hygiene," in which he indicts science-teaching in schools. "In our secondary schools for boys, 'science' means scarcely anything beyond physics and chemistry. . . . My conviction is, and has long been, that progress towards national enlightenment in social hygiene must remain slow and disappointing until we rectify these grave defects in our school programmes. We must seek, through genuine, if simple, biological teaching in the elementary and even more in the secondary schools, to correct the orientation of the national mind." Other articles are by Mr. C. J. Bond and Dr. L. Findlay.

Major J. Hall-Edwards, a pioneer worker in X-ray therapy whose name is widely known, has been elected an honorary member by the council of the British Medical Association in recognition of his services to medicine.

Prof. E. G. Coker, University College, London, has been awarded the Louis Edward Levy Medal of the Franklin Institute, Philadelphia, for his paper on "Photo-Elasticity" appearing in the March 1925 issue of the *Journal of the Franklin Institute*. The medal was "founded for the recognition of papers contributed to the Journal of the Institute, descriptive of the author's researches in physical science or of his engineering achievements, which have added largely to the sum of knowledge or aided greatly the well-being of mankind."

Dr. W. E. Gye has been awarded the Walker Prize of 100*l*. of the Royal College of Surgeons of England in recognition of his work in advancing the knowledge of the pathology and therapeutics of cancer during the past five years. The Committee appointed to advise the council of the College in the matter stated that the work suggests "new and hopeful lines of attack upon the problem of the cause of malignant disease."

The following have been elected to honorary membership of the American Museum of Natural History, New York City: Captain J. B. L. Noel, in appreciation of his valuable contributions to the science of geography through his explorations in the Himalayas, and especially in his remarkable ascent of Mount Everest; Kunwar Dillipat Shah Rai Bahadur, for the generous assistance which he extended to the Faunthorpe-Vernay Expedition, which has been so successful in securing for the American Museum of Natural History splendid examples of the Plains animals of India

The Museum of Practical Geology, Jermyn Street, London, S.W.1, is now open to the public at the following times: Week days (except Saturdays), 10 A.M. to 6 P.M.; Saturdays, 10 A.M. to 9.30 P.M.; Sundays, 2.30 P.M. to 6 P.M. The Library will be open from 10 A.M. to 5 P.M. on week days.

The *Transactions of the Faraday Society*, which have hitherto appeared three times a year, will in future be published bi-monthly in order to expedite the publication of papers. In addition to the six bi-monthly parts, reports of two general discussions will be published annually, one in the spring and one in the autumn. The new arrangement begins with Vol 22, 1926. The Publication Committee of the Society will be glad to consider papers on any branch of pure or applied physical chemistry, and under the new arrangement rapid publication will be ensured. Communications should be addressed to the Secretary and Editor, 90 Great Russell Street, London, W.C.1.

A general discussion on "Explosive Reactions in Gaseous Media" is being organised by the Faraday Society to take place on Thursday, May 13, at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W 1 The proceedings will be divided into two sessions The first, from 2.30 to 6.30, will deal with the subject generally, and Prof H. B. Dixon will preside. An introductory survey will be given by Dr. W. E. Garner, and papers initiating discussion will be presented by Prof. Dixon, Prof. W. T. David, Dr. S. W. Saunders, Dr. R. V. Wheeler, Prof. W. A. Bone, and Dr. C. Campbell. The second session, 7.45 to 10, will deal with explosive reactions considered in reference to internal combustion engines. Sir Dugald Clerk will preside, and he will give an introductory survey, being followed by Prof. David and Mr. H. T. Tizard. A dinner will be held between the sessions at the St. Ermin's Hotel. A full programme can be obtained from Mr. F. S. Spiers, 90 Great Russell Street, London, W.C.1.

The Geodetic Survey of Canada and the United States Coast and Geodetic Survey have recently completed a joint circuit of 1860 miles of triangulation in Eastern Canada and New England The 1300 miles in Canada extends from the international frontier south of Montreal along the St. Lawrence to Anticosti Island, then round the Gaspé Peninsula and the coast of New Brunswick to the head of the Bay of Fundy. There begins the 560 miles of the American net which extends via Albany northward to the point on the frontier south of Montreal. The circuit closed with an error of only 42 feet, which averages about one-quarter of an inch per mile.

The United States Department of Agriculture Library has just issued No. 11 of its Bibliographical Contributions, in the form of a list of manuscript bibliographies and indexes in the Department, including serial mimeographed lists of current literature. The bibliographies are classified by subject, 202 entries being divided under 35 headings, and a comprehensive index with cross-references is of valuable assistance in tracing items in greater detail The entry relating to each bibliography is descriptive, indicating its source of origin and giving a brief account of the ground covered by the material catalogued. The list has been made as comprehensive as possible, the assistance of the librarian and chief clerks of the various bureaux having been secured to attain this end.

Messrs J and A Churchill will publish at an early date a translation, by Dr. E. Fyleman, of Dr. B. Waeser's "The Atmospheric Nitrogen Industry," "The Chemistry of the Proteins," by Dr Dorothy Jordan Lloyd, and an addition to the "Recent Advances" series, entitled "Recent Advances in Biochemistry," by Dr. J. Pryde.

The Cambridge University Press will shortly publish Vol. 2 of Prof F. O Bower's "The Ferns (Filicales)," dealing with the Eusporangiatae and other relatively primitive ferns. The same house will also issue "The Southern New Hebrides: an Ethnological Record," by C. B Humphreys, being an account of the ethnological conditions of the five southern islands of the New Hebrides: Tanna, Anaiteum, Futuna, Aniwa, and Eromanga

Applications are invited for the following appointments, on or before the date mentioned.—A scientific officer for research in connexion with electrical ignition appliances—The Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (May 15, quoting Ref. A 81) Civilian education officers (Grade IV), Royal Air Force, with good academic and practical qualifications for teaching engineering subjects —The Secretary, Air Ministry, Adastral House, Kingsway, W.C.2 A research physicist, with experience in research—The Director, Research Laboratories of the General Electric Co., Ltd., Wembley. A museum attendant, with knowledge of preparing and mounting specimens—The Curator of the Museum, University College Hospital Medical School, University Street, W C 1.

Errata.—Nature of April 10, p. 516, end of penultimate paragraph in Col. 1; *for* "standard deviation, 74·7" *read* "standard deviation, 7·47."

Nature of April 17, p 557, Col. 1 The total power of the electrical machinery in the machinery hall of the Rugby Wireless Station is 1800 kilowatts and not 800 kilowatts as stated. The insulation referred to at the end of paragraph 3 as being designed for a quarter of a million volts is the insulation between antenna and earth.

Our Astronomical Column.

Magnetic 'Storm,' Aurora, and Solar Disturbance—A considerable magnetic disturbance was recorded at Greenwich on April 14, commencing with a sudden deflexion of the needles at 11 hr, and continuing until 11 hr on the following day. The extreme range shown by the Declination trace was 1¼°, and by the North Force trace 350γ. The disturbance thus ranks as 'great.' In this connexion, a letter received from Mr. Charles Leaf of Cambridge is of interest, in which he records a fairly well-marked display of the aurora borealis seen on April 14 between $21^h\ 20^m$ and $21^h\ 50^m$ G M.T, after which clouds made further observations impossible The aurora was seen as a moderately strong greenish glow exhibiting a marked 'pulsation' of intensity, no streamers were visible Mr C P. Butler of the Solar Physics Observatory, Cambridge, also observed the aurora He noted its greenish colour and that the auroral line $\lambda 5577$ was fairly bright.

At the time of these phenomena there were no large spots on the sun, although there were three comparatively small ones, and several areas of faculæ. One of the spots at the time of the commencement of the magnetic storm was 9° of solar longitude (or 0·7 day) east of the sun's central meridian. Although much diminished in size, this spot was the fourth recurrence of one of a very large pair of spots seen last December. Its earlier history has been outlined in these columns as the naked-eye spot, Nos. 1 and 4 (Nature, January 9, 30, February 27). When near the sun's central meridian on January 22 a moderate magnetic disturbance took place, but no marked movements of the needles were noted at the time of its two subsequent transits of the central meridian about February 19 and March 18

Mr. A. M. Newbegin, of Sutton, Surrey, has observed that the longitudinal zone of the sun containing this spot has produced a large prominence, which he saw with his spectroscope at the sun's limb on February 25, March 10, and March 23-24.

The Hamburg Observatory, Bergedorf—The report of the Director of this Observatory, Prof. R. Schorr, for 1924 has lately come to hand; it contains a record of numerous researches The transit circle is being used for the re-observation of stars observed by Rumker The 60-cm refractor has been used by Dr Graff for charting the stars surrounding 150 eclipsing variables, determining both their magnitude and their colour.

Dr. Baade used the reflecting telescope for photographic observations of several faint comets and interesting minor planets, including Ganymed, which he discovered He also obtained photographs of several clusters and nebulæ. He has now temporarily left Bergedorf on a visit to some of the North American observatories. Dr. Kruse has used the 26-cm. equatorial for photometric observations of variable stars, also for comets and minor planets The Lippert astrograph was used by Prof. Schwassmann and Dr. Haas for obtaining photographs and spectrograms of the Kapteyn selected areas. The exposures for the spectrograms ranged from half-an-hour to 5 hours. Dr. Haas also determined the spectral types of several faint stars for which sensible parallaxes have been found. They are mostly of late types, G to M, but B D. + 42° 3917 is of type A 3.

Progress is also being made with the "Geschichte des Fixsternhimmels" and the "Eigenbewegungs-Lexicon," which are extremely useful works of reference.

The work of detecting faint minor planets and periodic comets on their return to perihelion has been very successfully pursued

Research Items.

BLOOD CHARACTERISTICS AND RACE.—The first number (Jan.-Feb.) of vol. 36 of *Natural History*, the publication of the American Museum of Natural History, is devoted to the study of the present races of man, and contains, in addition to descriptive articles of primitive peoples, several papers dealing with anthropological questions of more general bearing. Among these is a review by Mr. R. Ottenburg of the present position of the study of the characteristics of the blood as a test of race relationship. The suggestion put forward by Dr. Hirschfeld and his wife in 1918 that the constituents known as A and B originated in Europe and Asia respectively, no longer holds good in the light of further and more extended observation. It is found that there are races in Africa, Asia, Australia, and America which show as high a proportion of A to B as do the North Europeans, the supposed exceptionally high proportion of A in the last named being the basis of Hirschfeld's conclusion. Six fundamental types are to be recognised according to the proportion of the three more common blood-groups. The European type is characterised by a relatively high proportion of Blood-group II., while two of the Asiatic types, the Indo-Manchurian and the Afro-South Asiatic on the fringes of the Indian Ocean, have more of Blood-group III. The Pacific American type, consisting almost entirely of Australian and American Indians, shows an enormous preponderance of Blood-group I. The Hunan type is remarkable in that it shows an unusual proportion of Group IV., which in every other type is the lowest. The figures seem to indicate the existence of transition races formed by the mingling of two adjacent races. The Jews apparently do not form a homogeneous group, but tend to assimilate to a local group, *e.g.* Berlin Jews to German, Spanish Jews to Arab, Rumanian Jews to Hungarian, and so on. The gypsies, however, correspond to the Indo-Manchurian type, which seems significant in view of their tradition of non-intermarriage and Central Indian origin.

AN 'EOLITH' FACTORY.—A sequel to the now famous study of the 'eoliths' produced in the course of the manufacture of cement at Mantes, which was made by Prof. M. Boule in 1905, appears in Nos. 1-2 of vol. 36 of *L'Anthropologie*. In 1924 Mr. Etienne Patte, at the suggestion of Prof. Boule, examined flints similarly produced by a cement factory at Beaumont-sur-Oise, and found them to be identical in form with the implements found in the pliocene of East Anglia for which a human origin is claimed. The method pursued in selection was identical with that followed by those who accept the Pliocene specimens as artefacts; that is, a process of repeated classification, selection, and rejection which ends in the assembly of a relatively small number bearing what are said to be indubitable traces of human purposive working. In this case the causes are mechanical, but the chipping is identical, and the result a collection of characteristic types, rostro-carinates, etc. More remarkable still, a crushing machine which consisted of two 'jaws' shod with iron, the lower being fixed, produced flakes, some of which showed an apparent secondary chipping and might have been taken for scrapers of an Upper Palæolithic or even Neolithic culture.

THE MARINE FISHES OF PANAMA.—The second part of this monograph, by Mr. S. E. Meek and Mr. S. F. Hildebrand (*Field Museum of Natural History*, Zool. Ser., vol. 15, 1925), includes the teleost fishes from the families Carangidæ to Pomacentridæ. Nine new species and subspecies are described, and in many cases a detailed study of Atlantic and Pacific forms has demonstrated differences of sufficient importance to warrant the institution of new species. The report is well illustrated, and the authors have not neglected to supply well-produced figures of hitherto inadequately figured forms. Useful working keys to the genera and species continue to form a prominent feature of the work, and, when completed, it should be an indispensable guide to the fishes of this region and yield valuable information for a detailed comparison of species and genera on both coasts of Central America.

FLUCTUATIONS IN FISHERIES.—We quite agree with Mr. B. Storrow (*Trans. Nat. Hist. Soc. Northumberland*, Nov. 1925) that to trace to their cause the fluctuations to which statistics show that all fisheries are subject, is one of the most important problems in fishery investigations, if not indeed the central problem on which all remedial measures depend. These fluctuations are seen by comparing the total landings year by year, or the catch per unit of power in unit of time. The latter is obviously the most accurate method, but boats themselves as units of power fluctuate so greatly, leaving out of all account the skill of their crews, that its measure of accuracy is not great. In any case, it cannot be applied to herring or any fish which is not distributed relatively evenly over the bottom or the surface of the sea where trawl or drift fisheries are regularly pursued. In writing on any fishery question there is always the personal factor which must come in, even in interpreting rigid facts, as exemplified by figures of catch of different areas as shown by Mr. Storrow to his readers in numerous graphs. The thesis here is that migrations of fish have more to do with fluctuations than any other factors, such as bad spawning or hatching, greater or less vitality of the young, or extraordinary occurrences causing the death of fish in vast numbers. As examples the herring, cod, haddock and mackerel are considered. Graphs are given either to show average catch per day's absence for each month, or the total catches year by year for a number of years in several areas, superimposed for each year upon one another. These should be similar if the same causes operate in all areas, but it is clearly brought out that peaks in some graphs so commonly overlie depressions in others that, if all were added together, the result would be so smoothed down that the facts would be hidden. To put it in another way, the total catch does not vary much year by year, while the catch in areas shows large fluctuations. There are great periodic changes in the flow of Atlantic waters besides minor fluctuations and, coinciding with these, are supposed to be wholesale movements of the fish themselves. Of these, statistics alone cannot give proof, which can only come by the identification of the areas from which the fish came, by markings or otherwise on the fish themselves.

CARABID BEETLES FROM THE KUMAON-TIBETAN FRONTIER.—In the *Entomologist's Monthly Magazine* for March 1926, Mr. H. E. Andrews contributes a paper on the Carabidæ obtained by Mr. H. G. Champion in the north of Kumaon and over the Tibetan frontier. During the expedition much new country was traversed at a great elevation, and the Tibetan frontier was reached near Shelshel and Laptel at about 15,000 ft. The species and varieties of Carabidæ enumerated number sixty-six, and twelve new species are described. Most of the species inhabiting the higher regions of the Himalaya are, as would be expected, palæarctic genera, and this appears to be the southern limit, at least in Asia, for a good many of them. A few, such as Dioryche and Colpodes, occur in tropical Asia and reach their northern limit in the Himalaya. Others, such as Tachys and Bembedium, are nearly world-wide. Sixteen species extend their range outside the Himalayan tract, occurring, in some instances, in Indo-China, Formosa, and the Malay Islands. One species, *Anchomenus quadripunctatus*, is holarctic in its range and extends into England.

EXPERIMENTS ON DAPHNIA.—M. Ramult records (*Bull. Internat. Acad. Polonaise Sci. et Lettres*, No 1, 2B, Jan.-Feb. 1925) observations on the effects of sodium chloride solutions, including Ringer and Van 't Hoff's solutions, on Daphnia and other Cladocera. These solutions restrain the passing of the parthenogenetic eggs into the brood-pouch; such restraining action begins to appear in N/30 sodium chloride, and in concentrations above N/10 is total. While the restraining action appears in individuals before the weakening of their other vital functions, the author thinks it may be assumed to be due to the enfeebling action of the solution on the egg-producing female. N/30 and higher concentrations exercise a restraining influence on the development of the egg, which is especially sensitive to such solutions in the membraneless condition, but after the formation of the membrane can develop in solutions up to N/16 to N/6. The eggs of the succeeding broods of the same female living in the saline solution show a decreasing resistance, probably corresponding to a lessening vitality. The different eggs of the same brood living in the solution exhibit differences in their power of development. Animals which passed through their whole development in the solution attained their maturity in the same period of time as, sometimes even earlier than, those from the normal culture. In the third generation bred in the solution (not stronger than N/15) both the period of embryonal development and of the attaining of maturity are as long as in the second generation, and the number of eggs produced by the females in the solution is not reduced. The eggs of the second generation are able to pass through their normal development in a concentration slightly higher than those of the first generation—this applies to solutions not stronger than N/20.

INTESTINAL FLAGELLATES IN TROPICAL AMERICA.—Prof R. W. Hegner (*Amer Journ Trop. Med.*, 5, May 1925) records the results of examination of stools made by him during the summer of 1924 in Honduras and in Colombia. The incidence of infection with *Trichomonas hominis* was 20·6 per cent, with *Chilomastix mesnili* 7·7 per cent., and with *Giardia lamblia* ·1 per cent. The author accounts for the high ncidence in the case of the first two (1) by the high emperature and moist climate of tropical America, which are favourable for the transmission of these flagellates, (2) by the insanitary habits of the natives, which also favour transmission, and (3) the diet, which is largely vegetable, of the general population. Prof. Hegner has previously shown that these flagellates grow and multiply rapidly in hosts that live on a vegetable diet, but they are largely eliminated from hosts that live on a meat diet. Comparison of these esults with those of Miss Jepps from the Federated Malay States and of Boeck and Stiles from the United States indicates a definite relation among human beings between a meat diet and the lower incidence of nfection with these flagellates, especially Trichomonas.

THE PERIOD REQUIRED FOR MITOSIS.—Modern methods of tissue culture permit observations on the process of mitosis and of the duration of the various phases. In view of the discrepancy in the times recorded by Levi (1916) and by Lewis and Lewis (1917), G. P Wright (*Journ. R Micr. Soc.*, Dec. 1925) has made observations on tissue from the heart of chick embryos of the 9th to the 12th day, cultivated in Pannett and Compton's saline medium to which embryonic extract had been added. Assuming that the telophase period lasts 5 min., and on this there seems to be fairly close agreement, the early prophase takes 8 min., the spireme 6½ min., the metaphase 5 min., the anaphase 4 min., the telophase 5 min., and the reconstruction 5 min.—a total of about 34 min. This is almost identical with Strangeways' record of 35 min. as the period of division of the choroidal cells of the chick, and it falls midway between the two limits, 25 min. to 45 min., found by Lambert and Hanes to be the time of division for the connective tissue cells of the rat.

A TAXONOMIC STUDY IN EVOLUTION.—From this general point of view, Mr. Francis W. Pennell examines the taxonomy of the genus Afzelia of the Scrophulariaceæ in *Proc. Acad. Nat. Sci. Philadelphia*, vol. 77, pp. 335-373, 1925. He concludes that the genus shows transition from the campanulate to rotate corolla, with a change from longitudinal to pore dehiscence in the anther of the stamen, with which change also runs a modification of the staminal filament from a broad flat hairy structure to a type with a slender, terete, glabrous distal region. Thus the flower, viewed as an organ to ensure pollination, has been so changed as to function in a new manner. Studying the distribution of the species in this genus, Mr. Pennell concludes that they show a striking disagreement with the "Age and Area" hypothesis of Dr. Willis. In Afzelia, the most modified and recent species appear to be the most widespread.

REGENERATION OF FERN PROTHALLI.—In the *Biologisches Centralblatt*, vol. 46, pp. 80-96, 1926, K. Linsbauer describes some interesting experiments on the regeneration of isolated cell groups obtained by cutting pieces out of fern prothalli. He finds that very small cell groups, which normally would have finally ceased to grow and divide, when isolated in this manner, may again begin to grow vigorously and practically give rise to prothalli. He concludes that this revival of growth cannot be traced to growth-promoting substances from the wounded cells, but to the accumulation of assimilates in the isolated prothallial fragments which normally would have been passed on to nourish the growing apical region.

CURRENTS IN THE RED SEA.—An account of current-meter measurements made during the hydrographic cruise in the Red Sea of the *Ammiraglio Magnaghi* in 1923–1924 is published by Prof. F. Vercelli, with numerous diagrams and illustrations (*Annali Hydrografici*, vol. 11). The recorded horizontal movement of the upper layers was found on analysis to be the sum of a to-and-fro tidal stream and a drift current, the latter varying with the monsoon season. The tidal streams persist throughout all depths, whereas the drift current decreases down to a depth of 100 metres in the channel off Bab-el-Mandeb, below which it reverses in direction. From the harmonic components of the tidal stream, derived from an analysis of the observed data, and the drift current, the calculated velocity of the upper layers is tabulated for every hour throughout a year. Accurate computations of the currents which will be met with by vessels navigating the Red Sea are likely to be of particular value in view of the difficulty often experienced in that neighbourhood in obtaining reliable 'sights' during the day owing to refraction.

RAINFALL IN THE NETHERLAND INDIES.—The Royal Magnetical and Meteorological Observatory of Batavia in *Verhandelingen*, No. 14, vol. 1, publishes the mean rainfall figures for 2715 rainfall stations in the Netherland East Indies, calculated from observations made during the period 1879–1922, by Dr. J. Boerema. The present publication contains nothing besides a mass of tables without a word of text. Very few of the stations are for the whole period of forty-four years, but the number of years over which the observations extend are given with each station, and the height of each station above sea-level is stated. In addition to the mean rainfall for each month and the year, the mean number of rainy days is also given, but what constitutes a rainy day does not appear to be stated; the results are in mm The mean maximum daily rainfall is also given for each month and for the year; it might perhaps have been more useful to give the absolute maximum rainfall for each month and year. A single entry of the absolute fall is given without reference to when it refers

SEASONAL WEATHER FORECASTING.—Remarks on the influence of the currents in the waters about Denmark upon the climate of Denmark and neighbouring countries by A. C. Johansen and A. J. C. Jensen, reprints from Physiological Papers, have recently been published in Copenhagen. The strength of the inflow into the Kattegat varies much from time to time, and a strong outgoing current in the surface layer is followed by a strong ingoing current in the lower layer. The authors have examined the correlation between the salinity of the bottom water of the Kattegat and the salinity and temperature of the surface water, also the correlation between the salinity of the bottom water in the Kattegat in the spring months and the air temperature in Denmark and neighbouring countries in the summer months. It is found that a high salinity in the lower layer of the northern Kattegat in April–May is normally followed by a low air temperature in June and July, and a low salinity is normally followed by a high air temperature. There is probably also a positive correlation between the salinity of the bottom water of the Kattegat in the spring months and the rainfall in Denmark in the early summer.

LEAKAGE OF CARBON DIOXIDE FROM SHIPS' HOLDS.—Special Report No. 24 of the Food Investigation Board, by Mr. A. J. Smith, describes leakage tests on two vessels (London: H.M.S.O., 1925; 9*d* net). Carbon dioxide was introduced into the empty holds, and, by analysing the gas from day to day, the amount of leakage was determined. The rate of leakage in port was increased to more than ten times its original value by opening the thermometer tubes. The leakage when the vessel was at sea was higher than when at rest in port.

TRANSMUTATION OF MERCURY INTO GOLD.—A further contribution to this question is made by Piutti and Boggio-Lera, whose results are published in the September-December issue of the *Rendiconti dell' Accademia delle Scienze Fisiche e Matematiche (Naples)*. The mercury employed was purified by repeated distillation in a vacuum, the two final operations being carried out in Jena glass apparatus under a pressure of the order 0·001 mm. This purified mercury was treated in three different ways: (1) A spark discharge was passed between electrodes of the metal in a highly evacuated tube; (2) an arc was passed between two very fine jets of the mercury in a vessel kept filled with hydrogen to prevent oxidation; (3) a fine stream of the mercury was allowed to fall through the arc passing between two specially pure carbon electrodes, also in an atmosphere of hydrogen. In no case was any formation of gold detectable, even by Stammreich's method of testing, which responds to so little as one one-millionth of a milligram of gold per kilogram of mercury. The view that mercury may undergo spontaneous transmutation into gold in Nature is suggested by the invariable presence of gold in commercial mercury, and it is possible that useful information on this phase of the subject might be acquired by the examination of deposits of cinnabar of different geological ages.

THE GLOW OF PHOSPHORUS TRIOXIDE.—Thorpe and Tutton, the discoverers of phosphorus trioxide, showed that this substance is oxidised with emission of light, and it has been suggested that the glow of phosphorus is really due to that of phosphorus trioxide formed in a preliminary reaction. It has also been suggested that in moist oxygen an intermediate substance, probably phosphine, is formed from phosphorus trioxide, and that the glow is due to this. An interesting account of the glow of phosphorus trioxide is given by Christina Cruickshank Miller in the *Proceedings of the Royal Society of Edinburgh*, 1925–6, vol. 46, part 1. It was shown that the glow depends on the presence of moisture and ceases in the absence of water. It was found that phosphine and other hydrides of phosphorus are produced, and the glow is attributed to the oxidation of these. The results throw much light on the still obscure problem of the glow of phosphorus itself.

MEASUREMENT OF HUMIDITY IN CLOSED SPACES.—Special Report No. 8 of the Engineering Committee of the Food Investigation Board contains an account of experimental work in hygrometry carried out at the National Physical Laboratory by Dr. Ezer Griffiths (London: H.M.S.O, 1925; 2*s*. net). The primary object of the investigation was to study apparatus for making humidity measurements, and a description is given of numerous forms of hygrometers devised to meet special requirements. The supreme importance of exposing the wet bulb of the wet and dry bulb hygrometer to moving air is emphasised. The special forms of this hygrometer described are: (*a*) a direct reading instrument; (*b*) instruments to enable readings to be taken without entering the enclosure; (*c*) a distant reading form The dew-point hygrometer is particularly suitable for use as a standard of reference in calibration work. Several industrial forms of dew-point apparatus are described. The hair hygrometer was given detailed study. It was found that the hai hygrometer showed a tendency to give high readings with lapse of time. The instruments which behaved most satisfactorily were those in which the tension force was small and the bearings and pivots of which were so well made that friction was reduced to a minimum A distant reading type of hair hygrometer was constructed on the Wheatstone's bridge principle. Th other instruments of this type that might be mentioned are (*a*) the form adapted for insertion into frui cases; (*b*) the combined hair and dew-point apparatus A hygrometer was constructed utilising a discovery o Orme Masson that dry cotton-wool when exposed to damp atmosphere generates heat. The instrument was constructed in the form of a differential resistanc thermometer, one coil being covered with cotton an the other by non-hygroscopic material. This type o hygrometer has certain inherent defects due t hysteresis.

Exhibits at the Optical Convention, 1926.

THE Optical Convention, 1926, was held at the Imperial College of Science and Technology, South Kensington, during the week April 12-17, under the presidency of the Astronomer Royal, supported by representatives of all branches of the optical industry and profession. An important part of the Convention was the exhibition of optical instruments and apparatus organised to demonstrate the advances that have been made in optics in Great Britain since 1912, the date of the previous Convention. During the week, more than 8000 visitors, in addition to members of the Convention, attended the exhibition. Many were attracted, no doubt, by the various entertainments and performances incorporating interesting optical illusions, but many also were attracted by a desire to study the concrete evidences of recent developments and the most modern products of British opticians, many of which, as the Prime Minister pointed out during the opening ceremony, are recognised the world over as achieving the high water-mark of technical perfection.

Considerable development might be expected in an industry during a period of fourteen years. When it is remembered that during part of that period, development was quickened by the urgency of war-time requirements, and later by the necessity of meeting fierce competition arising from depreciated foreign exchange rates, and also of keeping pace with rapid advances in science, it can easily be imagined that the manufacturer had a wide range from which to choose his exhibits.

Optical glass, the most important of the optician's raw materials, was exhibited in the rough lump and in the form of moulded slabs, disks and prisms by Messrs. Chance Bros. and Co., Ltd., and by Messrs. Parsons' Optical Glass Co. The latter firm exhibited a disk of hard crown glass, 32 in. in diameter, suitable for use in a 30-in. aperture telescope object-glass. Specimens of dense barium crown glass shown by Messrs. Chance Bros., illustrated the improvement in quality, particularly in regard to freedom from colour and bubbles, which has been effected in recent years in the production of this difficult glass. This firm now makes more than 100 different types of glass suitable for optical purposes, many of which were not manufactured before the War.

Some of the uses to which these new glasses have been put were well illustrated by the extensive range of new types of photographic lenses exhibited. The Ross Xpres and the Taylor-Hobson Aviar lenses were designed and produced during the War to meet the demand for large-aperture lenses giving the high quality of definition required in air photography. Further developments in the direction of the production of rapid anastigmats were represented by Messrs. Taylor, Taylor and Hobson's f/2·5 lens, suitable for reflex cameras, and also their f/2 anastigmat, which has a covering power of 55° and represents the limit so far reached in the production of wide angle, large-aperture lenses. Another exhibit by the same firm was a series of f/3·5 telephoto lenses, which marks an important advance in telephoto construction. This advance has been shared by the Teleros lenses of Messrs. Ross, Ltd., who had on view a 40-in. lens of that series fitted to a Ross Sports camera. Telephoto lenses of recent design were also exhibited by Messrs. J. H. Dallmeyer, Ltd., and by Messrs. Wray (Optical Works), Ltd.

The remarkable developments that have been effected in British-made surveying instruments were well shown in the various types of theodolites and levels exhibited by Messrs. C. F. Casella and Co., Ltd., Messrs. Cooke, Troughton and Simms, Ltd., Messrs. W. Ottway and Co., Ltd., and Messrs. E. R. Watts and Son, Ltd. These improvements have been largely directed towards securing optical perfection, reduction in dimensions and weight, greater rigidity, more effective guarding of vulnerable parts, and the introduction of means for saving time and labour in the making of observations. In the precise levels exhibited by these firms, the telescope with the attached bubble can be tilted independently of the vertical axis, which greatly facilitates and expedites field work. Provision is also made on many of the instruments for reading the bubble, the compass bearing, and the staff, from the telescope-end position, without change of position on the part of the observer. Messrs. Cooke, Troughton and Simms and Messrs. Watts exhibited levels embodying reversible bubbles, the use of which simplifies the adjustment of the instrument. Further simplification in the use of Messrs. Watts' instruments have been effected by the introduction of their "constant" bubble, which is so constructed that changes of temperature within the range 0° to 130° F. produce no change in the length of the air bell. Thus, when the instrument is being set it is necessary to observe only one end of the bubble.

With the exception of a few standard instruments or parts of instruments, the microscope apparatus exhibited by Messrs. C. Baker, Messrs. R. and J. Beck, Ltd., Messrs. Negretti and Zambra, Messrs. Ogilvy and Co., Messrs. James Swift and Son, Ltd., and Messrs. W. Watson and Sons, Ltd., represented an entirely new series of instruments and appliances for microscopical work computed and designed since the last Convention, and including all types of microscopes and microscope accessories such as are required for students' use, for industrial processes, for scientific investigations and for all classes of laboratory and research work. The modifications that have been introduced involve many important changes in mechanical design and construction, and also improvements in optical properties. One of the most striking alterations in mechanical design is that shown in the Beck Radial microscope. The general design is that of a small optical bench so arranged that as the inclination is changed from the vertical to the horizontal, or any intermediate position, the centre of rotation remains in the optic axis. The advantage of this arrangement is specially apparent in metallurgical work when a vertical illuminator is used. The adjustment, being once set, is not altered by the inclination of the instrument or by the focussing.

Of the many important instruments exhibited by Messrs. Adam Hilger, Ltd., the most outstanding were the Hilger interferometers, including those for demonstration purposes and for the examination of prisms and lenses, and the latest model, the Universal camera lens interferometer, which permits of the examination of all ordinary photographic lenses up to a clear aperture of 5¼ in., and from 4 in. up to about 33 in. focal length, as well as lenses of the telephoto type, process lenses, complete telescopes up to a total length of 12 in., and eyepieces. On this firm's stand were also a complete range of Hilger wave-length spectrometers, a permanent adjustment quartz spectrograph giving a spectrum from 2100 Å.U. to 8000 Å.U.; a vacuum spectrograph for the study of the furthest ultra-violet region, in which a concave diffraction grating of 2 metres radius is used, and the Hilger ultra-violet spectroscope provided with a fluorescent screen from which the wave-length may be directly determined Messrs. Bellingham and Stanley, Ltd, also exhibited quartz spectrographs and a range of polarimeters and spectrometers, including a compact instrument for the examination of the entire spectrum giving readings directly in wave-lengths

The ophthalmic section of the industry was well represented by about twenty-five different exhibitors. Many new types of spectacle lenses, eyeglass mounts and spectacle frames were shown. The ophthalmic instruments on view illustrated the development of apparatus for the detection of pathological conditions of the eye, as well as those for the mechanical measurement of visual errors. Among these may be mentioned the self-registering perimeters exhibited by several firms, the photographic ophthalmoscope, exhibited by the Cambridge Instrument Co., Ltd., by means of which it is possible to obtain photographs of the fundus showing both the optic disk and the macula lutea on one plate, and the combined corneal microscope and slit lamp, exhibited by Messrs. Clement Clarke, Ltd, in which both the illuminating system and the microscope are mounted on an arc which has its centre of curvature at the focus of the illuminating beam.

It is, of course, quite impossible in an article of reasonable length to give anything approaching a full list of the various interesting pieces of apparatus on view and described in the 320-page catalogue prepared for the use of the members of the Convention. In the preceding paragraphs reference has been made to only a few of the items on the stands of a few of the trade exhibitors, and many important items in important groups of instruments have had to be omitted.

The educative value of the exhibition was enhanced by the inclusion of a section devoted to optical instruments and apparatus designed by research workers for use in scientific investigations. These included an instructive collection of apparatus exhibited by the National Physical Laboratory, Teddington; the Technical Optics Department of the Imperial College of Science and Technology, South Kensington; the Department of Applied Optics, Northampton Polytechnic Institute, London; the Refraction Hospital, London; and by other institutions and scientific workers. Mention should be made of the selenium apparatus designed by Dr. E. E. Fournier d'Albe and E. O. Symonds for registering mechanically the passage of interference fringes, the Clarendon photoelectric photometer, exhibited by Prof. F. A. Lindemann and Dr. G. M. B. Dobson, by means of which very small areas, such as spectral lines on a photographic plate, can be measured to a high degree of accuracy; and the series of instruments exhibited by the Cambridge Instrument Co, Ltd., in which the stylus-on-celluloid method is used for recording various physical phenomena.

The historical section of the exhibition contained a valuable loan collection of more than 350 items of great historical importance, illustrating the evolution and development of various types of optical instruments and indicating the types actually made and in use at different periods. Our admiration for the many highly developed and finished products of modern science in the adjoining sections did not in any way detract from our admiration for these optical treasures of past generations, for did not each one represent a modest though none the less distinctive landmark along the path of optical progress? The magnificent and impressive display of present-day apparatus, instruments and methods which formed the Optical Convention 1926 Exhibition marks the farthest point yet reached along that path.

The Intermittent Theory of Radiation.

AN important paper on "The Intermittence of Electric Force" was read by Sir J. J. Thomson to the Royal Society of Edinburgh on December 21 We now know that the atom is made up of electrons and positive charges, and that the number of electrons in the atom of an element is equal to the atomic number of the element. We also know the masses of the electrons and the positive charges If, therefore, they obeyed the ordinary laws of electrostatics, we could calculate by the laws of dynamics the behaviour of the atom. The behaviour predicted in this way is not in accord with experiment. The reason of this discrepancy is doubtless that in the atom we are concerned with effects which occur in times and in distances very much shorter than those which occurred in the experiments by which the laws of electric force were discovered or tested.

Sir Joseph directs attention to the possibility of the electric force being intermittent in its action. The intermittence is so rapid that its effects are only apparent when we are dealing with events which occur in intervals as short as those in the atom. He illustrates this point by considering the properties of gases. So long as we test these properties on an 'engineering scale' they are completely explained by supposing that the gas exerts a continuous pressure on the walls of the containing vessel and that it obeys the hydrodynamical laws for a continuous fluid. It is known, however, that the pressure is not really continuous but consists of a succession of isolated blows following each other irregularly at very small intervals of time. By the methods now available for producing very high vacua we can get the gas in a state where it is impossible to explain its behaviour by the hypothesis of continuity. The gas has a structure in time, the fineness of which is determined by the interval between the collisions. The fineness of the structure for a given gas varies with the pressure, being coarse at low pressure and fine at high pressure

Sir Joseph supposes that the electric field has a structure in time, so that instead of the electric force being a continuous effect consisting of a continuous flow of momentum into the body under its action, it is really discontinuous and consists of finite increments of momentum separated by finite intervals of time This discontinuity in the nature of the force readily explains the occasional spontaneous dissociation of a system. It also gives a reasonable hypothesis to explain why a system sometimes radiates away its surplus energy as Rontgen rays.

The assumption of the intermittence of electric force leads to startling results when applied to light waves. The mathematical proofs given indicate that there can be no unlimited propagation of light waves diverging from a source. The waves must ultimately reach a region where they are reflected back.

It will thus be seen that the hypothesis demands a corpuscular theory of light. The energy of the light must be done up into batches which retain their energy undiminished as they travel out into space. This does not exclude, in fact it requires, the presence of electrical waves of Maxwell's type. We must picture the light unit as a central quantum vibrating with the period of the light and emitting electrical waves. None, however, is allowed to escape, and the energy lost by the quantum in radiation is restored to it.

Light, therefore, has a dual character. It consists of electrical waves and the quantum. The electrical waves give rise to interference effects and the quantum to photo-electric effects. The energy in the electrical waves surrounding the quantum does not alter as the system travels through space, and so the ratio of the energy in these waves and that in the quantum remain invariable. The mathematical proofs based on the theory of probability given in this paper are very neat and very easy to understand.

In a paper read before the Royal Society of Edinburgh on February 8, Prof. E T. Whittaker follows up Sir J J. Thomson's paper and shows that the Maxwell-Lorentz equations can easily be modified so as to represent Sir Joseph's ideas regarding light. What distinguishes Thomson's theory from the work of all other writers on the subject is that he pictures the structure of the light-quanta in terms of tubes of electric force When light is generated he invites us to picture a closed part of a loop in a tube of electric force to become detached and go off as a closed ring. This ring soon becomes circular and travels with the velocity of light in a direction at right angles to its plane, like a circular vortex ring. The energy of the ring remains constant until the ring is broken It is known, for example, that if cathode rays fall on a metallic plate and generate X-rays which fall on a second metallic plate, electrons are ejected from the second plate and their energy is of the same order as that of the electrons in the primary cathode rays and is independent of the distance of the plates.

The only explanation seems to be that the energy of the X-rays is contained in compact parcels between the plates. This phenomenon has led Einstein and other physicists to advocate corpuscular theories of light. In Thomson's theory we picture something similar to a procession of rings of cigarette smoke, moving forward through the air in front of the mouth of a smoker As the group moves through space, it sweeps over the interior of an infinitely long, straight cylinder, the axis of which is in the direction of propagation. Everywhere outside this cylinder the field is permanently null

Sir Joseph points out that it is not necessary to suppose that light consists exclusively of a procession of 'electric vortex rings' He considers that it consists of rings of electric force accompanied by Maxwellian waves These rings sometimes vibrate and produce waves of the type ordinarily considered Whittaker gives a justification of Thomson's hypothesis and a verification of the quantum relation.

Salient Features in the Stratigraphy, Tectonic Structure, and Physiography of the Commonwealth of Australia.[1]

A BRIEF summary of the salient features of the stratigraphy of the Commonwealth is essential for understanding its tectonic structure Pre-Cambrian rocks are developed in Western, Central, and South Australia The Proterozoic rocks of Northern Australia are partly formed of thick dolomites, possibly a forerunner of the Great Barrier Reef of to-day. Basic lavas and tuffs, 3000 feet thick, preceded a great ice-age in late Proterozoic or early Cambrian time Marine Cambrian strata occur chiefly in Northern and Central Australia and South Australia, with patches in Victoria, Tasmania, and Queensland Ordovician rocks attain a thickness of 40,000 feet in Victoria and Central Australia Igneous intrusions and unconformity separate the Ordovician rocks from the Silurian In the Devonian rocks of Queensland, coralline limestone, 7000 feet thick, is probably another ancestor of the Great Barrier Reef. In Carboniferous time a south-eastern shore of 'the Tethys Sea' is well defined in the north-west of Western Australia Carboniferous and Devonian time were periods of granitic intrusions and effusive rocks. In Permo-Carboniferous time half Australia was under ice This was the chief coal-forming epoch, followed by more coal (in Triassic and in Jurassic times) developed in immense epicontinental lakes in eastern and central Australia, near which carnivorous deinosaurs existed.

Marine Jurassic strata in Australia are only found in 'the Tethys Sea' of Western Australia The great dolerite-sills (comparable with the Karroo dolerites) of Tasmania possibly closed Jurassic time Cretaceous time witnessed great peripheral and central marine transgressions. The Neocomian Sea was probably cold, and epeirogenic uplift in east Central Australia replaced marine by lacustrine conditions; this uplift was probably accompanied by small local glaciation. In Western Australia the last of 'the Tethys Sea' is represented by the Lower Santonian with Uintacrinus (comparable with the Arriloor Beds of Southern India) Cretaceous strata were slightly folded in pre-Oligocene time. Eocene marine deposits are mostly wanting except, perhaps, in New Guinea, but the Winton series may be partly Eocene

Oligocene time was one of very extensive peneplanation, which was prolonged into the Miocene, and in places into early Pliocene time. A rock-crust, or 'petroderm' ('Hartrinde' of Walther) formed over the more arid parts of this peneplain Marine transgressions occurred all along the southern coast of Australia, mostly following on the eruptions of the 'older basalts.'

In Miocene time there were warm seas with large foraminifera (Lepidocyclina) and reef-forming corals, even in Tasmania The earliest marsupials are found there in the Miocene beds. Miocene brown-coal deposits up to 800 feet thick, formed partly of Fagus and Banksia, occur in Victoria 'Deep leads' of gold and tin were formed inland. In New Guinea the oil-belt was developed during the Miocene Period.

In Pliocene time the whole peneplain underwent differential movement which was strongest in eastern Australia. Alkaline lavas were erupted from tensional fault-planes in the old peneplain. Epeirogenic uplift (during the 'Kosciusko epoch' of E C. Andrews) now followed, and became accelerated in a late Pliocene epoch. The Rift Valley of Australia formed mostly during this uplift This later movement was accompanied by widespread eruptions of basalts with some andesites The Great Barrier Reef was already forming, and possibly commenced to develop—even earlier.

The southern edge of the Lake Eyre peneplain became tilted northwards, and that of Western Australia eastwards, bringing about interior drainage and local aridity The Pleistocene ice-age followed, together with a pluvial epoch, when Lake Eyre once more drained seawards Crocodiles and gigantic marsupials were then abundant in Central Australia The Tasmanian aborigines arrived in Tasmania by way of the Malay Bridge, possibly during a eustatic negative movement of the sea. As the Ice Age ended, the sea-level rose, drowning the coastal valleys. The rainfall decreased. Lastly, the Australian aborigines arrived, perhaps bringing with them the dingo. In the last few thousands of years the sea-level has fallen by about 15 feet.

---

[1] Substance of a lecture delivered by Sir T W Edgeworth David, K B E., F R S., before the Geological Society of London on March 29.

The salient features in the tectonic structure were briefly discussed, with especial reference to Suess's views as to the arrangement of the Australian arcs, and the physiographic features, chiefly with reference to the phenomena of arid erosion. The origin of the inland sand-hills of Central Australia is attributed to the disintegration of the widespread Permo-Carboniferous sandstones, for the later seas of that period transgressed over large areas of Australia, possibly in part through a eustatic rise of sea-level following on the melting of the great Permo-Carboniferous ice-sheets.

Ventilation and Comfort.

THE Medical Research Council has published a report on the "Methods of Investigating Ventilation and its Effects," by H. M. Vernon and others (Special Report Series, No. 100. Methods of Investigating Ventilation and its Effects. London: H.M. Stationery Office, 1926, 2*s.* net). Part 1 contains descriptions of two new instruments for the measurement of variations (*a*) in the velocity and (*b*) in the temperature of air currents. For the former purpose a new form of hot-wire anemometer was constructed which is very sensitive to changes of air velocity, while influenced little by changes in temperature. For the latter purpose a suitable thermopile was devised which was unaffected by changes in velocity. The combined use of these two instruments has thrown further light on the relative importance of temperature and air movement in ventilation. In Part 2 the results of a further calibration of Leonard Hill's kata-thermometer are given, which allow low-air velocities found in ordinary rooms to be measured with far greater accuracy.

Part 3 consists of an investigation of the extent to which objective indications of the kata-thermometer correspond with actual sensations of comfort. Acclimatisation is shown to have an important influence. It is concluded that the cooling power of 6, fixed as the minimum for sedentary workers in Great Britain by Leonard Hill, may reasonably be 5 for people acclimatised to summer weather, and 7 for people acclimatised to winter weather. "It was found that the various degrees of 'stagnancy' experienced in factory air were due to differences in the air temperature, whilst the various degrees of 'freshness' were due chiefly to differences in air velocity. The cooling power of the kata-thermometer combines these two variables better than any other known measure, and the correlation ratio of cooling power on air sensation was found to be 703 in summer and 790 in winter."

In Part 4, Dr. Vernon has studied the rate of cooling of the human body, as shown by fall of mouth and rectal temperatures, naked and clothed, after being warmed up by previous exercise, and has in this way thrown further light on the relative importance of air temperature, clothing, and air movements. The results tend to show that in order to induce cooling of men engaged in hot and heavy work, it is of most importance to reduce temperature and next clothing, small increase of velocity of air having comparatively little effect.

Work now in progress in the new wind tunnel built at the National Institute for Medical Research shows, however, that velocity can have a very great effect on warmly clad men, when it is sufficient to drive air through and so ventilate the clothing. By means of wind sufficient to evaporate the sweat effectively, men can be kept much more comfortable, and will in consequence work better, in hot atmospheres.

University and Educational Intelligence.

LONDON.—A University chair of bacteriology and immunology, tenable at the London School of Hygiene and Tropical Medicine, and a University chair of epidemiology and vital statistics, tenable at the London School of Hygiene and Tropical Medicine, have been instituted.

The following courses of free public lectures are announced: "The Influence of Water on Vital Processes," by Prof. J. B. Collingwood, at University College, on April 26, May 3, 10, 17, 24, and 31, at 5.30; "The Integration of the Circulation," by Prof. R. J. S. McDowall, at King's College, on April 27, May 4, 11, and 18, at 4.30; and "The Nature and Functions of the Fasciæ of the Human Body," by Prof. J. Kay Jamieson, at King's College, on April 30, May 7 and 14, at 5.30.

Applications for grants from the Dixon Fund for assisting scientific investigations, accompanied by the names and addresses of two references, must be made to the Academic Registrar, University of London, South Kensington, S.W.7, before May 15, and those for grants from the Thomas Smythe Hughes Fund for assisting Medical Research, accompanied by the names and addresses of two references, not later than June 15.

APPLICATIONS are invited by the Ministry of Agriculture and Fisheries for not more than five agricultural scholarships tenable for two years and annually of the value of not more than 200*l.*, plus, possibly, extra allowances for travelling and subsistence whilst the scholars are abroad. The application form, A.189/T.E., must be returned to the Secretary of the Ministry, 10 Whitehall Place, S.W.1, by June 30 at latest.

IT was stated in the House of Commons last week by Lord Eustace Percy, President of the Board of Education, that the Government is in general agreement with the recommendations of the Departmental Committee on the University of London, and that it is proposed to introduce legislation for the purpose of setting up a statutory Commission for the University accordingly.

THE presentation portrait of the late Sir Sydney Russell-Wells, painted by his nephew, Mr. John Wells, R.I., will be unveiled in the staff room of the Dreadnought Hospital, Greenwich, by Sir Humphry Rolleston, Bart., at 3 o'clock on Tuesday, May 4. The portrait, which has been subscribed for by the friends and colleagues of the late Sir Sydney Russell-Wells, represents Sir Sydney in his robes as Vice-Chancellor of the University of London. Those desiring to be present at the ceremony may obtain cards of invitation on application to Prof. R. Tanner Hewlett at the Seamen's Hospital, Greenwich.

THE Court of the Worshipful Company of Poulters has agreed to offer a scholarship of 60*l.* per annum for two years tenable at the Harper Adams Agricultural College, for the training of persons to be instructors in the practice and science of poultry husbandry. Candidates must be British-born and not less than sixteen years of age on October 1, 1926. They must produce satisfactory certificates of character and physical fitness, and should have passed an examination of matriculation standard. The successful candidate will be required to take an approved course of study leading to the National Diploma in Poultry Husbandry. The award will be made on the recommendation of the Principal of the Harper Adams Agricultural College, to whom all inquiries should be addressed.

Contemporary Birthdays.

April 25, 1862. Viscount Grey of Fallodon, K.G., F.R.S.
April 25, 1859. Mr. Henry R. A. Mallock, F.R.S.
April 25, 1874. Senatore Marconi, Hon. G.C.V.O.
April 26, 1879. Prof Owen W Richardson, F.R.S.
April 27, 1845. Dr. Douglas W. Freshfield.
April 28, 1856. Mr. Charles E. Stromeyer, M.Inst C.E.

Viscount Grey was educated at Winchester and Balliol College. A former president of Armstrong College, Newcastle, he was, until eyesight disabilities intervened, interested in most departments of natural history pursuits, to one of which he contributed a useful work, "Fly-Fishing" (1899).

Senatore Marconi was born at Griffone, near Bologna. His first and tentative experiments in wireless telegraphy were made in Italy in 1895. Coming to England in the following year, with an introduction to Sir William Preece, F.R S., who was then engineer to the Post Office, Marconi received marked encouragement at his hands at a crucial period, as also from Prof. J. A Fleming, F.R.S. In 1899 he was able to establish wireless communication across the English Channel, later (1901) between a station at Poldhu, Cornwall, and Newfoundland. The story is continued in a stream of later improvements, inventions and researches of various kinds, of which perhaps the most distinctive practical application (in alliance with other minds) is broadcasting. In 1909 Senatore Marconi shared the Nobel prize in physics with Prof. Braun.

Prof Richardson, one of the Royal Society's Yarrow research professors in physical science, was born at Dewsbury. He was educated at Batley Grammar School and Trinity College, Cambridge. Formerly professor of physics in Princeton University, U S.A., he returned to become Wheatstone professor of physics in the University of London (King's College) Prof. Richardson received the Hughes medal of the Royal Society in 1920 for his work in experimental physics, and especially thermionics. In the following year he was president of Section A of the British Association.

Dr Douglas Freshfield, the distinguished geographer and mountaineer, a former president of the Royal Geographical Society and one of the staunchest supporters of that institution, was educated at Eton, and graduated at University College, Oxford. His interest in mountain-climbing was already established more than fifty years ago, for it was in 1872 that he undertook for a considerable span the editorship of the *Alpine Journal*. "I have always tried," he once said, "to prevent mountaineering from becoming a mere form of sport. By precept and example I have done my best to persuade my comrades to keep their eyes open to all the interest, historical, scientific, and artistic, in which the mountains abound." Dr. Freshfield received the founder's gold medal of the Royal Geographical Society in 1903, and it is interesting to recall that Dr. Sven Hedin received a medal at the same time. Apart from contributions to physical geography in the Caucasus, Dr. Freshfield's valuable work in promoting geographical education was the subject of special comment He is the author of a life of Horace Benedict de Saussure.

Mr C. E. Stromeyer, for many years engineer to the Manchester Steam Users' Association, was born at Sutton. His book, "Marine Boiler Management and Construction," is a standard of reference.

Societies and Academies.

London.

Linnean Society, March 18.—**J. L. Sager**: Phyllody of the corolla in *Primula vulgaris* Huds. The specimens come from a plant growing in a garden in Exeter, all flowers of which show this monstrosity The petals are like the foliage leaves in all respects except size. The revolute venation characteristic of the leaf shows well in these petals. Calyx, stamens, and pistil appear normal. Mr. Samuel E Steer found this plant growing in a disused burial-ground at Lympstone, South Devon, in March 1925. He transferred it to his garden, where it has increased in size, and is now bearing about twelve flowers, all abnormal.—**R. T. Gunther**: An account of the early manuscript herbal of *Apuleius Barbarus*, which has been stated to have been written in A.D 1100 and illustrated in the monastery of Bury St Edmunds, it may therefore be the oldest-known English botanical work.—**G. P. Farran**: Biscayan plankton collected during a cruise of H.M.S. *Research*, 1900. (Pt. XIV.) The Copepoda. The Copepoda collected in deep water off the Bay of Biscay were mainly taken in numerous horizontal hauls with open tow-nets by day and night down to 100 fathoms, and by vertical hauls with closing nets by day down to 2000 fathoms. The horizontal hauls show a marked difference between day and night distribution, the population above 100 fathoms being approximately doubled by night by the upward migration, in large numbers, chiefly of *Metridia lucens*, *Pleuromamma robusta*, and *Pleuromamma gracilis* In the vertical hauls the maximum number of species was found between 500 and 700 fathoms, and of specimens between 150 and 250 fathoms. The average number of specimens per 100 fathoms vertical haul between 1500 and 2000 fathoms was only 4·6, and not all of them alive, as against 781 specimens between 150 and 250 fathoms. **Helena Bandulska**: On the cuticles of some fossil and recent Lauraceæ. The possibility is demonstrated of interpreting certain elements of the floras of the past by a comparative study of their cuticles with those of recent forms. By this means the Lauraceæ have been found to be the most abundant fossils with cuticle preserved in the Bournemouth Eocene; many have lanceolate leaves with pinnate venation and strong midrib Three species of Aniba and various species of Neolitsea, Litsea, and Lindera have been discovered. The physiological characters of the fossil Lamaceous cuticles described are such as at the present time are associated with the need for controlling transpiration, and may be of assistance in the interpretation of the nature of the flora and the climate of Middle Eocene time.

The Physical Society, March 26.—**Ivor Backhurst**. Obliquity corrections in radium estimation. Formulæ are given for obliquity corrections in radium estimation applicable to sources of the shapes most frequently occurring in practice The effect of scattered radiation is considered, and some experimental results obtained are shown graphically and compared with theory.—**Albert Griffiths** and **P. C. Vincent**: Viscosity of water at low rates of flow determined comparatively by a method of thermal convection. A method is described of determining the coefficient of viscosity of water by measuring the rate of convective flow in a long capillary tube, the driving head being obtained by the difference in density due to a difference of temperature between two vertical columns of water. The results show that the viscosity of water at low rates of shear in glass tubes is apparently no different from that at high rates. Novel features are (1) the method of obtaining the driving head; (2) the new method of introducing a coloured index in a closed capillary circuit, and an improved method of reading its position; (3) the almost complete elimination of what may be called the thermometric effect as distinct from the convective effect; (4) the elimination of the small residual thermometric effect from the final calculations.

PARIS.

Academy of Sciences, March 15.—H. **Deslandres**: The aurora borealis and magnetic perturbation of March 9, 1926, at the Meudon Observatory. A bright aurora borealis was observed at Meudon on March 9; its duration was short and coincided with a marked deviation of the magnetic declination registered on the magnetograph.—A. **Cotton**: An observation of the aurora borealis on March 9; observed at Sèvres. A magnetic disturbance was recorded at the Val Joyeux Observatory.—B. **Baillaud**: Remarks on the Catalogue of Fundamental Stars of the Paris Observatory.—Pierre **Copel**: A property of skew curves and its application to the demonstration of Beltrami's theorem.—Nicolas **Kryloff**: A method of approximate integration containing as particular cases the method of W. Ritz and that of least squares.—Leonida **Tonelli**: The method of adjunction in the calculus of variations.—— **Hadamard**: Remarks on the preceding communication.—Joseph **Pérès**: A theorem concerning the movement with two parameters of a solid.—— **Rogoff**: A rectangular plate supporting a load P concentrated at its centre.—Louis **Roy**: The propagation of waves on the elastic line with four parameters.—L. **Dunoyer**: A condensation pump working with a moderate primary vacuum. A description, with diagram, of a glass mercury vapour pump. Starting with a water-pump vacuum (10 to 30 mm. mercury), the pump is working within four minutes of lighting the burner.—Jean **Dubief**: The law of viscosity of fluids as a function of the density. Its relations with the equation of state.—Y. **Rocard**: The diffusion of light in liquids.—Mlle. O. **Jasse**: The structure of the bands 4511 and 4123 of the carbon monoxide spectrum. These bands have a more complex structure than Hulthén's band, but belong to the same class.—G. **Lejeune**: Contribution to the study of the oxidisability of organic substances.—Jean **Cournot**: The cementation of ferrous alloys with aluminium. The cementation of mild steel with aluminium is best carried out by heating in a muffle with finely powdered ferro-aluminium containing a little ammonium chloride.—T. **Karantassis**: Double decompositions between the halogenides of tin, arsenic, antimony, bismuth, silicon, titanium.—Maurice **Delaville** and Paul **Carlier**: The estimation of small quantities of potassium. The metal is precipitated as cobaltinitrite, and the cobalt determined by nitroso-β-naphthol. Working with quantities of potassium of the order of 1 mgm., the error is less than 3 per cent.—V. **Hasenfratz** and R. **Sutra**: The oxidation of harmaline and bromoharmaline.—R. **Lantz** and A. **Wahl**: A new synthesis of phenylrosinduline.—H. **Arsandaux**: The eruptive origin of the basic gneiss of Djabataouré (Togo).—Auguste **Loubière**: The flora and relative level of middle coal measures of Gages (Aveyron).—P. **Choux**: Some new Sapindaceæ of Madagascar.—A. **Guilliermond**: The action of the methods of silver impregnation on plant cells and on the relations of the vacuome and Golgi's apparatus.—Albert **Petit**: Contribution to the cytological and taxonomic study of Bacteria.—L. **Hackspill** and A. P. **Rollet** and Maurice **Nicloux**: The argon in the blood. From the results of the experiments cited, the authors conclude that argon, like nitrogen, is found in defibrinated blood in quantity corresponding to its solubility and to its partial pressure in air. The blood clot, dried in a vacuum, and burnt in the presence of copper oxide, gives no argon.—L. **Fage** and R. **Legendre**: The swarming and lunar rhythm of *Eulalia punctifera*.—P. **Sédallian** and J. **Loiseleur**: The fractionation of serum proteids and the freeing of antidiphtheric serum from albumen. The method is based on the gradual addition of sodium chloride, starting with serum of pH 4·7.—S. **Posternak**: The distribution of phosphorus in the serum and red blood corpuscles of the blood.—Louis **Léger**: A new Microsporidia with spiny spore cases.—S. **Metalnikov** and V. **Chorine**: The part played by Hymenoptera in the infection of *Galleria mellonella*.

March 22.—H. **Deslandres**: The magnetic disturbance of March 5, 1926, and the disturbances of the first months of the year. A magnetic storm was recorded by the apparatus at the Meudon Observatory, and at the same time auroral lights were noted at two different places—Grainville and Neauphlette. It is shown that there is a definite relation between the periods of these magnetic storms, since the intervals of time between the storms are multiples of the time of synodic rotation R.—Henry **Le Chatelier**: The theory of the furnace.—André **Blondel**: The measurement of the photometric yield of optical apparatus (objectives, telescopes, etc.).—G. **Friedel**: The radiograms of mixed crystals. Mixed crystals obtained by isomorphous crystallisation give radiograms which do not differ from those which would be given by a simple crystal of the mean parameter From this it is generally admitted that the mixed crystal will be like the pure crystal, governed by a strictly defined period, the mean of the pure constituent crystals. This view is adversely criticised, and it is shown that there is a serious limitation to the power of penetration of radiographic analysis, especially in cases where there may be isomorphous mixtures or pseudo-paramorph structures.—L. **Cuénot**: Description of a Tardigrade new to French fauna. This is intermediate between the uncovered Oreella and armoured Echinisci, and is a type of a new genus Parechiniscus, to which is given the specific name of Chitonides.—Jean Charcot was elected a free Academician in succession to the late E. **Tisserand**.—A. **Sainte-Laguë**: Unicursal and bicursal networks.—E. **Grynaeus**: The differential geometry of Euclidian space with constant curvature.—E. **Vessiot**: Conformal geometry of surfaces.—Maurice **Gevrey**: The analytical nature and prolongation of solutions of non-linear equations of elliptic and parabolic types with one variable.—J. **Favard**: Nearly periodic harmonic functions.—Boris **Grinberg** and Maurice **Paschoud**: The torsion of a hollow cylinder the section of which is limited by two excentric circles.—Pierre **Henry**: The velocity of deformation of metals at high temperatures.—Charles **Platrier**: Periodic winds and critical wind squalls for the flexion of pillars.—A. **Chatillon**: The different magnetic states of cobalt chloride.—V. **Posejpal**: The quantitative experimental control of the resonance absorption of X-rays.—Louis **Longchambon**: The rotatory dispersion of camphor. A criticism of the conclusions arrived at by applying the formula of Lowry and Cutter to the experimental results of the rotatory power of camphor in acetone.—Miramond de **Laroquette**: The ionometric measurement of X-rays incident per unit surface and X-rays absorbed per unit volume.—Pierre **Auger**: The amount of fluorescence in the X-ray region.—H. Colin and Mlle. A. Chaudun: The variations of the constant of hydrolysis with the concentration of sugar. The experiments are not in agreement with the hypothesis that the hydrogen ions alone produce the reaction; the nature of the acid and the viscosity of the solution also intervene.—H. **Forestier** and G. **Chaudron**: The thermomagnetic study of some ferrites. Ferrites of the general formula $Fe_2O_3.MO$ have been prepared, where M may be nickel, copper, lead, barium, calcium, cadmium, or zinc, and the variations of the magnetisation coefficient with temperature determined.—M. **Holweck**: The critical *K* potentials of light atoms. Reply to a note of A. Dauvillier.—Marcel **Laporte**: The mobility of the ions in gases. The author's experiments are not in agreement with the view that for a given gas the ions have one mobility only: the hypothesis that there may be several ion mobilities is discussed.—Jules **Ventre** and Emile **Bouffard**: The influence of sugar on the estimation of ammonia in grape must.—J. **Bougault**: An example of an oxide ether of a ketone hydrate.—Marcel **Bouis**: The synthesis of ethylallene $C_2H_5.CH:C:CH_2$.—F. **Salmon-Legagneur**: Mixed ketones derived from the a-mononitrile of camphoric acid.—A. **Demay**: The genesis of the granulitic gneiss of the Pilat massif, near Saint-Etienne.—L. **Petitjean**: New researches on the displacement of (meteorological) discontinuities.—Louis **Besson**: The influence of the temperature of one month on that of the following month. According to A. Angot, the temperature of any one month has no influence on that of the following month. A statistical study of 100 years' observations made at the astronomical and Montsouris Observatories does not confirm this view. A warm January is followed by a February with a temperature above the normal 13 times out of 19 at one observatory and 8 times out of 12 at the other. Similarly a cold February is followed by March with a temperature below the normal.—Mme. P. **Lemoine** and G. **Delepine**: Discovery of the genus Solenopora in the Jurassic of France.—Lucien **Daniel**: New researches on the heredity acquired by grafting on *Helianthus Dangeardi*.—M. and Mme. Fernand **Moreau**: Sexual reproduction in lichens of the genus Collema and the theory of Stahl. Observations opposed to the Stahl theory of sexual reproduction in Collema.— — **Aversenq**,— **Jaloustre**, and— **Maurin**: The development of *Ricinus communis* in a culture medium rendered radioactive by the addition of thorium-*X*. Thorium-*X* in small doses (10 micrograms every fifteen days) improved the general development of the castor oil plant, the increase in the number and quality of the seeds being especially marked.—Antonin **Nemec** and Mihovil **Gracanin**: The influence of light on the absorption of phosphoric acid and potash by plants. — — **Parat**: The constitution of the Golgi apparatus and of the idiozome; true and false dictyosomes.—Boris **Ephrussi**: The unequal acceleration of the different phases of cell division by rise of temperature.—M. **Bridel** and C. **Béguin**: The biochemical synthesis, with the aid of emulsion from almonds, of a-ethyl-*b*-arabinoside.

ROME.

Royal Academy of the Lincei, February 7.—F. **Cavara** and A. **Chistoni**: Hybridisation of *Papaver somniferum* L. in relation to the morphine content of the opium. By hybridisation of the white and black varieties of *Papaver somniferum* L., it is possible to raise both the morphine content and the yield of the opium.—E. **Bompiani**: Projective invariants of contact between plane curves.—Harry **Levy**: Certain properties of the spaces for which Riemann's symbols with five indices are annulled.—Bruno **Finzi**: Vertical space motions in correspondence with uniform translations.—Francesco **Sbrana**: Dynamic effect of a fluid circulating round two cylinders with parallel axes.—Giorgio **Abetti**: The altitude of the solar chromosphere.—Enrico **Fermi**: The quantisation of the perfect monatomic gas.—A. **Pontremoli**: The duration of emission of monochromatic radiations and the mean life of the stationary states.—Pietro **Saccardi**: A colour reaction of the skin relative to the genesis of the melanins. The colour reactions obtained with *p*-phenylazoxycarbonamide confirm the epidermal origin of the cutaneous pigment and indicate that the ability to produce the colourless pro-pigment which generates melanin is a specific and autochthonous property of the Malpighian layer.—Ugo **De Castro**: Physico-biological conditions and determinism of Kottmann's reaction.—C. **Sibilia**: The action of certain enzymes of Fusarium. The actions produced by the amylase and pectinase of *F. echinosporum* and *F. fuliginosporum* are described.

VIENNA.

Academy of Sciences, March 4.—F. **Urbach** (Communication from the Radium Institute, No. 185): On luminescence and absorption particularly that of sylvine subjected to Becquerel radiation. Sylvine shows radio-luminescence and after Becquerel-radiation thermo-luminescence and phosphorescence.—J. **Zellner** and colleagues: Contributions to comparative vegetable chemistry (xii.). Chemistry of barks. Barks of privet, beech, elder, and alder have been examined. Phytosterin, ceryl alcohol, and several other substances have been found.—R. **Klapholz** and J. **Zellner**: Contributions to comparative vegetable chemistry; *Œnothera biennis*.—J. **Pollak** and E. **Gebauer-Fülnegg**: The action of chlorosulphonic acid on phenols.—E. **Gebauer-Fülnegg** and F. **Riesenfeld**: Studies on aryl-sulpho-chlorides.—K. **Federhofer**: The construction for the centre of curvature of plane curves.—L. **Waldmann**: The geological structure of the Moldau-Danube primitive rocks on the survey sheet Gmünd II.

March 11.—H. **Spandl** communicated his work, prepared in part with the assistance of the Academy, on the fauna of subterranean waters (Wien, Verlag Speläologisches Institut, 1926).

Diary of Societies.

SATURDAY, April 24.

Royal Sanitary Institute (at Guildhall, Hull), at 2.30.—H. Eldridge: The Economic Collection of Town Refuse.—W. Nicholson: The Present Position with regard to Smoke Prevention.

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 2.—J. G. Taylor: Coal and its Banded Constituents.—Discussion on Paper by F. J. Johnston on The Use of Breathing Apparatus in Mines.

Royal Institution of Great Britain, at 3.—Dr. W. T. Calman: The Shipworm (2).

MONDAY, April 26.

Royal Irish Academy (Dublin), at 4.15.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Rev. Dr. H. U. W. Stanton: The Qur'an and its Doctrine of God.

Institute of Actuaries, at 5.—Notes concerning Some Practical Points that arise in the Valuation of Widows' Funds.

Institution of Structural Engineers (Students' Meeting) (at Abbey House, Westminster), at 6.—E. S. Andrews and others: Discussion on Theory *versus* Practice.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne) (Annual General Meeting), at 7.—B. A. Robinson: Modern Methods of Measurement (Lecture).

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.

Railway Club (at 65 Belgrave Road, S.W.), at 7.30.—L. Hiller: The Principles of Signalling.

Royal Society of Arts, at 8.—C. R. Peers: Ornament in Britain (Cantor Lectures) (2).

Royal Society of Medicine (Odontology Section), at 8.—W. Warwick James: Do Epithelial Odontomes increase in Size by their own Tension?—Dr. E. W. Fish: The Circulation of Lymph in Dentine, with some Observations on the Metabolism of this Tissue.

Royal Geographical Society (at Æolian Hall), at 8.30.—C. F. Rey: A Recent Journey to Gudru and Gojam (Abyssinia).

TUESDAY, April 27.

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: Organs of Multiple Function (3): Feathers.

Zoological Society of London, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the month of March, 1926.—Dr. J. Beattie: Exhibition of Radiographs of a young *Macacus rhesus*.—Prof. G. Elliot Smith: On the Brain of Cænolestes.—Dr. R. Broom: (*a*) On the Organ of Jacobson and some other Structures in the Nose of Cænolestes; (*b*) On a Nearly Complete Skeleton of a New Eosuchian Reptile.—J. W. Low: Contributions to the Development of the Pelvic Girdle. I. The Pelvic Girdle of *Menopoma alleghaniense* Harlan.—O. M. B. Bulman and W. F. Whittard: On Branchiosaurus and Allied Genera.

Institution of Civil Engineers, at 6.—H. R. Lupton: The Triple-Expansion Steam-Engine, as applied to the Pumping of Water; with Special Reference to the Plant at Lea Bridge.

Institute of Marine Engineers, at 6.30.—Refrigeration.

Royal Photographic Society of Great Britain (Kinematograph Group), at 7.—W. Vinten: International Standardisation of Kinematograph Standards.

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.

Institute of Metals (North-East Coast Local Section) (at Armstrong College, Newcastle-on-Tyne), at 7.30.—Annual General Meeting.

Royal Anthropological Institute, at 8.30.—C. W. Brown: Stone Implements from North-West Peru.

WEDNESDAY, April 28.

Newcomen Society for the Study of the History of Engineering and Technology (at 17 Fleet Street), at 5.30.—Comdr. A. D. Turnbull: The Stevens Family—Engineers and Inventors.

Radio Society of Great Britain (at Institution of Electrical Engineers), at 6.

Institution of Automobile Engineers (at Manchester College of Technology), at 7.30.—G. Rushton: The L.G.O.C. Methods of Omnibus Repair (Lecture).

Royal Microscopical Society (Industrial Applications of the Microscope Section), at 7.30.—R. and J. Beck, Ltd.: Exhibition of the Swan Photomicrographic Apparatus for Workshop Use and Radial Metallurgical Microscope.—H. Wrighton: Demonstration of the Preparation of Metallic Micro-Specimens.—At 8.—J. H. G. Monypenny: Some Micro-Structural Features of Modern Rustless Steels.

Royal Society of Arts, at 8.—J. Paterson: Horse Traction and Motor Traction.

British Psychological Society (Medical Section) (at Medical Society of London, 11 Chandos Street, W.1), at 8.30.—Dr. N. H. M. Burke: What is a Mental Illness?

THURSDAY, April 29.

British Science Guild (Annual Meeting) (at Mansion House), at 4.30.—Sir Richard Redmayne: The Future of the Coal Mining Industry.—Dr. E. F. Armstrong: Dyestuffs.—Capt. P. P. Eckersley: Broadcasting and Electrical Industry.

Royal Society, at 4.30.—C. H. Best, Dr. H. H. Dale, J. P. Hoet, and H. P. Marks: Oxidation and Storage of Glucose under the Action of Insulin.—C. H. Best, J. P. Hoet, and H. P. Marks: The Fate of the Sugar disappearing under the Action of Insulin.—J. P. Hoet and H. P. Marks: Observations on the Onset of Rigor mortis.—J. C. Mottram, G. M. Scott and Prof. S. Russ: On the Effects of Beta Rays from Radium upon Division and Growth of Cancer Cells.

Institute of Pathology and Research (St. Mary's Hospital, W.2), at 5.—Sir Almroth E. Wright: The General Outcome of Thirty-six Years' Work on Immunisation (Lecture).

London Mathematical Society (at Royal Astronomical Society), at 5.—Miss H. P. Hudson: Linear Dependence of the Schur Quadrics of a Cubic Surface.—Prof. G. N. Watson: On an Expansion Due to Abel.—B. A. Edwards: On Periodic (2-2) Correspondences between Two Planes.—C. G. F. James: On Scrolls in a Linear Congruence.—A. C. Dixon: The Solving Nuclei of Certain Integral Equations whose Nuclei are Homogeneous of Degree −1.—M. Hanna: Algebraicability of Integrals.—R. G. Cooke: Gibbs's Phenomenon in Fourier Bessel Series and Integrals.—J. Brill: On the Motion of an Ideal System referred to Natural Co-ordinates.—Prof. G. H. Hardy and J. E. Littlewood: (i) On the Strong Summability of a Fourier Series; (ii) On Parseval's Theorem.—S. Bochner and Prof. G. H. Hardy: Note on Two Theorems of N. Wiener.

Royal Institution of Great Britain, at 5.15.—Sir William Bragg: The Imperfect Crystallisation of Common Things (1).

Chemical Society, at 8.—Prof. W. E. S. Turner: Additive Relationships in the Properties of Glasses (Informal Lecture).

Child-Study Society (at Royal Sanitary Institute), at 5.30.—Annual Meeting.—At 6.—A. Farquharson: Homeland Survey for Children (Lecture).

Institution of Electrical Engineers, at 6.—B. S. Cohen, A. J. Aldridge, and W. West: The Frequency Characteristics of Telephone Systems, and Audio-Frequency Apparatus and their Measurement.

Illuminating Engineering Society (at Royal Society of Arts), at 7.—Dr. J. Kerr and others: Discussion on School Lighting (Modern Requirements and Recent Progress).

Institute of Chemistry Students' Association (London), at 8.—Open Evening.

FRIDAY, April 30.

Institution of Mechanical Engineers (Informal Meeting), at 7.—C. W. J. Taffs and others: Marine Oil-Engines in Practice.

Institution of Electrical Engineers (Scottish Centre) (at Y.M.C.A. Hall, Dundee), at 7.30.—Capt. P. P. Eckersley: The Past, Present, and Future Development of Wireless Telephony (Lecture).

Junior Institution of Engineers (at Royal United Service Institution), at 7.30.—Air Vice-Marshal Sir W. Sefton Brancker: Air Transport (Gustave Canet Memorial Lecture).

Royal Institution of Great Britain, at 9.—Dr. W. H. Eccles: Wireless in the Empire.

SATURDAY, May 1.

Royal Institution of Great Britain, at 3.—Dr. P. C. Buck: The Song Form in England as represented by Stanford.

Royal Institution of Great Britain, at 5.—Annual Meeting.

PUBLIC LECTURES.

MONDAY, April 26.

University College, at 5.30.—Prof. J. B. Collingwood: The Influence of Water on Vital Processes. (Succeeding Lectures on May 3, 10, 17, 24, and 31.)

TUESDAY, April 27.

King's College, at 4.30.—Prof. R. J. S. McDowall: The Integration of the Circulation. (Succeeding Lectures on May 4, 11, and 18.)

THURSDAY, April 29.

University College, at 5.—Prof. E. A. Gardner: History of Ancient Sculpture.

FRIDAY, April 30.

King's College, at 5.30.—Prof. J. Kay Jamieson: The Nature and Functions of the Fasciæ of the Human Body. (Succeeding Lectures on May 7 and 14.)

University College, at 5.30.—Sir Jagadis C. Bose: The Nervous Mechanism of Plants.

Coal Utilisation and Research.

THE Report of the Royal Commission on the Coal Industry, some aspects of which were presented by Prof. Henry Louis in an article in NATURE of March 20, is still under consideration and discussion. It is now generally understood that the report refuses to prescribe for the sick man any tonic or pill with the pleasing promise of a lightning cure, but insists on the necessity for a systematic application of the principles of economic hygiene to daily life as the primary essential to recovery. Even such labels as low-temperature carbonisation and electrification on the medicine bottles are not held to guarantee a cure. It is not that the spirit of the Commission has been cautious, conservative, or narrow. Its report is, indeed, quite remarkable for breadth of view, and for what appears to be a well-balanced consideration of the very numerous and varied factors which are operative in the problem presented. These characteristics can certainly be claimed for Chaps. iii. and iv. on utilisation of coal, and research, with which the present writer is more immediately concerned.

The position as regards actual and potential methods of consuming coal is admirably stated in Chap. iii., while Chap. iv. deals with the existing provision for research connected with coal, particularly 'organised' research, and with proposals for extending that provision. Under pre-treatment of coal, the adoption in the eighteenth century by British ironmasters of the use of coke in their blast furnaces is given the first place, initiating an industry which now employs 40,000,000*l.* of capital, and yields not only coke, but also tar, sulphate, benzole, and surplus gas. The position of the parallel carbonisation process, that of the gasworks, is indicated by the statement that the capital now engaged in it is 160,000,000*l.*—not very far short of the capital of the mining industry itself. Yet these two industries, in which coal is systematically treated before use, represent only some 37 million tons, while the coal consumed in its raw state amounts to 147 million tons, and the statement is made that, while for some purposes, such as large boiler plants, it is doubtful whether it would be economical to carbonise the coal before burning it, there is no doubt that a large proportion of the 147 million tons is consumed in a very wasteful manner.

The consideration of pollution of the atmosphere by smoke, the possibility of supplying oil from coal, and the position of low-temperature carbonisation, follow naturally with some reference to the use of pulverised solid fuel for firing furnaces and of the so-called colloidal fuel, that is, finely divided coal mixed with fuel oil. There is probably no one remedy for the smoke nuisance which would compare in importance with the use of some form of smokeless solid fuel in the domestic grate, and the interest in low-temperature carbonisation is stimulated by that idea. But the pronouncement of the Commission based upon a memorandum furnished by Dr. Lander is inevitably very guarded:

> "We have given close attention to the question of low-temperature carbonisation, but we can find no evidence that the system has yet been anywhere established on a commercial scale for a period sufficiently long to enable the claims that are made on its behalf to be fully tested."

It is not that carbonisation at a low temperature is a technically unrealisable process, since it is in essence a reversion to older practice. The difficulties are quantitative and commercial, and the problem is to overcome those difficulties in a fashion quite opposite to that adopted by the gas industry, which has developed by carbonising at high temperature and obtaining the maximum possible yield of gas—the carbonisation product which displays a greatly enhanced thermal efficiency in use with a correspondingly increased monetary value. Research on this subject is likely to have to go far back into the properties of coal itself, and the possible means of utilising and modifying such properties so as to arrive at a cheap and rapid process which will give the results required without incurring excessive costs in the installation of plant, and the working of the process itself. Encouragement is forthcoming from demands of different origin, since apart from all question of smoke abatement there is the national need for home supplies of liquid fuel, including motor spirit, and the desirability of finding some sort of use for low-grade coals, at present of no commercial value. If it were possible to subject to this process the bulk of the 147 million tons of coal now consumed in the raw state, the greater part at least of present British requirements of oil could be supplied from home sources, instead of being imported from abroad. Nor is the Commission pessimistic.

> ". . . the evidence we have taken has given us the impression that we may be within measurable distance of a solution of both the technical and commercial problems that arise. We recommend that the Government should give sympathetic consideration to any proposals of the Fuel Research Board for the further investigation of the process on a commercial scale."

There is no doubt that here a great difficulty presents itself. So far as concerns the scientific and technical research to which reference has been made above, into the properties of coal itself, the path is comparatively smooth, but the solution of what are grouped under the term of 'Commercial problems' is another matter. The Fuel Research Board has already gone so far as to undertake, without charge, the testing-out of low-temperature carbonisation plants on a commercial scale in order to obtain reliable information and to give it to those concerned. This is, as the writer can say from experience, no easy matter to carry through in such a way as to obtain trustworthy results, but it is practicable. The commercial interpretation of such results in a form to have any general application is, however, much more difficult, and the Fuel Research Board has so far held its hand at that stage. If, too, the financial backing of pioneering industrial adventures in this field is to be undertaken, it will have to be with eyes open to the very large costs which are only too easily incurred in such work without tangible results.

The Commission lays great stress on the co-ordination of coal-using industries, and its report should go far to counteract the mistaken ideas only too easily derived from the ill-balanced report of the Coal Conservation Committee issued in 1918. The Commission says:

> "It has been strongly impressed upon us as the outcome of our enquiries that it is an error to suppose that the only, or even the principal, object to be aimed at in this connexion is the most economical method of producing electricity. The object to be aimed at is the most economical and efficient way of utilising the energy embodied in the coal. The question is not co-ordination, as is often supposed, of two industries—coal and electricity—but of several—coal, electricity, gas, oil, chemical products, blast furnaces, coke ovens, etc. Two or more methods, dealing with two, three, or more of these, would be used simultaneously in combination, one feeding the other. The point of importance is, that no obstacles, whether of State regulation or industrial organisation, should be placed in the way of the development of such combinations in whatever manner engineering and chemical skill and the economic conditions may indicate as the most suitable."

Arising out of such considerations, the Commission "venture to suggest for consideration the formation of a Standing Conference composed perhaps of the Chairman and other representatives of those bodies we have mentioned," these being the Coal Commissioners (whose appointment is recommended elsewhere), the National Gas Council, and the Electricity Commissioners. Its primary task would be to ensure that while a healthy competition should be maintained where it was legitimate between these various interests, their energies should be developed in a manner complementary in the main to each other. Moreover, it is proposed that a survey, which from the nature of the case should be a continuous process undertaken by a body of a permanent character, should be made of the heat, light, and power requirements of the various industries of the country as a whole.

The Commission has concerned itself seriously with research into matters connected with coal as of primary importance, reviewing the present provision and suggesting developments. In all such schemes one outstanding point is often overlooked. If an industry is to reap the full value of research work done within it or on its behalf, it is essential that in the executive ranks of the industry itself, in its direction and management, there should be men willing and able to give effect to the results obtained and discoveries made. For this reason, the conversion of an industry from the empirical to the scientific is a gradual process, and is not to be done simply by the attachment of a research staff (with the formulation of a programme) to an industry which remains at heart unconvinced of the value of scientific work. The following sentence in the report is no doubt inspired by some such conviction: "It is also essential that the industry as a whole should become imbued with the spirit of science in order that it may utilise to the fullest extent the results of modern scientific developments." Another point of importance recognised is that the existing supply of research workers for the fuel industry is quite inadequate to meet such demands as are contemplated, and the recommendation is made "that the Colliery Owners' Research Association encourage the scientific training of students for the work of the Research Association, and for the survey, and that for these purposes it be authorised to provide scholarships and arrange with universities for suitable courses."

The field of research surveyed is a large one, including as it does occurrence and constitution of coal, coal winning, and coal utilisation, each with its subdivisions, hygiene and safety being given prominence in the coal-winning section. Work already in hand by the Fuel Research Board, the Safety in Mines Research Board, the Geological Survey, the Colliery Owners' Research Association, and the National Federation of Iron and Steel Manufacturers, is described, as also that carried out in conjunction with the University of Leeds by the Gas Investigation Committee of the Institution of Gas Engineers and by the National Benzole Association. It is noted that the Bergius process for the 'liquefaction' of coal and synthetic methods for the conversion of water-gas mixed with additional hydrogen into motor-spirit are receiving attention.

Then comes a section on the future of research work, which begins with an expression of opinion that the attitude of the British Coal Owners' Research Association (as indicated by Mr. Evan Williams, President of the Mining Association, in evidence) "indicates an insufficient appreciation of the importance of this question," and further emphatic statements, such as, "While research alone will not overcome the difficulties from which the Industry is now suffering [a qualification which the writer is glad to see made] we feel strongly that the steady and continuous investigation into all pertinent problems is essential if the industry is to prosper and to provide good wages and conditions for its workers"

Recommendation is made that the British Colliery Owners' Research Association be rapidly expanded, and that the managing council of the Association should be composed of representatives of the owners, managers, mining engineers, workers in the industry, the Mines Department, and the Department of Scientific and Industrial Research. A sum of 100,000*l.* should be provided for the establishment of a headquarters, a highly qualified director of research appointed, and such continuity as will attract the right men for the staff and render possible the obtaining of useful results in work which is necessarily slow, should be secured by guaranteeing an income averaging 40,000-50,000*l.* per annum for at least seven years. The funds are to be provided partly by the owners and partly by the Department of Scientific and Industrial Research, which is to take the initiative in organising and developing the Research Association. According to this scheme there would then be three large organisations, each dealing with one aspect of the coal problem: (*a*) The Colliery Owners' Research Association, expanded as indicated above, (*b*) The Safety in Mines Research Board, and (*c*) The Fuel Research Division of the Department of Scientific and Industrial Research. Co-ordination of the work is to be effected by the Department of Scientific and Industrial Research.

Such are the recommendations on research made by the Commission, and they have no doubt been carefully considered. It is plain that they place the Department of Scientific and Industrial Research in a highly responsible position at the centre of a highly elaborated organisation for dealing with a subject, that of research, which from its very nature is particularly difficult to organise. The maintaining together of sufficient elasticity in administration, insight and efficiency in the various directing bodies and their staffs, and goodwill in all concerned, will call for a very exceptional power of co-ordinating these estimable but not all-pervading qualities. The research programme is, however, so comprehensive as to give large scope for choice and initiative in its translation into active research, and even a fractional fulfilment of its promise would be a great national benefit. One note of warning may be sounded. If those engaged in the coal industry begin to make the assumption that research and pioneering work are essentially the concern of the nation or some association, and no longer that of the firm or the individual, many of the paths of progress, and quite probably the best, will be left unexplored.

JOHN W. COBB.

The Science of the Humanities.

A Dictionary of European Literature: Designed as a Companion to English Studies. By Laurie Magnus. Pp. xii+594. (London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., 1926.) 25*s.* net.

"BEAUTY is Truth, Truth Beauty," wrote Keats, in passionate protest against all attempts to divorce them or to see in one the antipathy of the other. A similar recognition is growing that the oft-assumed antithesis between literature and science is a wanton and needless invention. The humanities of science has yet to be written, perhaps, though odd chapters have appeared from time to time; but the science of the humanities, if by such a phrase we may indicate the scientific treatment, in the widest sense of the word 'science,' of the material of the humanities, has for some time had its expositors.

The volume before us is a notable example of this larger view. It is, we believe, the first attempt yet made to apply, on such a restricted scale as the single volume, the comparative method to the literature of Europe. Prof. Saintsbury in his "Periods of European Literature" divided the subject into twelve "Periods" and marshalled a dozen specialists for the work, each of whom wrote a history of his chosen and allotted period. But if English studies are to be made as valuable a discipline as the Greek and Latin which they are displacing in the upper forms of the public schools and in the universities, there is need of a reference book covering the whole field in a single volume. Smith's "Dictionary of the Bible" and Lempriere's "Classical Dictionary" were written on these lines; and Mr. Laurie Magnus's "Dictionary of European Literature" takes a like direction and aim. It is, moreover, an application of scientific method to vast and scattered material.

Such a task is, of course, stupendous in no hackneyed sense of that word. The mere labour of reading, collecting, and collating the mass of material demands great industry and patience; but the crux of the difficulty comes when the digested and assimilated mass has to be turned into the flesh and blood of a live book. This is the ultimate test by which the work is to be judged. Have we here only another catalogue, exact and compendious, if you like, but still only a good catalogue of facts? Or are there spaciousness of view and single-mindedness of aim that give a unity to the whole? So far as we have been able to judge, the book stands this severe test.

The bulk of the articles consists of well-documented and up-to-date biographico-critical accounts of authors in all countries, with résumés of the literary history of each country under its own name. The author throughout combines an unflagging spirit with a calm and, so far as we have seen, an unbiassed critical judgment, and he is very often singularly happy in his mental picture of the writer whom he is treating. It would be pointless on the part of a reviewer to complain that too little space is given where he would have liked, or expected, more; and too much where his own taste and judgment would have led him to give less. Such personal disappointments are inevitable in all dictionaries and anthologies. It is perhaps only less pointless to say that, rarely here and there, we could have spared a little of the space devoted to the personal side of the particular author being treated, so as to have a fuller exposition of his work and message. This is, however, but by the way.

A valuable feature of the book is supplementary to these biographical and critical accounts of authors. In ordinary histories of English literature, or studies of single authors, names occur which are imperfectly understood. Thus, Renaissance, Reformation, Humanism, Romance, and similar terms cross several centuries and all countries. They are English names for European phenomena, and the English student is commonly very inadequately seized of their European meaning and value, and of the relation borne by the English part to the European whole. Within the circumscribed limits set by a single volume, Mr. Laurie Magnus has given a vivid and considerable elucidation of these generic phenomena. The reader may well turn immediately, for example, to the article on "Nature, Natural, Naturalism."

Another important set of topics is that of the classical writers. Tennyson is called Virgilian, and so on, and the metaphor is accepted easily, but the European vogue of Virgil, Cicero, Plato, and the rest cannot be grasped by students unless they consult special textbooks, usually in a foreign tongue. The "Dictionary of European Literature" endeavours to supply this information under the name of each classical writer. In such questions, too, as the influence of "Climate," the changing treatment of "Woman," the literary motive of "Death," there are similar articles bringing together information from various places and times, and fusing the constituent parts into a combined and intelligible whole.

The admirable preface to the book should be read to gather its purpose and aim. Its sub-title tells us the book is "designed as a companion to English studies." In our judgment it is, taking it all in all, a pleasant yet learned, stimulating yet judicious, companion, of fine but tempered enthusiasms. Its best virtue, perhaps, is that, as guide, it gives us zest to roam free and know more.

Pyrometric Methods.

(1) *Methods of Measuring Temperature.* By Dr. Ezer Griffiths. (Griffin's Scientific Text-Books.) Second edition, revised. Pp. xii + 203. (London: Charles Griffin and Co., Ltd., 1925.) 10*s.* 6*d.* net.

(2) *Pyrometers: Recent Developments in Pyrometric Appliances and Methods for Calibrating Temperature-Measuring Instruments; with Notes on Electric Furnaces.* By Dr. Ezer Griffiths. Pp. xi + 126. (London: Sir Isaac Pitman and Sons, Ltd., 1926.) 7*s.* 6*d.* net.

THERE are few physical investigations which do not call at some stage for a determination of temperature, although the conditions of the experiment and the accuracy demanded may vary within very wide limits. Hence the modern development of thermoelectric, resistance, optical, and radiation pyrometers, supplementing the mercury thermometer and referred to the gas thermometer as a standard, the latter instrument being too troublesome for practical routine determinations. So many industrial processes also now require accurate measurements of temperature that manufacturing works will be found to possess installations which would formerly have been seen only in a physical research laboratory. There is thus a need for scientific descriptions of the methods of measuring temperature, for the use of the industrialist as well as of the laboratory worker. The methods must be understood if they are to be employed to any purpose, and serious errors result from the use of instruments the principle of which is imperfectly realised.

(1) The first edition of Dr. Ezer Griffiths's book was welcomed as a valuable survey of modern methods of measurement of temperature. It has now been revised, mainly in the sections which deal with optical pyrometry. It gives a full account of most of the devices which find application in practice, and is not encumbered with descriptions of obsolete or untrustworthy methods. The diagrams showing the electrical circuits are very clear, and the directions for the use of the instruments are satisfactory. Since the practical metallurgist has to calibrate his instruments mainly by the determination of fixed points, a table of such points might well have been given, the particulars on this subject being rather scanty. Full details up to 450° are given, but for the higher temperatures fuller use might have been made of the recent work of the U.S. Bureau of Standards. References to the literature are given at the end of each chapter.

Experience in industrial pyrometry proves that two sources of error are most commonly found. Thermocouples undergo changes in course of use, so that the value of their indications does not remain constant. As a pyrometer which reads wrongly is worse than none at all, it is important that calibration should be repeated at intervals, and that the metallurgist should be fully acquainted with the methods of checking the accuracy of his instrument. The procedure is simple, and this work gives full particulars. The other error is less obvious. In a reheating furnace, for example, the temperature is never uniform throughout, and it is of the utmost importance that the pyrometer should be so placed that the temperature indicated should be that of the object being heated. This is often not the case, and one may sometimes see furnaces in which the temperature of the objects heated obviously differs by 100° or more from that shown by the pyrometer, owing to the placing of the latter. In a book of this kind, a chapter on the subject of the placing of pyrometers in the spaces being heated would have been useful. The accuracy of the eye of a trained man, such as a steel hardener, is remarkable, and it is to be hoped that the more general use of pyrometers will not lead to a complete abandonment of the practice of visual determination of temperature, this being often a valuable control of the indications of a pyrometer.

(2) Dr. Griffiths's second book contains a very brief outline of the most modern types of pyrometer, together with some special applications to difficult practical problems, such as the determination of the temperature of rapidly moving parts and of the windings of transformers. It will be found useful in industrial works, the descriptions being clear and to the point. A short chapter is devoted to furnaces for high temperatures. The account of the Ajax high-frequency induction furnace does not quite accurately describe the latest type, but it is well that this very useful method of attaining high temperatures should be mentioned. The only optical pyrometers described are those of the disappearing filament type, the author rightly regarding this as by far the most simple and trustworthy.

C. H. D.

The Earliest Herbal written in England.

The Herbal of Apuleius Barbarus, from the early Twelfth-century Manuscript formerly in the Abbey of Bury St. Edmunds (MS. Bodley 130). Described by Dr. Robert T. Gunther. Dedicated and presented to the President and Members of the Roxburghe Club by Edward George Spencer-Churchill, 1925.

BOTANISTS and palæographers are greatly indebted to the Roxburghe Club, and especially to Capt. E. G. Spencer-Churchill, for the magnificent facsimile copy of the "Herbal of Apuleius Barbarus," which has been reproduced photographically from the original manuscript in the Bodleian by the Clarendon Press.

The value of this publication is not only greatly enhanced, but is also rendered of extraordinary interest, since Dr. R. T. Gunther has compiled a very valuable introduction in which the history of the "Herbal" and its relation to other herbals is fully discussed. The appendices are of equal value, as in Appendix I. the herbs described in the Bodley MS. are set out in order, with notes on the text and identifications of the plants described and figured, so far as this has been found to be possible. This difficult work of identification of figures, often copied from earlier works, has been done partly by the late Mr. James Britten, whose name is an assurance of the meticulous care with which the work has been done, and after his death by Dr. A. B. Rendle.

The interest of the MS. Codex lies in the fact that it includes the earliest herbal believed to have been written and illustrated in England, the date being about A.D. 1100; also that it once belonged to the Abbey of Bury St. Edmunds. The history of the Codex and its wanderings is given, in the early pages of the introduction, up to the time that it was presented to the Bodleian some 220 years ago. But for Dr. Gunther having consulted the manuscript in an endeavour to trace the origin of a drawing of the "Saxifrage of the Antients," copied from an old manuscript by John Goodyer, the Codex might still have reposed, receiving scant attention, in Bodley's library.

The illustrations amply justify the reproduction of the manuscript in facsimile. Most are based on traditional 'Dioscoridean' drawings of remote antiquity. The most complete series of such early plant drawings are to be found in the manuscript illustrated about A.D. 512 by Greek artists as a wedding gift for Julia Anicia, daughter of Flavius Anicius Olybrius, Emperor of the West. Some of these with their descriptions were no doubt derived from Crateuas' paintings of plants executed in the first century B.C., combined with the text of the "Materia medica" of Dioscorides. The paintings illustrating these early herbals appear to have been copied one from another without reference, except in rare cases, to the plants, with the result, as may be seen in Apuleius's "Herbal," that many have become so conventionalised as to be scarcely recognisable.

It is much to be regretted that certain chapters are missing from this "Herbal," in particular those describing the mandrake and the *Herba Basiliske*, but this defect has been remedied by including in the introduction a reproduction in colour of the mandrake from MS. Ashmole 1431, and descriptions of both plants in English from Cockayne's translation of the Anglo-Saxon "Apuleius." Two very interesting plates of German figures from an Italian MS. in the Library of Trinity College, Cambridge, illustrating the mandrake, rosemary for sore eyes, devils being cast out by a herb, and *Herba Delfion* or (?) delphinium, with the flowers transformed into dolphins or fishes, conclude Dr. Gunther's valuable introduction.

The value of the appendix lies in the citation of the titles of the chapters and the modern botanical names, reprinted from Cockayne's edition of an Anglo-Saxon version of the "Herbal," the Dioscoridean and Theophrastan synonyms, notes on the colours of the roots, leaves and flowers in the illustrations in the MS., and suggestions as to the correct identification of the figures. These, as might be expected when it is possible to suggest determinations, are often entirely different from the names given in the Anglo-Saxon version. The figures are all of interest, but some, such as *Cotyledon umbilicus*, *Herba Narcissus* and *Herba Hipperis*, show how much has been lost by repeated copying.

In the second appendix a useful table is given showing the variation in the numerical order of the plants described in the Ashmole 1431, Anglo-Saxon MS. V., and the Bodley MS. 130, here reproduced, and the printed edition of the "Herbarium of Apuleius" of 1526. A complete index concludes this very interesting volume.

Our Bookshelf.

Chemical Synonyms and Trade Names: a Dictionary and Commercial Handbook. By William Gardner. Second edition, much enlarged. Pp. vi + 271 + 56. (A companion volume to the first edition, containing the additional Synonyms in the second edition, is also issued. Pp. 56. 7*s.* 6*d.* net.) (London: Crosby Lockwood and Son, 1925.) 30*s.* net.

THE number of entries in this dictionary is now between 16,000 and 17,000, several thousands being new to the second edition. The added material has, for an obvious reason, been placed at the end of the book with a separate pagination, but owners of the first edition may purchase it in the form of a companion volume. From the outset it was clear that this publication would meet a want, and we know of no book which covers the same ground so usefully and, withal, so accurately. Not only will it appeal to those who traffic in chemicals and their raw materials, but the general reader will also find in it much to interest him, *e.g.* the composition of many commodities that he uses in daily life: the ingredients of soaps, water-softeners, perfumes, dyes, drugs, disinfectants, and so forth.

The expert, knowing the extreme difficulty of making such a dictionary all-inclusive, will not expect to find everything he seeks, and he may be disappointed not to find more information concerning the nature of proprietary articles; but he will be interested to learn that the excellent disinfectant which has usurped the name of one of England's most famous poets, owes its efficacy to the presence in it of sodium hypochlorite. It is common knowledge that chemists can no more answer the question: What is a chemical? than the related one: What is a chemist? Nevertheless, we believe that most of them would be surprised to find in a dictionary of chemical synonyms such names as briquettes, hop-flour, molasses, gin, and Apollinaris!

Contributions to the Ethnology of the Kwakiutl. By Franz Boas. (Columbia University Contributions to Anthropology, Vol. 3.) Pp. vi+357. (New York: Columbia University Press; London: Oxford University Press, 1925.) 21*s.* net.

THIS volume consists of Kwakiutl texts with translations for which the material was obtained from a half-blood Indian of Fort Rupert, British Columbia, who speaks Kwakiutl as his native language and has been trained in phonetic writing by Prof. Boas himself. It is a continuation of Vol. 35 of the annual report of the American Bureau of Ethnology. The greater part of the texts deal with the social organisation of the people, and they have this advantage for the student, that they deal with concrete examples, described in minute detail, of such social elements as inheritance and succession, naming, marriage, and the like.

The section which is particularly welcome, however, is the transcript of sixty-five dreams These are of interest from the point of view of both the psychologist and the student of religion A number of the dreams are of an ordinary type merely reproducing everyday activities. Of the others, some describe relations with the dead. In one a son was told by his father of his discomforts in the spirit world, and on waking he burned two pairs of blankets and food for the soul of his father. Two dreams deal with the Shaman's crystal: in one the dreamer finds a crystal in the stomach of a seal; in the second a crystal is forced into the dreamer's body by a gull which had spat it out. A man well known as a 'true' dreamer anticipated the news of the death in England of a former missionary. It is stated that this dream was told to the writer the morning after its occurrence, and the letter containing the news of the death not received until some time after. The familiar nightmare of falling from a height is recorded. A number of the dreams are interpreted as foretelling epidemics and death.

The Anglo-Saxon Cemetery at Girton College, Cambridge: a Report based on the MS. Notes of the Excavations made by the late F. J. H. Jenkinson, M.A. By E. J. Hollingworth and M. M. O'Reilly. Pp. vii+38+12 plates. (Cambridge: At the University Press, 1925.) 4*s* net.

THE Anglo-Saxon Cemetery at Girton College, which lies a few yards north of the Roman road from Cambridge to Godmanchester, was discovered in 1881 in the course of building operations. About 150 cremation interments and 75 to 80 skeletons were then brought to light. Further discoveries were made in 1886; but while the authors of the book have been able to avail themselves of the careful notes of the late Mr. Jenkinson from the earlier excavations, the conditions under which the later examination was made precluded anything like a detailed record. The authors have performed a pious duty to their College and a real service to archæology in working up the material provided by these notes and by the actual objects, some on loan from Girton College, which are now in the University Museum of Archæology and Ethnology at Cambridge The cemetery was evidently of considerable size, and presents several points of considerable interest. Cremation and inhumation were practised contemporaneously throughout the whole period of pagan Saxon occupation. A fragment of pottery suggests that the site may have been occupied so early as the Middle Bronze age, and two Roman cremated burials were also found.

Die Schalltechnik. Von Dr. Richard Berger. (Sammlung Vieweg, Heft 83.) Pp. iv+115. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1926.) 8 gold marks.

IT is strange that in text-books dealing with the practical applications of our knowledge of sound, each author considers it necessary to employ a special vocabulary to describe sound phenomena, and each author employs a different one. This monograph provides an illustration, for the first part of it is devoted to well-known theories of the propagation and production of the various types of waves, which are described in a new nomenclature. Theory is then somewhat abruptly set aside and a description of practical technique is commenced. This part of the book is much more helpful, for it describes work carried out in Germany which had for its object the prevention of noise with moving machinery, and the insulation of other portions of a building from such noise. The work of Sabine and Watson on the acoustics of buildings is touched upon, but the list of absorption coefficients given is not up-to-date. Sound-signalling, including the effect of wind, sound-ranging and direction finding are also described, the work of the Danish and German artillery sections providing most of the material. The final section deals with the work of Miller in the United States on the analysis of sounds produced by musical instruments and by the human voice.

Volumetric Analysis: with a Chapter on Simple Gravimetric Determinations By A. J. Berry. (Cambridge Physical Series) Third edition. Pp. vii + 151. (Cambridge: At the University Press, 1925.) 9*s.* net.

THIS work was first published in 1915, and the fact that it has reached a third edition, in spite of the appearance of a large number of books covering the same ground, is good testimony to its popularity and value. The treatment is clear and scientific, an excellent feature being the judicious interweaving of explanatory theoretical matter with the practical instructions. In the recent edition is included a new chapter on simple gravimetric determinations which contains much useful advice to the young student concerning general principles. The author is under no illusion that analytical chemistry can be taught exclusively from books: it is a craft as much as a science, and in the learning of it, practice in doing must take precedence over theoretical explanations, important as these are at the proper stage. It is a pleasure to note the author's strong recommendation of Masson's method for standardising hydrochloric acid with Iceland spar, which is not only very simple but also, as he states, yields results of extreme accuracy.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Transmutation of Elements.

IN a letter to NATURE of January 30, 1926, Dr. Davies and Prof. Frank Horton give some considerations about the transmutation of mercury and lead which agree completely with those given by me in a lecture delivered in Amsterdam on January 29, 1926.

I considered the two possibilities of transmutation by absorption of electrons or by disruption of the atomic nucleus. Since I thought the latter more probable in the cases mentioned above, I laid most stress upon this possibility and gave the following considerations :

Aston found the atomic weights of the isotopes of mercury to be 202, 209, 199, 198, 201, 204. Assuming that, for example, the isotope 201 suffers a transmutation into gold by disruption of the nucleus, this process can be indicated by the following equations :

$$\begin{array}{rl} & \mathrm{Hg} - \alpha - \theta = \mathrm{Au} \\ \text{atomic weight} & 201 - 4 \quad = 197 \\ \text{atomic number} & 80 - 2 + 1 = 79 \end{array} \qquad . \quad . \quad (1)$$

or

$$\begin{array}{l} \mathrm{Hg} - 4\mathrm{H} - 3\theta = \mathrm{Au} \\ 201 - 4 \qquad\quad = 197 \\ 80 - 4 \ \ + 3 = 79 \end{array} \qquad . \quad . \quad . \quad (2)$$

In the case of the transmutation of lead into mercury, the inactive isotopes having the atomic weights 206, 208 and 210, we may assume, for example, that the isotope 206 suffers a transmutation giving an isotope of mercury :

$$\begin{array}{l} \mathrm{Pb} - \alpha = \mathrm{Hg} \\ 206 - 4 = 202 \\ 82 - 2 = 80 \end{array} \qquad . \quad . \quad . \quad (3)$$

But we may also assume that the other isotopes 208 and 210 undergo a transmutation. In that case we obtain :

$$\begin{array}{l} \mathrm{Pb} - 2\alpha - 2\theta = \mathrm{Hg} \\ 208 - 8 \qquad\quad = 200 \\ 82 - 4 \ + \ 2 = 80 \end{array} \qquad . \quad . \quad . \quad (4)$$

and

$$\begin{array}{l} \mathrm{Pb} - 2\alpha - 2\theta = \mathrm{Hg} \\ 210 - 8 \qquad\quad = 202 \\ 82 - 4 \ + \ 2 = 80 \end{array} \qquad . \quad . \quad . \quad (5)$$

In the case of the transmutation of lead into thallium we can assume, for example, the following process :

$$\begin{array}{l} \mathrm{Pb} - \alpha - \theta = \mathrm{Tl} \\ 208 - 4 \qquad = 204 \\ 82 - 2 + 1 = 81 \end{array} \qquad . \quad . \quad . \quad (6)$$

We see that of the different transmutation possibilities, (3) is most simple Moreover, I suspected this process could be expected first, as lead is the end-product of the spontaneous radioactive transformations.

In connexion with these considerations I pointed out that the best method of learning the nature of the transmutation is to examine spectroscopically whether the process is accompanied by the formation of helium or hydrogen, and to determine the atomic weight of the heavier products.

With a new apparatus which promised to enable us to study the problem successfully, my co-worker Dr. Karssen and I carried out a series of new experiments. While using the old quartz-lead lamp, negative results were obtained only if the current strength was lower than 15 amperes, but now, with our new lamps of somewhat different dimensions, spectroscopically negative results were found even using ± 60 amperes. The lamp showed distinctly different properties in burning and sparking. This proves that the phenomena taking place in the quartz-lead lamp depend on influences unknown until now, so that the transmutation in the quartz-lead lamp is not so easy to reproduce as we expected.

In connexion with this subject we are studying now the quartz-lead lamp more closely, and in the meantime we are applying our second sparking method, which we intend to extend to still higher voltage and higher current-densities.

Though we have already secured quantitative data, we prefer to publish the results later. A. SMITS.

Potassium and the Heat of the Earth.

IT has been widely recognised that the disintegration of the uranium and thorium in rocks has exerted a profound and probably controlling influence on the earth's thermal history. Hitherto, however, it has not been realised that potassium as an emitter of radiothermal energy is in the aggregate of the same order of importance as uranium or thorium. This surprising result has emerged in the course of a joint inquiry into the geological significance of the radioactivity of potassium and rubidium. The latter element is negligible geologically on account of its extreme rarity, despite the fact that its total activity is greater than that of an equal amount of potassium. Nevertheless, we have included rubidium in our discussion, since measurements of the activity of potassium have usually been compared with those obtained with rubidium, and our preliminary estimate of the amount of heat generated by the potassium in rocks depends on that comparison.

The β-rays emitted by rubidium are fairly homogeneous ; their velocity has been estimated from experiments on their deflexion in a magnetic field (Bergwitz), and by comparison of their absorption coefficient with those of radioactive rays of known velocity (Hahn). These experiments point to a velocity of 0·60 *c*, the corresponding kinetic energy of a β-ray from rubidium being $2{\cdot}04 \times 10^{-7}$ ergs. In the case of potassium, Hahn has concluded that the average velocity of the β-rays cannot differ much from 0·90 *c*. We probably make adequate allowance for the heterogeneous nature of the potassium rays by assuming for them the value $\mu = 20$ cm.$^{-1}$ aluminium. Using this result in conjunction with Lenard's curves of absorption of β-rays of different velocities, we obtain for the average velocity of the potassium rays the value 0·85 *c*, a result in substantial agreement with that of Hahn. The average kinetic energy of a β-ray from potassium is thus $7{\cdot}30 \times 10^{-7}$ ergs.

We next require the half-periods or the disintegration constants of rubidium and potassium. Hahn and Rothenbach compared the activity of the β-rays from rubidium with that of the β-rays from UX$_1$, and thus found for rubidium a half-value period of $0{\cdot}7 \times 10^{11}$ years, this result being uncorrected for the different values of the number of ions per cm. and the Loschmidt numbers (per gm.) for the substances compared. Applying the necessary corrections, we find $T_{\mathrm{Rb}} = 1{\cdot}4 \times 10^{11}$ years. Hoffmann also has compared the activity of rubidium and of potassium with that of uranium, using two different methods, and he concludes that his results are in agreement with that of Hahn and Rothenbach, though slightly lower. Correcting Hoffmann's results to take account of the absorption of the rays in his apparatus and in the active film employed, we find $T_{Rb} = 1 \cdot 1 \times 10^{11}$ years from the results of the first method, and $T_{Rb} =$ *ca.* $0 \cdot 8 \times 10^{11}$ years from those of the second. The half-value period of rubidium cannot therefore differ much from 10^{11} years, and we have adopted this value as the most probable approximation.

The data for potassium are not yet established with the same degree of accuracy. Estimates of the total activity of rubidium relative to that of an equal weight of potassium vary between 7·0 and 1·4, indicating that the half-period of potassium lies between 50 and 11 times that of rubidium. Fortunately, Hoffmann's delicate measurements (referred to above) reduce the range of these extremes very considerably. His two methods gave results indicating that the half-period of potassium is between 14 and 22 times that of rubidium, the lower value being of superior reliability. Taking all the available data into consideration, we conclude that a ratio of about 15 appears to be the most representative in our present state of knowledge. This gives for the half-value period of potassium, T_K = about 15×10^{11} years.

We are now in a position to calculate the annual heat production from one gram of potassium and rubidium respectively, and consequently to calculate further the annual heat production due to the presence of these elements in one gram of any rock of known composition. The calculations are embodied in the accompanying table, and, for comparison, the results for average igneous rock are given, and the annual heat productions due to uranium and thorium (together with their disintegration products) per gram of rock are included.

Element.	Uranium	Thorium	Potassium	Rubidium
Loschmidt Number, N, atoms per gram .	.	.	$15 \cdot 5 \times 10^{21}$	$7 \cdot 09 \times 10^{21}$
Half-value Period, T, in years . . .	.		15×10^{11}	1×10^{11}
Disintegration Constant, λ, year^{-1} .	.	.	$4 \cdot 6 \times 10^{-13}$	69×10^{-13}
Annual No. of Atoms disintegrating per gram $n = \lambda N$			$7 \cdot 1 \times 10^{9}$	49×10^{9}
Kinetic Energy, E ergs per β-ray	..	..	$7 \cdot 30 \times 10^{-7}$	$2 \cdot 04 \times 10^{-7}$
Energy liberated per gram per year $nE/(4 \cdot 19 \times 10^{7})$ cal	(7900×10^{-4})	(2300×10^{-4})	$1 \cdot 24 \times 10^{-4}$	$2 \cdot 38 \times 10^{-5}$
Contents in grm per gram of average igneous rock	6×10^{-6}	15×10^{-6}	$26{,}000 \times 10^{-6}$	$m \times 10^{-6}$
Heat generated in cal. per gm of average rock per year	$4 \cdot 74 \times 10^{-6}$	$3 \cdot 45 \times 10^{-6}$	$3 \cdot 22 \times 10^{-6}$	$2 \cdot 38\ m \times 10^{-11}$

The geological consequences of the radioactivity of potassium are clearly of great importance, for the heat generated within the rocks is now found to be considerably greater than the amounts hitherto calculated from uranium and thorium alone. For average granite the heat annually generated per c.c. becomes 40×10^{-6} calories instead of 30×10^{-6} calories. For average plateau-basalt the corresponding new estimate is 12×10^{-6} cal. per year instead of 9×10^{-6} cal.

A rough estimate of the mean thickness of the granitic layer of the continents can be arrived at by equating the amount of heat escaping at the surface with the heat generated within the granitic layer. Taking a column of unit cross-section, the heat lost per annum averages 60 calories, and evidently this can be entirely supplied by 15 km. of average granite. Seismic data have until recently been held to indicate about 30 km. for the average thickness of the granitic layer of Eurasia (Oldham, Wiechert, Angenheister, Gutenberg, and others). Within the last few months, however, Stoneley has shown that dispersion affects the validity of estimates such as that of Gutenberg, and Jeffreys has found that the necessary corrections reduce the estimates of thickness to 15 km. Recognition of the effects due to potassium thus brings about a satisfactory accordance which otherwise could never have been achieved.

Beneath the granitic layer, heat is supposed to accumulate until the latent heat of basaltic material is supplied, and fusion takes place. The average time required for the accumulation of 270 cal. per c.c. of basaltic material now becomes 22·5 million years instead of 30 million years. These figures are, of course, highly speculative, and are introduced merely to illustrate the geological significance of potassium.

Our investigation was partly stimulated by the possibility that the radioactivity of potassium might have been of considerably greater effect in early geological time than it is now, and so have led to the extensive intrusions of granite that everywhere characterised the earlier pre-Cambrian eras. It is, however, not yet possible to draw any such conclusion; nor will it become possible, unless the activity is found by future investigations to be confined to a still undiscovered isotope which has been appreciably wearing out through geological time.

Use of Thermit in Ice-Breaking.

THE remarkable results obtained by Dr. H. T. Barnes and his co-workers at Oil City and Franklin in alleviating disaster owing to ice-jams in twenty-four miles of the Allegheny River have received widespread attention.

The effectiveness of the undertaking is guaranteed by competent engineers on the spot who watched all the operations, and the success of the thermit treatment was even greater than Dr. Barnes himself had anticipated.

The physical aspect of the action of thermit on ice is an interesting one which deserves consideration altogether apart from the question of ice engineering. One pound of thermit when ignited gives 1500 British thermal units, less than a pound of coal. Hence, if a container of 100 lb. is ignited, 150,000 B.T.U. is released, and, as it takes eighty of these units to melt a pound of ice, we see at once by division that a little less than one ton of ice (about 1900 lb.) will be melted; or, a ton of thermit will melt under favourable conditions 95 short tons of ice.

This in itself is an important result, because, if 95 tons of ice are melted at the right time in the right place, a very considerable effect may be produced where there is a current of water to push the ice down a river. The above consideration is of course at once grasped by every engineer and physicist.

The remarkable effects which appear to be produced by the action of thermit packed in solid ice is clearly not to be referred mainly to the above. Thermit (iron oxide and powdered aluminium) ignited in the open attains rapidly a temperature of about 3000° C., and there is then nothing in the way of an explosion.

When, however, thermit is ignited, *closely surrounded by solid ice*, the photographs obtained by Dr. Barnes indicate a highly explosive action quite different from that in the open. Here we have to deal perhaps with the results due to an *impulse* rather than with either heat or with pressure over a considerable interval of time. Those who have tested a new gut fishing-cast and have proved that it will stand a steady strain of six pounds weight are familiar with the experience that it may snap when they strike quickly at a half-pound trout. A tap on a pin may fracture a block of ice which has withstood a blow from an axe. A small hot flame will fracture a large plate of glass. These are examples of impulsive effects, quick action being essential.

Now let us return to the container of 100 lb. of thermit yielding 150,000 B.T.U., and let us further recollect that each B.T.U. can do work amounting to 778 foot-pounds. On multiplying these numbers together we arrive at 117,000,000 foot-pounds or about 60,000 foot-tons, sufficient to raise a 10,000-ton ship vertically six feet against gravity. Imagine now a vessel weighing 10,000 tons dropped six feet on to a river seriously blocked with ice. There would be smashing and cracking of the ice in all directions, and, with water pressure behind them, blocks of ice might well be released. It is further desirable to contemplate not only the explosive action of the thermit, but also the effect of the radiation, from a high temperature source, which may pass for a considerable distance through the ice, causing changes which recall Tyndall's famous experiment on 'flowers of ice.' Much of the water in a river is above the freezing point, and if this is allowed to seep into the enlarged surface of partially disintegrated ice, melting is accelerated. It appears to be conceded by engineers that thermit is better than black powder, and black powder than dynamite, for ice-removal.

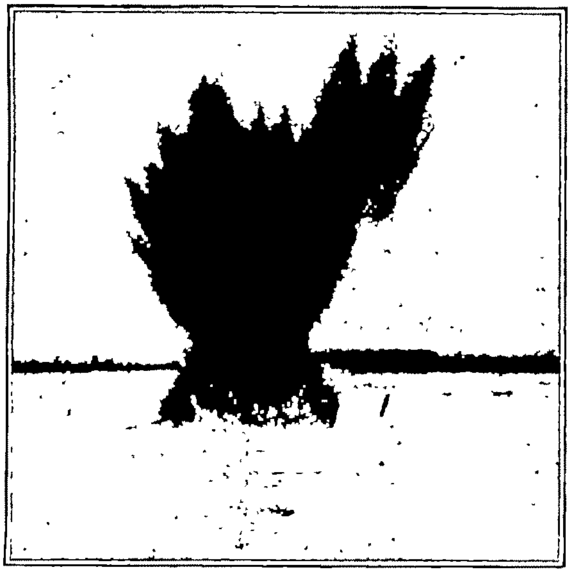

Fig. 1.—Ice exploding due to a charge of 90 lb of thermit in the River St. Lawrence at Chimney Island, below Ogdensburg, N.Y. The mine was placed four feet down in slush-ice underhanging to a depth of eight feet the solid surface ice two feet thick. The bright flames forty-five feet high give a reversed image in the photograph, and, below, the disrupted ice is seen raised six feet. (Photo by W. A. Connolly, Morrisburg, Ontario.)

The interesting question is to what extent we have to attribute the effects of thermit to (*a*) heating, (*b*) explosions, (*c*) high temperature radiation. It is on this account, and for the further reason that there is an actual possibility of disintegration of ice into atomic gases, that the experiments on thermit are of such a highly interesting character to the physicist no less than to the engineer. There is, of course, no suggestion that the laws of conservation of energy are not obeyed. Yet it is clear that the investigation of the action of thermit presents a problem of great importance which requires money, time, and skilful research work in the laboratory as well as in the field.

The Problem of X-ray Line Intensities.

Referring to the experiments mentioned by the present writer in recent issues of Nature (January 30, p. 153; March 27, p. 448), and other work not yet published, we have had on several films and on one plate lines of wave-lengths 1·040 and *1·038*[1] respectively. It seemed impossible to regard these lines as being due to mercury, since either the Hg$L\alpha_1$ or the Hg$L\beta_1$ line has not been present. The films and plate represented good photography, and the exposures were over a wide range, so that these lines fell about midway.

The problem is to account for these lines, which will be referred to collectively as the '1·040 line.' This line does not always occur, even faintly, on changing the substance on the copper anticathode, but it does appear when the substances are such that they might contain an element of atomic number 87 (see first citation above).

We have had lines *1·038* and *0·930* on one plate, and 1·040 on films as stated above; these occurring when the presence of bromine seemed out of the question, and the *0·930* line has not yet appeared except once and then with the *1·038* line. These two lines were obtained under the following conditions: Commercial potassium phosphate (monobasic) melted on the anticathode. Optical spectrum revealed the presence of calcium only as an impurity. X-ray exposure 12 hours. Voltage 60,000. Current 5 to 8 milliamperes. Shearer tube with water-cooled parts. Müller spectrograph. Plate distance 80·04 cm. Slit 0·1 mm. Angle of oscillation 5°-17°. Oil backing pump and mercury pump used. All lines clear and well defined. Plate clear with no fogging except along one side. The bromine absorption edge sharp and almost completely obscured along part of its length by side fogging (see below).

Some further incidental particulars are: The *0·930* line was weak compared with the *1·038* line. Three copper-anticathode lines were present, counting the α_2 and α_1 lines as one, which were resolved. The characteristic copper lines were very strong and had so-called satellites on the longer wave-length side, which were probably due to an imperfection in the rocksalt crystal. The only other lines were weak lines *1·436* and *1·242*, probably due to the zinc and mercury, the former from the brass of the apparatus and the latter from the mercury used in exhaustion—as might be expected with a 12-hour run.

It is to be noted that the Rb$K\alpha_2$ line has a wave-length of 0·928. Experimental error in the measurements cited above 0·003. If *other* experiments had given evidence of bromine being present in the tube, or in the compounds used, the above line could be expected, for the Br$K\alpha_1$ line is 1·0377.

---

[1] Accurate micrometer measurements have been made in those cases where the values are given in italics, all of which are in Ångstrom units; and the bromine absorption edge has served as a check in measuring the region between it and the Cu$K\beta_1$ line.

It has occurred to the writer that whenever a very weak radiation, corresponding in wave-length closely with that of a BrK line—perhaps an α_2 incident radiation—falls on a film or plate, the bromine in the emulsion, or the emulsion in conjunction with the bromine, is stimulated into greater photographic sensitivity and a comparatively strong line appears, especially under the conditions of our experiments, *e g.* long exposure.

This hypothesis would seem to give a satisfactory explanation of the appearance of the '1·040 line.'

As an incidental feature, on the plate we had a slight fogging along one side or edge which partly obliterated the *0 930* line, showing that slight darkening may obscure a weak line, as was stated by the writer in connexion with the suspected $87L\beta_1$ line (see citations above). The stronger lines were not, however, reduced in intensity by the slight side-fogging.

In conclusion, it will be seen that if the above view is in the main true, then the following radiations, in terms of lines, though very weak, would give rise to more or less strong lines. Hg$L\beta_2$ 1·0375, As$K\beta_2$ 1·038, ($87L\alpha_2$ 1·039), (Br$K\alpha_1$ 1·0377), Tl$L\beta_4$ 1·0371; Rb$K\alpha_2$ 0·9277, (Br$K\beta_1$ 0·931), Cd second order $K\beta_2$ 0·928 The brackets indicate complete exclusion from consideration or doubt in respect of stimulation Some of these radiations can be eliminated by control experiments, so that it may be possible to find out the element which is operative if the effect is not due to a complex of lines The optical spectrum would be helpful here as a guide, but in our case it has not revealed an element corresponding with either of the two lines in question, as might be expected.

It seems important that the whole bromine X-ray spectrum (K) should be determined if there is anything in the idea here advanced

Perhaps one of your readers would kindly offer a better explanation of the matter than here attempted, bearing in mind that there is a tendency for all the lines in question to be shifted perceptibly towards the longer wave-length side, and on this account our line 1·032 (*loc. cit*) may be the same as the *1·038* line.

F. H. Loring.

Relative Intensities of the D_1 D_2 Lines of Sodium in Comets and in Low Pressure Laboratory Sources.

Sodium D lines of emission were identified beyond any possible doubt in the heads of the following comets: Wells, (1882*a*), Great Comet, 1882 (1882*b*); 1910*a*; Halley's Comet (1910*c*); and Brooks' Comet, (1911*c*) The appearance of these lines has always been of temporary character at perihelion. The spectra of the first three comets were observed either visually or by means of a prismatic camera, so that the only reliable determinations of wave-lengths are furnished for the comets Halley and Brooks. The spectrum of the former was taken by E. C Slipher (*Lowell Observatory Bull.* 52) with the slit spectrograph of Lowell Observatory, and that of the latter by W. H. Wright (*Lick Observatory Bull* 209) with the Lick refractor.

Slipher gives for the sodium lines only one wave-length, 5891·9, which is sufficiently near $D_2 = 5890{\cdot}2$. It seems as if the other component, D_1, was entirely absent, although there remains an element of doubt as to the sufficiency of the dispersion employed. If 5891·9 is merely a blend of D_2 and D_1, their relative intensities should be about 3·5 to 1.

In the spectrum of Brooks' comet, Wright found both components, D_2 with wave-length 5889·4, and D_1 with wave-length 5895·5. He says. "Both of the D lines are present, forming a close double, D_2 being much the brighter." The relative intensities were estimated as 3 to 1.

Thus there would seem to be good astronomical evidence to the effect that sodium D lines are present in the spectra of certain comets and that they show very unequal intensity, D_1 being much weaker than D_2. If we take into account that D_1 may blend with the band 5897·5 of high-pressure carbon monoxide, as suggested by Fowler (*Monthly Notices, R.A.S.*, 70, 490, 1910), the contrast between D_1 and D_2 will be still greater. Laboratory conditions for the excitation of these high-pressure bands, however, would scarcely lead us to expect to find this spectrum in comets.

R W Wood has shown (*Phil. Mag* (6) **27**, 1018, 1914) that it is possible to excite D_2 by fluorescent methods with an intensity excessively greater than D_1.

One of us has recently observed the excitation of the D lines with relative intensities strongly suggestive of their appearance in comets, and under conditions of excitation which also are somewhat similar. The tube used was provided with a hot cathode about five millimetres in length, richly coated with oxides containing very minute traces of sodium as impurity. The anode was a nickel cylindrical Faraday cage entirely enclosed (except for an observation slot) in which the end opposite to and about one millimetre from the hot cathode consisted of iron gauze This grid-plate combination was maintained about 200 volts positive with respect to the filament

Using as high a filament temperature as could be safely maintained, and a residual gas pressure of carbon monoxide of about 10^{-4} cm or less, the radiation inside the cage exhibits chiefly the comet-tail bands with traces of the Ångstrom bands of carbon monoxide. Close to the hot filament, however, the D lines can be observed with an estimated intensity ratio $D_2 : D_1 = 5$ when the sodium spectrum is brighter than the comet tail spectrum. As the partial pressure of the sodium decreases, however, this ratio becomes much larger and of the order of 25 to 1. Indeed, when the sodium spectrum is fainter than the comet-tail spectrum, D_2 is the only line which can be observed visually. Conditions here obviously suggest those of a comet near perihelion, and it is hoped that further experimental work may shed more light on this interesting phenomenon.

Applied Entomology.

I write to invite attention to the state of applied entomology, which seems to be capable of improvement in Great Britain and in other countries. We entomologists, whose profession it is to control or destroy the insects which carry diseases of men and domestic animals, or destroy our crops, can indeed claim that we have met with a certain measure of success, but some of us feel that the success is much less than might be expected, in view of the great amount of work which is done.

Entomology may be divided into two parts—the study of form and the study of function. It is the former (anatomy, both of adults and of early stages, systematics, etc.) which leads to correct identification, and enables us to preserve an orderly arrangement in our study of the half-million species of insects which are already known This is clearly of great importance, and on the whole one may say that it is well done. But the study of function—physiology in a wide sense of the word—is of even greater importance, because it is on a knowledge of all the vital activities of the insects that we base our control of them. I believe that the physiology of insects has been done in a superficial and disjointed manner, and that the reason is that the majority of workers feel compelled to produce results of some obvious practical importance. I believe that real progress will not be made in applied entomology until this mistake is realised, and until we devote time and labour to the study of the fundamentals of insect physiology.

For example, we know that the spread of plague is to some extent influenced by the effect of temperature and humidity on certain species of fleas; but we do not understand why high temperatures are fatal to some insects, or whether the effect of humidity on insects should be measured as relative humidity, or as saturation deficiency, or in what other way. Again, we know that the greater part of the response of an insect to its environment can be analysed into a number of tropisms, which are relatively simple. We scarcely study these problems of psychology, though it is possible that if we knew the stimuli which control the insects' behaviour we could predict or even alter the behaviour. As an example of this, it has been recently shown that if certain stimuli, such as darkness, are supplied, a species of mosquito will come freely to lay its eggs in water containing arsenic, which is fatal to the larva as soon as it leaves the egg. Then, again, most of the poisons which we use are in favour because they are known to be toxic to vertebrates. We lave the fair face of Nature with copper sulphate, and then powder her with Paris green, but we cannot find enough time to make a thorough study of the toxicology of insects.

I believe that progress in the control of noxious insects is at present hampered by our ignorance of the physiology of insects in general. By physiology I mean not only the study of the functions of isolated parts of an organism, but also the extremely difficult task of understanding the relations between the living insect and the whole of its environment, inorganic and organic.

The Anomalous Flocculation of Clay.

In recent years it has become common to speak of the flocculation of clay by calcium salts as being 'anomalous,' the particular anomaly being that whereas clay suspensions containing a little sodium chloride are stabilised by the addition of sodium hydroxide, in the case of calcium the flocculation is said to be facilitated rather than repressed by the addition of the alkali. Careful experiments, however, made with a highly purified clay suspension, have convinced us that this anomaly does not exist, and that calcium and sodium compounds behave alike except in respect to the concentration required for flocculation. The following figures show the concentration in equivalents of cation required for flocculation to be half completed in one hour, this being determined nephelometrically:

	Concentrations multiplied × 10⁴.	
	Sodium.	Calcium.
All chloride	70	5·6
All hydroxide	480	16 8
Two equivalents of chloride to one of hydroxide	560	19 3

These results are parallel and do not suggest anything more than that compounds of calcium are much more powerful flocculants than those of sodium

In carrying out this work, however, a much more interesting phenomenon has been noticed. If to a dilute clay suspension be added gradually increasing quantities of certain mixtures of chloride and hydroxide, and the effect on the flocculation or otherwise of the clay determined nephelometrically after one hour's standing, it is found that the flocculating effect first increases very rapidly with concentration, then rapidly falls off and then again increases without further falling off. The following table shows this for a few mixtures, and also exhibits the similarity in behaviour between sodium and calcium compounds. ' + ' means flocculated (one-half or more down in one hour), and ' – ' means no flocculation observed in an hour.

Conc × 10³ for Sodium Conc. × 10⁴ for Calcium.	5	20	40	60	80	100	120	140	160	180	200
$NaCl : NaOH$, 50 : 1 .	–	+	–	–	+	+	+	+	+	+	+
$NaCl : NaOH$, 175 : 1 .	–	+	+	+	–	–	–	–	+	+	+
$CaCl_2$, $Ca(OH)_2$, 2 : 1 .	–	–	–	–	+	+	+	–	–	–	+

In the case of sodium compounds, the phenomenon is exhibited with ratios for chloride to hydroxide varying between 25 and 175 to one: for calcium it is only shown in the neighbourhood of the ratio 2 to 1. Other mixtures do not show a minimum in the flocculation curves.

Interesting information is being obtained from the *p*H measurements of the mixtures at critical points, and it is hoped to publish a complete account of the observations shortly.

Khartoum, March 16.

X-ray Identification of the Higher Fatty Acids.

The fatty acids of higher carbon content than stearic acid are of general interest because of their occurrence in oils and fats now employed for edible purposes. Ultimate chemical analysis of higher fatty acids is inconclusive, because of the very slight percentage differences in the elementary composition of these closely related homologous substances, but X-ray examination gives data which are more decisive (Müller, *Chem. Soc. Trans.*, 1923, 123, 2043; Müller and Shearer, *ibid.* p. 3156).

In pursuance of our researches on acids from vegetable fats, including arachis or peanut oil (Morgan and Bowen, *J. Soc. Chem. Ind.*, 1924, 43, 346*T*; Morgan and Holmes, *loc. cit.*, 1925, 44, 108*T*, 219*T*, 491*T*), we have recently isolated from this oil an acid melting at 77° which has been shown by X-ray examination to be a C_{26} acid, almost certainly possessing an unbranched carbon chain. We are indebted to Dr. E. A. Owen of the National Physical Laboratory for the X-ray photograph.

This physical evidence confirms an observation published recently by Holde and Godbole (*Ber.*, 1926, 59, 36), who have shown that arachis oil contains a hexacosoic acid (m.p. 79°), this acid giving by alkalimetric titration a molecular weight of 394 (calculated 396).

As the chemical constitutions of higher fatty acids from arachis oil have recently been a matter of controversy (Ehrenstein and Stuewer, *J. prakt. Chem.*, 1923, 105, 199, and Cohen, *Proc. K. Akad., Wetensch., Amsterdam*, 1925, 28, 630), we are now examining the chemical and physical properties (including crystal structure) of certain higher fatty acids having branched carbon chains of predetermined configuration.

The Campaign against Prickly-Pear in Australia.

WORK OF THE COMMONWEALTH PRICKLY-PEAR BOARD.

By ALAN P. DODD, Officer-in-Charge of the Investigations.

THE Commonwealth Prickly-Pear Board was instituted in 1920 to study the possibilities of the control of the prickly-pear pest in Australia by means of biological agencies. Previous investigations had established the fact that in its native home, America, prickly-pear is attacked by various insects and fungus diseases that appear to be confined to plants of the cactus family.

The Board at once commenced operations in North America, and has employed investigators in that country since; a more or less comprehensive survey has been carried out in the cactus regions of the United States, and brief excursions have been made into Mexico. South America, Argentine and Uruguay have been explored to a considerable extent. In the present year more extensive operations are planned in Mexico.

During the earlier portion of the work, attention was paid to the fungus and bacterial diseases of the cactus family, but owing to the need for special research in this subject and the inadequacy of the Board's finances, the work was allowed to lapse temporarily. However, in 1925, a research scholar in mycology was appointed and has commenced studies in the laboratories of several universities in the United States.

THE WORK IN AMERICA.

The cactus family is botanically a rather isolated group, and has evolved a considerable insect fauna that appears restricted to plants in the family. In the United States alone, the Board's entomologists have made known more than sixty species of insects that are primarily cactus feeders; in Mexico and South America other species occur; a number of these has proved new to science.

The work in America consists of the study of the insects in the field, and the breeding and forwarding of numbers of reared material, free from parasitic enemies, of all species that promise to be of use in the control of prickly-pear in Australia. Before shipments are sent, tests are carried out with each insect in order to ascertain the possibility of its being able to develop on other plants. These tests have given interesting results, and more than one insect has been eliminated because the tests showed that it was capable of sustaining its life cycle on certain economic plants. The tests are repeated in Australia against economic plants and native trees.

To date, about forty different species of cactus insects have been forwarded to Australia, in most cases many thousands of each.

THE WORK IN AUSTRALIA.

In Australia the Board has established a central laboratory at Sherwood, near Brisbane, and field stations at Westwood, near Rockhampton, Chinchilla, two hundred miles west from Brisbane, and Gravesend, on the Moree-Inverell railway in New South Wales. Sherwood acts as the quarantine station where the insects are received from America and bred through one generation to eliminate further the risk of the introduction of parasites that might exercise a serious check on the rapid multiplication of the desired insects; the bred material is then distributed to the field stations. The equipment at the field stations consists of insectaries and a great many breeding cages of various types. The function of these stations is to rear the insects in sufficient numbers to permit of liberations in the open.

Throughout the investigations one of the chief difficulties has been the acclimatisation of the introduced insects. It must be remembered that the seasons in North America are the reverse of those in Australia; thus, when an insect should be hibernating in the North American winter it must be actively feeding in an Australian summer. With most of the insects, repeated shipments over a period of two or three years have been necessary to secure their establishment in the rearing cages; indeed, certain species have quite failed to adapt themselves, either through the unsuitability of caged conditions, or to differences in climate.

Another phase of the work has been the study of the adaptability of the insects to Australian prickly-pears The two main species involved in Australia are the common pest pear, *Opuntia inermis*, and the spiny pest pear, *O. stricta*; lesser pests are the velvety tree pear, *O. tomentosa*, the smooth tree pear, *O. monacantha*, and the tiger pear, *O. aurantiaca*, while several other forms are found in scattered quantity. Very few cactus insects will attack all prickly-pears indiscriminately; most of them show a decided preference for certain forms, and in some cases will readily attack one pear and refuse to live on another.

INSECTS SUCCESSFULLY INTRODUCED INTO AUSTRALIA.

Of the insects successfully introduced into Australia, the most widely known are the cochineals, of which the most important is the wild cochineal, *D. tomentosus* Three strains of this insect have been brought into the country from Texas, Arizona, and Chico, California, the two first by the Board, the last by independent action. All three will live readily on the two chief pest pears, but the virulence of the attack varies. The Chico cochineal is most destructive to the common pest pear, *O. inermis*, the Texas form favours the spiny pest pear, *O. stricta*, while the Arizona strain seems to be equally suited by either plant. These cochineals are being widely spread throughout Queensland and New South Wales. They are doing splendid service in many places, especially in dense pear in timbered areas, breaking up the plant masses and destroying old plants; but probably the most useful feature of their work is the manner in which they attack the young seedlings. The Indian cochineal, *D. indicus*, was introduced in 1913 by the Queensland Prickly-Pear Travelling Commission, and will exist on the smooth tree pear, *O. monacantha*, only, completely destroying large clumps of this plant in the space of a few months.

Of the plant-sucking bugs, several species of the genus Chelinidea have been acclimatised; *C. tabulata* has been liberated in many places and has increased at a very rapid rate in the field; in fact, in some localities, millions must now be present from small numbers set free in the past two or three years. *C. vittiger* has also been released at various places.

Of the internal-feeding caterpillars, one species, *Melitara junctolineella*, has been readily acclimatised; about a million have been liberated, and it is now firmly established in several localities. These caterpillars are solitary in habit, and tunnel within the joints or pads of prickly-pear. A related insect is *Melitara prodenialis*, but the caterpillars are social in habit, a number feeding together within the pear pads; recently this species has been set free in the Westwood district, and promises to be especially useful as a pear destroyer.

One of the most recent of the Board's importations has been strikingly successful in so far as rapid increase is concerned. This insect is *Cactoblastis cactorum*, a social caterpillar allied to the Melitaras. Less than three thousand larvæ arrived from Argentine in May 1925, but the increase has been so great that in February and March 1926, nine months later, sufficient stocks had been raised to warrant the release of two and a half millions throughout the pear areas. These caterpillars are voracious feeders, and should the increase in the field be sustained at one-half the rate experienced in the cages, great destruction of pear should be brought about.

Many other insects are being bred and acclimatised, and the Board is continuing the introduction of new forms, believing that the control of prickly-pear by biological means can only be brought about by the combined attack of a variety of insects operating on the different parts of the plant.

Chemical and Physical Action at Surfaces.[1]

By Dr. Eric K. Rideal.

THE subject of colloid chemistry is intimately associated with the properties and peculiarities of interfaces, of which those formed by liquids and solids are the most important. The difficulties met with in an exact study of reactions taking place in colloidal systems are greatly enhanced by their dispersity, and in addition the application of thermodynamic methods to the treatment of the two-dimensional interfacial phases becomes a problem of great complexity when these phases are subdivided and not plane but curved. For these reasons the increasing attention which is being devoted to surface phenomena is a development to be welcomed. As the late Lord Rayleigh first indicated, the properties of oil films on water studied by Miss Pockels give us valuable information on molecular magnitudes, a view which has been emphasised and amply confirmed by the able experiments of numerous investigators, notably Devaux, Langmuir and Adam.

An examination of the process of spreading of oil films and their conditions of equilibrium presents several features which can be compared with phenomena occurring in three-dimensional systems. If a crystal of myristic acid be placed upon the surface of water a process of surface solution occurs, molecules are torn off the edge of the crystal in contact with the water by hydration of their polar or hydrophilic groups and float on the surface as a two-dimensional vapour. This process of surface solution continues until the vapour attains, as measured by the fall in surface tension of the water, the critical 'vapour pressure' value necessary for conversion into a two-dimensional liquid, the so-called expanded film of Adam. The liquid undergoes further two-dimensional compression by continued surface solution from the crystal, and if the temperature be sufficiently low, the expanded film is converted into a condensed film which may be liquid or solid. If the temperature be high, no formation of a condensed film occurs but the film remains in the expanded state. Compression does not proceed indefinitely, for the substance possesses but a finite surface solubility at a constant temperature and a saturation equilibrium is attained.

Both the rate of spread, which in the case of a rapidly spreading acid, such as oleic acid, rarely exceeds a linear speed of 25 cm. per second, as well as the progress of surface saturation and the transformation of the two-dimensional vapour into the expanded and condensed states, can readily be followed by observing the changes in surface tension at different points on the water when a cylinder of the acid is plunged below the surface. In the case of the spreading of solid acids, the rate of surface solution is so slow that no pressure gradient exists in the expanding film, but for acids which spread quickly molecules go into solution so rapidly that those already on the surface are actually pushed out by those entering, causing a local lowering of the surface tension.

For the long-chain fatty acids the molecular adhesion by the hydrocarbon tails is so great that these two-dimensional films, even at high temperatures, are analogous to vapours rather than gases. Substances which can exist in a state equivalent to two-dimensional gases on a water surface over the ordinary experimental temperature range must possess chains less than eleven carbon atoms long; these are appreciably soluble in water and their surface concentrations must be calculated by means of the Gibbs Thomson equation. It is found that if the force-area curves calculated in this manner for substances such as the short-chain fatty acids or alcohols on the surface of water, or at interfaces such as benzene-water or mercury-water, be plotted, they reproduce in all respects the pressure volume curves obtained by Amagat for gases at high pressures.

Not only can we examine the behaviour of matter in its various states in this two-dimensional system, but a knowledge of the variation of the equilibrium pressures with the temperature, and the application of the Clapeyron equation, also yields values for the latent heats of 'spreading' of these substances. We may note in addition that the potential difference existing at the boundary between a homogeneous aqueous phase and its vapour is profoundly modified by the presence of such films. From a knowledge of the surface concentration and the change in potential effected by the presence of the film, the change in electric moment caused by the introduction of one molecule of the fatty acid into the surface phase may be determined. If these be calculated for a number of organic substances, many interesting results are obtained: thus the electric moment of the fatty acids appears to reside entirely in the carboxyl group and is of a value equivalent to that produced by separating a proton and an electron to a distance of 0·06 Å.U. The moment of the alcoholic hydroxyl group is some twenty per cent. smaller. Very considerable changes in electric moment are caused by the introduction of the halogens or amino groups in place of hydrogen. Careful analysis of these changes may throw some light on the vexed question of polarity, which appears to be of some importance in organic chemistry.

---

[1] Based upon two lectures delivered at the Royal Institution on February 2 and 9.

The experimental examination of the behaviour of gases and vapours at solid surfaces is a much more difficult problem, for whereas a liquid surface is a surface of equipotential, it is almost impossible to obtain solid surfaces uniform in surface energy. Calculations from the compressibility of cubic heteropolar crystals, such as rock salt, of the surface energies of various planes, have been made by Born and more ecently by Jones; the data, although admittedly only approximate in character, indicate enormous variations from face to face. Microscopic examination of the process of crystal growth, solution and etching, likewise support this conception of a variation in the forces of adhesion to crystal facets and edges. The change from a super-cooled liquid to a crystal may be regarded as resulting in a diminution in the potential nergy of the surface as well as of the material in the nterior.

These speculations lead us to the idea that the surface of a metal prepared, say, by the reduction of he oxide at low temperatures, is not a regular and uniform, if somewhat undulatory, checker board of equipotential points, but consists of portions of minute crystal edges, planes and corners in addition to numerous keletal chains of atoms awaiting the opportunities provided by thermal agitation for slipping into a more ompact crystal lattice. Both the interatomic distance, as well as the number and variety of atoms around one particular atom, affect the field of force which contributes to the adhesional potential energy of the surface. By a process of summation we may regard he surface as containing patches of varying activity n which substances are adsorbed but not with equal acility. Adsorption on a very active patch is associated with a large heat evolution and presumably also with a large decrease in the free energy of the system, nd the patch may become saturated with gas before the less active patches are more than sparsely covered. This conception of a variation in the 'availability' of surface, as an explanation for the experimental data indicating different saturation maxima for various gases nd vapours, cannot, however, be considered a general ne, for we find that many vapours, and possibly some ases, especially when near their critical points, may be adsorbed in layers more than one molecule thick. A ifference in the amounts of two vapours adsorbed at aturation may be interpreted as due to a difference in lm thickness.

Whilst the first or unimolecular layer is held on xtremely firmly, the decrease in free energy resulting n building up the subsequent layers is but small; their formation may be regarded as due to an increase in the molecular cohesion of a molecule resulting on adsorption rather than a direct attraction of the surface for a molecule some distance away. As a convenient analogy we may cite the example of a weak magnet holding a string of iron filings. A second filing may be attached to the free end of one already hanging from the magnet, but if the first one be removed a filing will not be drawn towards the magnet from the position originally occupied by the second.

In catalytic actions also which appear to be limited in action to the primary adsorbed film, we find that those portions which are unstable and readily adsorb gases are also catalytically active. Since the measure of the catalytic efficiency of a metal is the rate of reaction, it is clear that a relatively large area of the active surface is required. A variation in the closeness of packing, as well as an introduction of foreign elements, frequently alters the rate of reaction. There appear to be at least three different types of such active surfaces on carefully prepared nickel: on one all hydrogenation reactions, including saturation of ring compounds, may be performed; on a less active area, simple double bonds undergo hydrogenation but not ring compounds; and a third area facilitates only the reduction of nitro groups. In the case of carbon containing both iron and nitrogen, there exists a large area, inactive catalytically, for the oxidation of oxalic acid; but in addition there exist areas of active carbon, active carbon-nitrogen, active carbon-nitrogen-iron and active carbon-iron complexes; these all possess different specific surface activities and different temperature coefficients for the reaction velocities. Since the products of reaction must leave the surface before new reactants can approach, it is possible that there is an upper as well as a lower limit to the strength of field on the surface which is most desirable for an efficient catalyst.

There has been a great deal of speculation, founded upon little experimental work, as to the nature of the union between substrate and adsorbate and the mechanism by which some of these complexes are rendered active. That complex organic molecules are attached by particular groups, usually the polar or lyophilic group, to metals and oxides can be demonstrated in a number of cases; the union, however, is not so intimate as in a true chemical compound of the heteropolar type, for a ready distinction in ease of reduction is to be noted in the case of films of copper or nickel oxide and films of oxygen adsorbed on the metals. Again, a few interesting observations scattered in the literature would lead us to conclude that there exists an intimate connexion between the catalytic activity of a metal and those electrons in the metal capable of being ejected in thermionic emission. Hydrogen and oxygen, it is stated, commence to combine rapidly on a platinum wire which has been heated to such a temperature that the rate of thermionic emission becomes sensible; also a tungsten wire poisoned with a suitable impurity neither effects catalysis nor emits thermions. Finally, the investigations of Richardson on the possibility of different rates of thermionic emission from different parts of a metal surface are suggestive in connexion with the concept of areas of different activities.

Whilst our present knowledge of the mode of adsorption and type of binding is very incomplete, our information on the mechanism of activation is still scantier. It is in many cases difficult to obtain a measure of the true energy of activation, not only on account of the possible variation in stability of these adsorption compounds with the nature of the surface, but also because the velocity of the reaction, from the variation of which with the temperature these energies are obtained, may be determined by some other factor than the excitation of the reactant. Apart from these additional complexities, the fundamental problem of the mechanism of molecular activation in simple uni-, and possibly also in the case of bimolecular gas reactions, cannot be said to have received a successful solution.

Almost a decade has passed since Langmuir published his most stimulating paper on surface action, which did much to renew interest in this field. An enormous volume of experimental work has been accomplished during this time and the complexities of the subject have undoubtedly increased. In spite of this it is as full of interest as it was in the time of Faraday, and whilst many of the problems unsolved then await solution now, our knowledge of the processes occurring at surfaces still continues to increase.

Obituary.

Prof. W. J. Lewis, F.R.S.

THE sudden and unexpected death of Prof. W. J. Lewis deprives mineralogy of a well-known personality. He passed away peacefully in his sleep in the afternoon of April 16 at the house of his sister, Mrs. G. T. Pilcher, at Godalming, Surrey. William James Lewis, the second son of the Rev. John Lewis, was born at Llanwyddelan in Montgomeryshire on January 16, 1847, and was educated at Llanrwst Grammar School. Entering Jesus College, Oxford, as a scholar in 1865, he took first classes in Mathematical Moderations in 1867, in Mathematical Finals in 1868, and in Natural Science in 1869. He gained the Senior Mathematical Scholarship in 1871, and was elected a Fellow of Oriel College in 1872. Not being married, he held this fellowship until his death, and the funeral service was conducted in the chapel of Oriel College.

For a time (1870–71) Lewis was an assistant master at Cheltenham College, and in 1875 he became an assistant in the Mineralogical Department of the British Museum, which at that time was under the keepership of Prof. Story-Maskelyne in the old building at Bloomsbury. On account of his health he retired from this position in 1877, and was succeeded by Sir Lazarus Fletcher. At that time Lewis was ordered abroad and given only a year to live; but in spite of that he reached his eightieth year. He took the opportunity of joining two solar eclipse expeditions, making observations on the polarisation of the corona.

Lewis had studied crystallography under Prof. W. H. Miller at Cambridge in 1874, and in 1879 during Miller's illness he acted as his deputy. He took the Cambridge M.A. degree by incorporation in 1880, and since then had lived in rooms in Trinity College. In 1881 he was appointed professor of mineralogy in succession to Miller, who had held office since 1832. Between them they had thus held the chair for ninety-four years; and it seems to have been Lewis's ambition to beat the record created by Adam Sedgwick and McKenny Hughes, who had sat tightly in the Cambridge chair of geology for ninety-nine years. Fortunately, under the new regulations, this state of affairs cannot be repeated. The professorship of mineralogy, founded in 1808, had previously been held by E. D. Clarke, the botanist J. S. Henslow, and the celebrated William Whewell, Master of Trinity, and it has been closely connected with the development of the sciences of mineralogy and crystallography. The Millerian system of notation now in general use for the planes of crystals was conceived by Whewell and elaborated by Miller and the crystallographic constants still accepted fo many mineral-species were first published by Mille in his classical treatise on mineralogy. The Cambridg collection of minerals contains much material o historical value and interest, and it has been considerably added to by Lewis, notably by the acquisitio of the Carne and the Wiltshire collections.

Lewis encouraged many more students than in th old days, and mineralogy soon became a popula Tripos subject taken in conjunction with geology He was not a prolific author, the list of his origina papers being limited to twenty-one titles, many o them only short notes. The earliest, in 1875, on th crystallography of some organic compounds, wer published in the *Journal of the Chemical Society*, an others on the crystallography of various mineral (glaucodote, miargyrite, stephanite, albite, etc.) appeared in the *Philosophical Magazine* (and reprinte as the *Proceedings of the Crystallological Society*), th *Proceedings of the Cambridge Philosophical Society*, an the *Mineralogical Magazine*; some of them being als translated into German in the *Zeitschrift für Krystallographie und Mineralogie*. Lewis delighted in th intricacies and difficulties presented by twinne crystals, and in devising geometrical methods fo dealing with the rhombohedral system of crystal In later years the material described had been collecte by himself during his many trips to the Binnentha and other mineral localities in Switzerland. In 191 at the age of seventy-two years, when alone in th Lengenbach quarry, he had the misfortune to slip an break his leg. There he lay in the snow all night, an in the morning he found a piece of wood to bind as splint, thus enabling him to crawl out and fortunatel attract attention.

The most important work written by Lewis was hi "Treatise on Crystallography," published in 1899 i the series of Cambridge Manuals. In the preparatio of this book he spared no pains, and it remains the be text-book on geometrical crystallography. He als wrote in 1913 a history of the parish of North Wraxha in Wiltshire, which included a life of his friend Franc Harrison, the late rector.

Lewis acted as secretary of the Crystallologic Society from its foundation in 1876 until its amalgamation with the Mineralogical Society in 1883, and wa librarian of the Mineralogical Society since 1890 an president in 1909–12. He joined the Chemical Societ so long ago as 1869, the Royal Astronomical Society in 1873, and was elected a fellow of the Royal Society in 1909. To many Cambridge men he was well known as the director of the Cambridge University Scholastic Agency, which he founded as a private venture in 1884, long before the official Appointments Board; and in connexion with this he worked out an insurance scheme. L. J. S.

WE regret to announce the following deaths:

Sir Henry Christopher Mance, past president of the Institution of Electrical Engineers, on April 21, aged eighty-six years.

Admiral Sir John Franklin Parry, K.C.B., formerly Hydrographer of the Navy, and president in 1919 of the International Hydrographic Conference held in London, on April 21, aged sixty-two years.

News and Views.

IN our supplement this week Prof Eddington deals with a subject which has become of the greatest importance in cosmic physics, namely, the source from which the stars derive the enormous quantities of energy which they radiate continuously into space. The character of this source and the manner in which it is tapped are fundamental questions which lie at the very heart of the problem of stellar evolution, for so long as they remain undetermined the problem cannot be solved Indeed, the very idea that stars evolve at all is derived from the observation that they radiate more energy than they receive from extraneous sources. Internal energy, or its equivalent, must, therefore, be transformed into radiation, and the change in the star brought about by the transformation is its course of evolution. Historically, it is true, the problem has been attacked most strenuously by observing the actual course of the change, regardless of its origin, on the assumption that the statistical distribution of stars with respect to physical characteristics represents the history of a single star. This method of attack, however, so long as the fundamental problem of the source of stellar energy is ignored, can, by its very nature, lead to nothing more than a description of a process of which the mainspring is unknown, and it now appears doubtful whether even that degree of success has been attained, for our confidence in the identity of a star's course of development and the statistical curve has been rudely shaken. It is therefore a matter for satisfaction that we are at last in a position to deal with the problem radically, and Prof. Eddington's admirably impartial and penetrating discussion clears the ground for action.

THE one definite conclusion that emerges from the researches of Prof. Eddington and others is that if the history of a star follows the statistical curve, or any curve approximating to it, there must be a transformation of matter into radiation by annihilation of electrons and protons, unless current theories are hopelessly on the wrong track. The existence of such a transformation, revolutionary as it would have appeared a few years ago, has perhaps been accepted somewhat too readily, and Prof. Eddington very opportunely directs attention to some of the difficulties which it involves. It may, as he says, be possible to wriggle out of them, but it would be much more satisfactory if they released us of their own accord. It may be questioned, however, whether he has given sufficient weight to the physicist's objection to a critical stellar temperature of transformation, at any rate, the physicist is entitled to invite him to pursue his reply to its logical conclusion Speaking of the less drastic change of hydrogen into helium as an example, he says: "But helium exists, and it is not much use for the critic to urge that the stars are not hot enough for its formation unless he is prepared to show us a *hotter place*." The critic might retort that protons and electrons also exist, and presumably were created, and if a critical temperature suffices for their destruction, it might also permit their creation. If that process also takes place in the stars, the whole problem takes on a different aspect. But whether occurring in the stars or elsewhere, the creation of matter can scarcely be ignored in a cosmology which gives a prime importance to its annihilation.

ON May 6 Prof. Sigmund Freud reaches his seventieth birthday, and the occasion is being celebrated by the International Psycho-Analytical Association, branches of which are now established throughout Europe, in the United States, and in India A sum of money raised by the various constituent societies of the Association will be presented to Prof Freud to be used by him in aid of some work or individual worker in the field of psycho-analysis, and a large number of his co-workers and associates from various countries will be present in Vienna on May 6 to take part in the commemoration. Further, there will be special articles in the two European journals devoted to the study of psycho-analysis—*Die Zeitschrift* and *Imago* (Vienna)—and also in *The International Journal of Psycho-Analysis* (London), written by intimates and co-workers of Freud. Almost synchronising with his birthday is a new development in London in the shape of the first Psycho-Analytic Clinic, to be established this month by the Institute of Psycho-Analysis, which will become, it is hoped, a worthy memorial to Freud's work and inspiration In his own town of Vienna (Freud's actual birthplace was Freiburg, but since 1860 he has been associated with Vienna), of which he was made a freeman about two years ago, the municipal authority wished to make some public recognition of its great citizen, but Freud declined the honour Indeed, it is characteristic of Freud that he has always refused to come personally into the limelight, no matter how far and wide the echoes of his work reverberate.

To scientific workers it is unnecessary to stress the significance of Freud's work: it will suffice to say that whatever the future may reveal to modify his discoveries, through his work the whole outlook of psychology has been once and for all altered. Further, owing to this change, innumerable spheres of thought have been influenced and future investigators will utilise, knowingly or unknowingly, those discoveries in the realm of mind which are the outcome of Freud's genius aided by his life's unremitting labour. In accord with the continuous development of his thought, this year has seen the publication of a volume embodying his latest research on the important subject of anxiety: in "Angst, Hemmung, und Symptome," the problems of anxiety, inhibitions in relation to anxiety, and the creation of anxiety-neurosis are shown in fresh aspects. Freud himself has written that he does not know whether the developments from his work will be much or little, but that he has made many beginnings and has stimulated much thought and inquiry. The verdict of posterity will surely subscribe to his estimate save on the score of its modesty.

ON May 4 occurs the bicentenary of the birth of Major-General William Ray, a distinguished military engineer and one of the originators of the trigonometrical survey of Great Britain. Born in Lanarkshire and educated at Lanark Grammar School, at twenty years of age Ray entered the army and was immediately employed on road-making and map-making in Scotland. This was long before Telford's beneficent labours. Rising steadily in the service, Ray saw active service in Germany during 1759–63, and in 1765 became surveyor-general of the coasts and engineer for making military surveys of Great Britain. By 1783 he had become colonel of the Royal Engineers, and in the following year he measured the famous base on Hounslow Heath, 27,404 feet long. This work attracted much attention at the time, and the Royal Society awarded Ray the Copley Medal. From this base line the triangulation was carried down to the south coast, a verification base line of 28,535 feet being measured on Romsey Marsh, and on September 23, 1787, Ray met the French Commission which had carried the survey of France northward from Paris. With this work Cassini, Mechain and Legendre had been connected, the object being the determination of the relative positions of Greenwich and Paris observatories. Shortly after this Ray went to Lisbon for his health. He returned in April 1790, but died suddenly at his house in Argyll Street, London, on July 1, 1790, while engaged in correcting proofs of a paper for the Royal Society. Many of his maps are in the British Museum.

THE institution of experiments in the care of animals, which will be followed with much interest, are recorded in the "Reports of the Council and Auditors of the Zoological Society of London for 1925," presented at the annual meeting of the Society on Thursday, April 29. Observations on a limited scale have indicated that animals, especially natives of tropical climes, thrive better in the presence of radiant light and heat and in an atmosphere of cold fresh air associated with warmed shelves. Accordingly, the cave-shelters in the new rock-work enclosure behind the Mappin Terraces, which accommodate a troop of 80 Hamadryas baboons, have been fitted with wooden shelves warmed from below by electric radiators and lighted from above by quartz incandescent lamps, which are permeable to ultra-violet rays. Some of the outside rocky ledges have also been warmed electrically and lighted by quartz lamps which can be turned on to diffuse 'artificial sun-light' when the weather is dull. Similar fittings, which, for upwards of a year, have been tested with delicate monkeys, such as a young orang-utan and marmosets, in the full-size model of part of a proposed new Ape and Monkey House, have given most promising results. In furtherance of the same policy, an attempt has been made to utilise the full value of natural light by replacing the ordinary glass of the whole roof of the lion house by 'vitaglass,' which is permeable to the ultra-violet rays of the sun. The success of these experiments would cause a revolution in the lighting and heating of the shelters and cages in zoological gardens, and a much-needed amelioration in the living conditions of many tropical animals, which in most gardens and under the best conditions are subject to a heavy disease and death rate.

DR. H. J. ROSE delivered a lecture on "Prehistoric Greece and Mother-right" to the Folk-Lore Society on April 21. The lecture was an elaboration and extension in the light of further research of an article contributed by Dr. Rose to *Folk-Lore* in 1911, and a confirmation of his earlier conclusion that no evidence of mother-right existed in early Greece. Such possible sources of evidence as the well-known inscription at Kos, the Code of Gortyn, the two plays the "Suppliants" and the "Eumenides" of Æschylus, and the genealogies from the old historians and from Pausanias which have been interpreted by many authorities as indicating a matrilinear system, were discussed in detail. The entries of the Kos inscription, which state specifically that the right to participate in the sacred rites was derived from the mother, are regarded by Dr. Rose as exceptional cases, probably due to the peculiar position occupied by heiresses under Greek law, and the stories of the Danaids and of Orestes and Clytemnestra as told by Æschylus were rejected as warranting an assumption of mother-right after a close consideration of the plays themselves. The genealogies were compared with the earlier traditions on which they were based, and were shown to be frequently at variance with them and not therefore wholly trustworthy as evidence. The paper is to be published in an early issue of *Folk-Lore*.

A LOST city of the Mayas in Yucatan is described in a further account of Dr. Gann's journey of exploration in Central America, which appeared in the *Morning Post* of April 19 and two succeeding days. A reference to a migration of the people of Chichen Itza eastward to "the settlement of the priest of Coba," in a recently translated portion of the Book of Chilam Balaam, appeared to confirm information given to Stevens in 1842 and suggested a search in the neighbourhood of Chemax, an Indian settlement in the Chichen Itza region. The result was the discovery of a city of considerable size and at present unique in presenting three distinct types of Masa civilisation. The oldest style of Maya architecture is here represented by an enormous temple, stelae, and ranges of arched rooms. It is followed by the Tuluum type, represented by flat-roof, stucco-covered buildings Last comes the Labaantum type—a great stairway similar to that discovered by Dr. Gánn and Mr. Mitchell-Hodges during their expedition last year. In no other town have these three styles previously been found together. The city probably was founded about A D. 926. Although it was occupied throughout the Toltec domination, it nowhere shows the influence of that people. A remarkable structure discovered on the road to Coba was a raised causeway, 32 ft. wide, and said by Dr Gann's native guide to be fifty miles long It was built of limestone rubble, and had been cemented on the surface Dr. Gann is of the opinion that it must have been a sacred way for ceremonial use from Chichen Itza to Coba Nothing like it is known elsewhere in Maya culture.

AT the meeting of the Circle of Scientific, Technical and Trade Journalists on April 19, Mr. J. G Pearce opened a discussion on "A Clearing House for Information: its Value to Science and Industry, and its relation to the Press" Mr Pearce gave an account of the work of the Association of Special Libraries and Information Bureaux, with which he is prominently associated. He remarked on two main characteristics of these times. the vast increase in the amount of "fact-information" available, as a consequence of scientific and industrial research, and the greater appetite for such information on the part of the general public The press fulfils a most useful function in making such information known, but much of it is stored away and unknown to those in need of it. On the Continent efforts have been made to initiate vast schemes of filing and tabulating all available information. But such methods, though admirable as repositories for the future historian, are too complicated for everyday use. He therefore advocated the establishment of information bureaux and the setting up of a "clearing house" which would prepare a directory of sources of information in Great Britain. In the course of the discussion a letter from Mr. Bradford, the Director of the Science Library, South Kensington, was read. He referred to the unique resources of this Library and the tabulation of foreign bibliographies which is being undertaken, and suggested that a simple extension of its organisation would suffice to convert the Science Library into a general bureau of information There was an interesting discussion, and general agreement was expressed with the principle of linking up existing libraries and rendering their contents better known To the technical journalist, any steps likely to make such information more readily accessible will be of special value.

ANY misgivings as to the nature and effect of the restoration work on the Sphinx carried out by Mr. Baraize under the Egyptian Department of Antiquities during the past winter should be allayed by the detailed account given by the Cairo correspondent of the *Times* in the issue of April 23. There is no doubt that the work was urgently necessary. It would appear that the head was in an exceedingly bad condition Huge cracks and cavities had appeared in the head-dress, part of which, together with the back of the neck, had been completely eroded. In fact, there was danger that the head might topple forward. There was also a deep gash on the left side of the head. All these cracks have been filled in, masonry has been built on to the back of the neck to preserve the centre of gravity, and two pieces of the head-dress found on the ground have been replaced A hole in the head, which might have been made anciently by treasure hunters, and is large enough to take a man standing erect, has now been fitted with an iron cover. The clearing away of the sand, which had silted up to the shoulders, has revealed the serious extent of the erosion caused by wind-blown sand, after the limestone casing repaired by Tothmes IV and the Ptolemies had been removed for building purposes. In contrast, the stonework now uncovered has all the appearance of being new. An interesting result which has emerged owing to the work of restoration, is the confirmation of the story that the monument was repaired by Tothmes IV. The striking lack of proportion between the head, the body and the paws has also been revealed.

PROF R WHIDDINGTON in his Friday evening discourse at the Royal Institution on "The Luminous Discharge through Rare Gases," delivered on April 23, stated that it has been known for a long time that when a gas in a glass tube is reduced in pressure, a stage arrives when an electric current can be passed with comparative ease along the length of the tube. One of the most striking effects of the current is the luminosity it produces in the gas. The tube becomes a source of light, just as the filament of an electric lamp does when the current passes through it. There is this fundamental difference, however, between the two cases. In the electric lamp filament the current is regarded as being carried wholly by electrons which, in threading their way through the closely packed and practically immobile atoms of the metal filament, produce the heat which raise it to incandescence. In the case of the gas in the discharge tube, the atoms are free to move as well as the electrons, which involves (*a*) that the atoms, when bombarded by the current-carrying electrons, frequently lose electrons themselves, becoming ions, and therefore assist in carrying the current by moving in a direction opposite to that of the electrons; (*b*) the gas in the tube emits light of a definite set of colours characteristic of the gas. In the case of the rare gases (argon and neon have been examined so far) new effects have been observed and interpreted. If a tube containing neon is viewed in a rotating mirror, it will be observed to be crossed by two sets of dark bands. The very broad sets are due to the alternating nature of the electric supply, but the very narrow bands are due to the mechanism of conduction of the current by ions and electrons.

As part of his course of lectures on "Organs of Multiple Function" delivered at the Royal Institution, Prof. J. Barcroft on April 21 dealt with the spleen. Of all the bulky organs of the body the function of this alone has not been fully elucidated. The ancients are alleged to have improved the athletic potentiality of their runners by cutting this organ completely out, their argument being that the spleen was the seat of that unpleasant sensation, the stitch; but this does not appear to be justified by the records. Later it became associated with testiness of character. It is nowadays sometimes excised without fatal or even very distressing effects. Thomas Gray expressed his view of the spleen as being for the purpose of regulating the quantity and quality of the blood. Within this phrase can be grouped a multitude of functions. We may address ourselves to two: one affecting the quality and the other the quantity. The spleen is a muscular bag which when it distends becomes engorged with blood; yet this blood is not ordinary blood. For the spleen is also a sieve, at least functionally, and it appears to sift out and fill itself with red corpuscles of a certain kind. The variety selected is that which is reputed to be the oldest, and is most easily broken down by exposure to reagents, such as dilute salt solution. These corpuscles appear in many cases to die in the spleen, so that the spleen has become the reputed cemetery of red corpuscles. As regards quantity, in many animals the extent to which the spleen can absorb blood is such that a considerable proportion of all the blood in the body can be held by the spleen. When the body needs blood the spleen empties itself into the general circulation. This is the case when exercise is taken, when the animal is slowly poisoned with coal-gas or if the animal loses blood by hæmorrhage. On the other hand, if unnecessary quantities of blood are in circulation, the spleen dilates and blood is withdrawn. Such would appear to happen when undue strain is put on the heart

EDUCATION and research in forestry continue to make good progress at Oxford. The Imperial Forestry Institute started work in October 1924; and its first annual report has just been issued by the Director, Prof. R. S. Troup. Advanced courses of instruction in the ordinary forestry subjects were given by the Director and eleven lecturers, of whom two, a silviculturist and an entomologist, are attached to the Institute by the Forestry Commission. The students, 22 in all, included 11 post-graduate probationers for the British and Colonial Forest Services, 8 forest officers on leave from the Colonies and India, and 3 students doing special work on the structure and properties of wood A special feature in the training was the practical instruction given on the Continent for the purpose of studying the latest developments in silvicultural systems, forest management and exploitation. Some of the Colonial students studied systematic botany at Kew. The staff of the Institute was fully occupied during the year in giving courses of instruction, in procuring equipment and material for study and in other preliminary duties, and had no opportunity for research work; but this will be prosecuted when the Institute is in full working order. At the School of Forestry, Oxford, 32 students attended during the academic year 1924–25 the usual courses of instruction for the Degree and Diploma in Forestry.

IN his inaugural address on April 20, Prof. Lelean, the newly appointed professor of public health in the University of Edinburgh, said that it is a hard doctrine for individuals that the grown-ups of every generation have already had their day. But it is a worse doctrine for the race that 95 per cent. of the available funds should be spent in tinkering with the present C3-ridden generation while only 5 per cent. is expended upon the evolution of a new generation so fit that it can defy disease. Expectant mothers and growing children should be placed under conditions so physiologically-favourable that the next generation will be overwhelmingly A1. He urged the elimination of non-essentials in education, and stated that some at least of the younger children are being pressed beyond their mental powers, and that a large proportion of the older children, especially in the better-class day schools, are being seriously overworked—the result of too high examination standards and overloaded curricula. He advocated a lowering of the present examination standards and education curricula, a reduction in the amount of home work, and a seat for some physiological expert—preferably the school medical officer—on every education committee in Great Britain.

THE first conversazione this year of the Royal Society will be held on Wednesday, May 12, at 8.30 o'clock.

SIR NAPIER SHAW, honorary member of the International Meteorological Committee, has been elected an honorary member of the Norwegian Academy of Sciences, Oslo, in the Class for Mathematics and Natural Science.

THE tenth lecture of the series, "Physics in Industry," being given under the auspices of the Institute of Physics, will be delivered by Mr. H. E. Wimperis, Director of Scientific Research, Air Ministry, who will take as his subject, "The Relationship of Physics to Aeronautical Research." The lecture, which will be open to the public, will be given in the Physics Theatre, Royal College of Science, Imperial Institute Road, South Kensington, S.W.7, on Tuesday, May 11, at 5.30 P.M.

IN our issue of December 26, 1925, p. 935, Prof. R. A. Sampson, President of the International Time Commission, announced that a new series of wireless time signals issued by the International Time Bureau at Paris would be in operation from the stations Eiffel Tower (FL) and Lafayette, Bordeaux (LY), from January 1 until April 30. It has now been decided to continue them as at present for a further period. Notice will be given when a change is made.

THE Society for Experimental Biology held its spring meeting at the Marine Biological Laboratory, Plymouth, on April 17 and 18. The programme included a symposium on the regulation of the environment and its effect on plants and animals, by Messrs. J. T. Saunders, W. H. Pearsall, and B W. Keen, dealing respectively with marine and fresh-water plankton and soil organisms and conditions. Dr. F. S. Russell contributed a paper on the factors affecting the vertical distribution of plankton, and Dr. E. M. Delf and Mr. A. D. Cotton discussed certain aspects of the ecology of marine algæ. There were numerous exhibits, as well as further papers on ciliary control, muscle contractility, and the œstrus cycle. About eighty attended the meeting, which included excursions to Cawsand and concluded with a dinner.

BY an Order of the Committee of Privy Council, Lieut.-General Sir William B. Leishman, director-general, Army Medical Services, has been appointed a member of the Medical Research Council. The vacancy thus filled was consequent upon the recent approval of amendments to the Royal Charter of the Medical Research Council, which provide *inter alia* for an increase in the number of members from ten to eleven. Under the amended charter, two of the eight scientific members will retire in each year, and one of the three other members in each second year, the scientific members being not eligible for re-appointment before the end of one year after retirement

THE Minister of Health will open the new laboratories of the Pharmaceutical Society of Great Britain on Wednesday, May 5. These laboratories were established by the Society for the testing of those therapeutic substances which will be scheduled under the Therapeutic Substances Act 1925. They comprise among other substances such important medicinal agents as digitalis, strophanthus, ergot and pituitary extract, the purity and potency of which cannot adequately be determined by chemical means The laboratories are being carried on under the direction of the council of the Society with the assistance of an advisory committee, including among others Sir Humphry Rolleston, Sir Nestor Tirard, Dr. H. H. Dale, and Prof. W. E. Dixon of Cambridge. Dr. J. H Burn has been appointed director of the new laboratories, and it is intended that pharmacological research should be carried on in addition to the routine testing of therapeutic substances.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned.—An assistant lecturer in mechanical engineering at the Brighton Technical College—The Secretary, Education Offices, Old Steine, Brighton (May 26). A professor of physiology at the Royal College of Surgeons in Ireland—The Registrar of the College, Dublin (May 28). Part-time lecturers in public health, and forensic medicine and toxicology, in the University of Bristol—The Registrar (May 30). A principal of the County Technical School, Stafford (candidates to be engineers) — The Director of Education, County Education Offices, Stafford (May 31). A head of the engineering department of the County Technical College, Wednesbury, and county lecturer in engineering for South Staffordshire—The Director of Education, County Education Offices, Stafford (May 31). A chemist at the Aeronautical Inspection Department Test House, Kidbrooke, S E.—The Secretary, Air Ministry, Adastral House, Kingsway, W C 2 A temporary metallurgist under the Directorate of Metallurgical Research, Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S E.18.

Our Astronomical Column.

FIREBALL ON APRIL 9.—Mr. W. F Denning writes that a brilliant fireball was observed passing over the east of England on April 9 at 11.30 P.M. G M.T It was seen from various places in the eastern counties and so far north as Westgate, Durham, but the late hour at which the object appeared must have greatly limited the number of its observers. The meteor was of remarkable brilliancy, for it vividly illuminated the country-side, and its sudden apparition on a moonless night was of somewhat startling character. It moved slowly and the nucleus threw off a number of red sparks, but the duration of flight did not exceed five seconds according to the careful estimate of a spectator near Harwich

The radiant point appears to have been in Virgo, at 208° − 11°, and the height of the object declined from 71 to 42 miles during a path of about 71 miles with a velocity of 15 miles per second. The meteor passed from over the south part of Essex to north of Norfolk, its motion being directed from S by E. The radiant in Virgo is that of a well-known April shower which has been frequently recognised in past years, and particularly on about April 8.

RELATIVITY SHIFT OF SOLAR SPECTRUM LINES.—In the *Proceedings of the National Academy of Sciences*, vol. 12, No 2, Dr. C. E St. John, of the Mount Wilson Observatory, makes a further contribution to the problem of the relativity shift of the solar spectrum lines. In a study of 331 iron lines, he finds a general displacement to the red, as required by the theory of relativity, but the amount of the displacement agrees with the theoretical value only for the lines of moderate intensity. Strong lines are displaced about 50 per cent. too much, and weak lines about 30 per cent. too little The explanation offered is based on the assumption that the deviations from theory are connected, not directly with intensities but with the levels in the sun's atmosphere at which the lines originate, these levels being indicated by the intensities. The observations can then be accounted for in terms of three disturbing influences: (1) The relativity displacement, affecting all lines in all parts of the sun; (2) radial movements of the atmospheric gases, downwards at very high and upwards at very low levels, these produce a maximum effect at the centre of the disc and no effect at all at the limb; (3) differential scattering, tending to widen the lines at the red edges, and producing a much greater effect at the limb than at the centre of the disc because of the greater depth of atmosphere traversed. The last-named influence is held to account for the so-called 'limb-effect,' which has long been known

Research Items.

Prehistoric Discoveries at Prestatyn.—Some interesting evidence bearing upon the possibility of the survival of a palæolithic people in Wales into the Neolithic and Bronze and even into the Iron Ages has been obtained from excavations carried out during the last two and a half years in the neighbourhood of Prestatyn. According to a recent lecture by Mr. F. Gilbert Smith, delivered under the auspices of the Dyserth and District Field Club, the 'Byrn Newydd' people began to settle in that area after the last phase of the Ice Age. The original site of occupation is directly on the boulder clay, now from one and a half to five feet below the present surface level. The implement-bearing zone begins at a depth of about one foot. Of three mounds or islands in a basin of boulder clay, one, the smallest, which had been used as a workshop, had been sealed, after its abandonment, by a deposit of two feet of tufa, and had thus remained untouched by the influence of later cultures. The implements found here included a large number of typical Tardenoisian form with battered backs and cores. They are of chert of exceptional quality, and are worked with great skill. Conclusive evidence for the contact between this culture of epipalæolithic type and that of a later phase is furnished by the discovery of a flint spear-head and a polished stone celt in a 'fire-place' on one of the larger islands in association with artefacts, in the main of the type found in the workshop.

Magic in Madeira.—Mr. James Hornell has recently made a study of superstitions connected with the evil eye in Madeira, and has published in the *Journal of the Royal Anthropological Institute*, Vol. 55, Pt. 2, an account of those in which the horns of various animals or substitutes therefor are used to avert evil. There is little overt evidence of this use, and indeed it was denied except in the case of protecting pigs against "bad air." Further inquiry showed, however, that the horns were used in several different ways. In fishing-boats they are employed as amulets against envy or the evil eye, but great secrecy about them is preserved, and they are kept in lockers under the decking. They are only mounted on the prow as a general observance when returning home on the popular festival of May 1—a pagan, not a religious festival. Horns are also used, but rarely, to protect crops. Though horns are not placed outside a house or over the door, the owner's possessions are protected by keeping a pair inside. The horns of a black goat or sheep are held to be the most efficacious. The familiar sign of the horns made with the hand is used and the amulet itself and its name are employed as a deadly insult to a married man, imputing infidelity on the part of his wife. It is probable that the use of an amulet in the form of horns is to be traced to a devil cult, the special efficacy of the goats' horns being significant in view of the belief that the devil when presiding over the witches' assemblies normally took the form of a horned goat. Further, it is to be noted that the amulet should be black.

Fœtal Ossification.—The economic conditions which existed in Switzerland during the later years of the War gave Messrs. Kupfer and Schinz opportunities of collecting in slaughterhouses a series of specimens which illustrate every stage in the development and growth of fœtal calves ("Beiträge zur Kenntnis der Skelettbildung bei domestizierten Saugetieren auf Grund rontgenologischer Untersuchungen." Von M. Kupfer und H. R. Schinz. Denkschriften der Schweizerischen Naturforschenden Gesellschaft. Band 69.) Every stage has been X-rayed, and complete records made of the sequence in which the centres of ossification make their appearance in the bones of the limbs. The results of this investigation are graphically summed up in 68 text figures, while 26 photographic plates set out very clearly some of the data on which conclusions are based. These conclusions are that in spite of the dissimilar purposes served by the limbs of the ox and of man, yet the number of centres of ossification which appear in the limbs of each is the same, and the order in which these centres appear is also the same. In the limbs of the calf all centres have appeared by the time of birth, whereas in man their appearance is extended until the age of puberty is reached. The authors also discuss the laws of ossification as revealed by their studies; their conclusions are in agreement with those which have been formulated by anatomists for the centres of the human body. Besides observing centres of ossification, the authors of this monograph have reinvestigated the cartilaginous skeleton which is laid down in the limbs of the fœtal calf. The shaft of the fibula, after being laid down in cartilage, disappears, all save its extremities, which become ossified and persist. The digits corresponding to man's great toe and thumb have no embryological representation at any stage, but those which correspond to man's second and fifth digits are formed in cartilage and afterwards undergo atrophy. Thus it will be seen that this monograph contains much new and exact information and should be accessible to all who are investigating skeletal problems. Fortunately for the progress of knowledge, the authors were able to publish their results through subventions placed at their disposal by societies in Zurich.

Expectation of Life.—It is well known that the expectation of life at birth, *i.e.* the average duration of life, has considerably increased during the last thirty years; for males in London from 41·2 years to 53·8 years. This has been brought about chiefly by a falling death-rate in infancy and the early years of life. It is not so well appreciated that the expectation of life of the elderly has not correspondingly increased during this period. This fact is discussed by Prof. Raymond Pearl (*Natural History*, vol. 26, 1926, p. 26), who finds that the evidence available does not indicate that any increase is occurring now, or has occurred, in the recorded expectation of life of persons who live to the age of 75 years or more. Still less is there any evidence that the biological upper limit of the human life span has been raised.

Marine Biological Research.—The recent issue of the *Journal of the Marine Biological Association* illustrates the general interest at the present day in the basal conditions of the environment in relation to the living organism, conditions which are at the root of economic research. The marine laboratories are naturally concerned with water-living organisms, and there are records of work by Atkins on the silica content of water, by Orr and Harvey on the nitrite and nitrate contents respectively, and by Poole and Atkins on the penetration of light into sea water. For the latter a new apparatus, consisting of photometers and photo-electric cells, is described. The other authors also bring forward improvements in technique but much further research on this side is necessary especially for the quick estimation of combined nitrogen. The greater concentration of the latter in deeper water is what is to be expected, as the phytoplankton necessarily uses up the combined nitrogen the organic proteins thus formed being afterwards broken down to simple compounds giving determinate cycles analogous to phosphates, etc. Of other matter, Russell's pelagic young of fishes is the second half of a research dealing with the vertical distribution of the macroplankton off Plymouth; it has a tentative list of distribution types, but we prefer to regard this work as preliminary to a deeper and more continued investigation. Miss Lebour completes the life histories of the Euphausidæ of the English Channel, the elucidation of which was of importance, as they are fed on largely by herring, hake, and other fishes. Dr. Amemiya records salinity experiments on the development stages of oysters. Lastly, the work of Fox on lunar periodicity in reproduction is confirmed by Orton in oysters, the normal forms in 1925 showing "three maximal percentages in spawn in the weeks after the July, August and September full moons."

FREQUENCY CURVES IN HERRING INVESTIGATIONS.—In his report of "Norwegian Fishery and Marine Investigations," Vol. iii, No. 4, Dr. Einar Lea has given an important reply to Miss Catherine W. M. Sherriff's report on her mathematical analysis of random samples of herrings ("Fisheries, Scotland," Sci Invest., 1922). Miss Sherriff was able to show that some of the empirical curves of frequency for the length of fish and for the number of rings counted on the scales, could be very well represented by one or other of the theoretical curves of variation, while others which were bimodal could be represented by the addition of two such curves. Prof. d'Arcy W. Thompson wrote an introductory note to Miss Sherriff's report, and it is the import of this note, rather than the results obtained by Miss Sherriff, which has attracted Einar Lea's attention. Lea infers that Prof d'Arcy Thompson considers the conformity between the empirical curves of frequency and the theoretical curves of variation to be a criterion in deciding whether a sample of herrings contains a single year group or several. Mathematicians will follow with interest the argument by which Lea comes to the conclusion that empirical curves of frequency, of which the similarity to theoretical curves of probability or variation cannot be doubted, may arise from and represent processes which have nothing to do with variation and variability in the sense given to these terms by Prof. d'Arcy Thompson. The curve of frequency for the length of the herrings in a random sample may easily show sufficient degree of similarity to a theoretical curve of variation even though the individuals in the sample belong to several age groups, and the curve of frequency for the number of rings on the scales may also have a form which is so like a theoretical curve of variation that it might be mistaken for one, without this fact arguing against the assumption that the rings are annual rings; and that consequently the curve of frequency represents the distribution of age in the shoal from which the sample comes.

INFLUENCE OF TEMPERATURE ON THE LOCUST.—In the *Bulletin of Entomological Research* for March 1926, Prof. V. P. Pospelov describes some experiments showing that temperature during breeding exercises great influence on the development of the locust *Locusta migratoria* L.) There is a certain limit of favourable temperature below which development of the genital products in the imagines ceases and the insects easily succumb to bacterial diseases. Young insects kept at a temperature of 35°-38° C. and with humidity near the saturation point developed rapidly, became adults, and commenced oviposition. In a second experiment, insects during their first two instars were kept under these same conditions. When in the third instar, they were transferred to a temperature of 30° C. by day and 20° C. by night with humidity at about 70 per cent.; they became sluggish, ate very little, and those which ultimately became adult failed to mature sexually and died without laying eggs. Observations were also carried out with reference to the occurrence of *Coccobacillus acridiorum* in the blood, and the results obtained confirmed the opinion of Mereshkovsky that this organism is a normal symbiont of locusts, but becomes a parasite under unfavourable conditions of temperature and humidity.

PLANT COLONISATION OF THE SEA-SHORE.—Prof. F. W. Oliver has an interesting account of the spread of *Spartina Townsendii* in the Seine estuary, between Havre and Tancarville, in the *Gardener's Chronicle* for March 20. Unlike the process of colonisation in Poole Harbour, where Spartina follows upon Zostera, on the Seine Spartina is settling upon virgin ground. As Spartina appears to have been unknown in the Havre district ten years ago, the advance made by the plant since is a very striking example of its powers of rapid colonisation. A further striking point is that in various local patches Prof Oliver seems to find clear evidence that Spartina, the coloniser, has in its turn been ousted and replaced by *Glyceria maritima*. The species is unusually luxuriant in its growth and is apparently particularly favoured by some of the local habitat conditions. In *Modern Science* for April 1926 Prof. Mangham of Southampton discusses another sea-shore coloniser, *Sueda fruticosa*, an almost evergreen, tough, woody shrub, which he suggests might be tried out as a practical method of delaying or arresting the inward movement of mobile shingle banks in various seacoast areas.

NATURAL WOUND HEALING IN TREES.—Mr. T. Swarbrick has a paper on this subject in the *Journal of Pomology and Horticultural Science* (vol. 5, No. 2, March 1926). The outstanding result is that in all the species of trees examined (in a Yorkshire area), study of the natural processes involved in healing showed that, if the wounds were made during the months May to August inclusive, they were soon blocked against the entry of disease organisms; on the other hand, wounds made in September and October may block partially, and wounds made during November to April, scarcely at all, as the result of natural changes at the cut surface. Anatomical and micro-chemical details are supplied as to the nature of this process of blocking, which is mainly due to a gradual plugging of vessels and tracheids by 'wound gum' secreted from the starch containing cells in the neighbourhood of the cut. Such blocking is much more rapid than any subsequent healing by the inward growth of callus tissue from the periphery of the cut stump These data would seem to be of interest in connexion with the practical operations of pruning, etc., by which cut surface of woody branches are exposed to the entry of disease organisms at various seasons.

MYCORHIZA.—Dr. M. C. Rayner has commenced in the *New Phytologist* (vol. 25, No. 1, 1926) a monographic account of this subject which will be of very great value to botanical workers. The literature of the subject, whilst very extensive, is so very scattered, the problem of association of fungus and flowering plant being capable of attack from so many points of view, that as a result the subject certainly lacks adequate presentation in modern text-books, and there is no doubt that an impetus to the study of a widespread phenomenon should be the result of this publication. Dr. Rayner's first instalment of this study, with its account of Kamienski's pioneer work upon Monotropa, its full analysis of the classic researches of Frank, with its quotation from the original papers and reproductions of some of the figures published by these earlier authors, certainly provides most botanists with a sounder basis upon which to commence its examination than could be readily provided otherwise save by long searching through the literature. It was also a happy idea to quote again de Bary's original definition of symbiosis, in view of the long controversy as to the relative value to flowering plant and fungus of their close relationship. De Bary, as Dr. Rayner points out, clearly intended symbiosis to include all cases of mutual relationship in life of two organisms, including parasitism.

Records of Plants.—The *Kew Bulletin* No. 2 for 1926 contains some very good photographs of the remarkable tree *Clistoyucca arborescens* Trelease, which grows in 'forests' in the Mohave desert, Los Angeles, California; it is separated from the genus Yucca mainly on account of the very thick perianth segments and the absence of a style C. E. Hubbard gives the full taxonomy of a useful fodder grass, *Paspalum Larranagai* Arech., "Vasey grass," a native of South America, it has now been introduced into North America and South Africa. L. A. M. Riley supplies notes on the flora of Rapa Island, visited by the *St. George* during the Pacific Expedition, 1924–5. Rapa is 250 miles to the S.E. of the Australs, and of the seventeen species collected there, four are apparently new to science. Under the heading "Spolia Mentawiensia," Mr. C. Boden Kloss states that it is proposed to give an account of the results, mainly zoological and to be published in various journals, which were obtained by a collecting expedition in 1924 in the Mentawi group of islands to the west of Sumatra. A beginning is made by an account of the flora by Mr. H. W. Ridley. Mr. W. B. Turrill has some notes on the flora of the nearer East in the same number of the journal.

Magnetic Observations.—The March issue of the *Journal of the Washington Academy of Sciences*, 16, p. 109, 1926, contains an interesting lecture on "The Magnetic and Electric Survey of the Earth, its Physical and Cosmical Bearings and Development," by J. A. Fleming, of the Department of Terrestrial Magnetism, Washington. The lecture sketches very briefly the historical development of terrestrial magnetic and electric observation up to its present extensive and detailed though still incomplete stage. There are now about fifty active magnetic observatories, of which less than 20 per cent. carry on electric work; 40 per cent are in Europe, and less than 20 per cent. in the southern hemisphere. The polar regions are naturally very scantily supplied, a most regrettable fact in view of the interest and importance of the auroral and magnetic phenomena which there attain special intensity. As regards the general magnetic field, even in well-surveyed regions magnetic observations must be continually repeated at regular intervals in order to keep the magnetic charts up-to-date, on account of the rapid and incalculable secular variations in the earth's field: these changes are complicated even over the deep sea.

Colorimetry.—A considerable portion of part 2 of volume 27 of the *Transactions of the Optical Society* is devoted to the methods of specifying and matching colours, and Mr. J. Guild, of the National Physical Laboratory, adds considerably to our knowledge of the theory and technique of the subject by his three papers. The standard method of specifying a colour is by the amount of each of three chosen 'primary colours' which, when mixed together, match the given colour. Mr. Guild points out that so long as the three primary colours produce white when properly mixed, no special significance attaches to the particular colours chosen, but for convenience he uses a red of wave-length 63×10^{-6} cm. obtained by a Wratten No. 71 filter, for the green a wave-length about 54×10^{-6} cm. obtained by a Wratten No. 62, and for the blue a wave-length 45×10^{-6} cm. by a Wratten No. 49 B filter. For colours of high spectral saturation which are not conveniently dealt with by the trichromatic instruments, Mr. Guild has devised a monochromatic plus white colorimeter which retains the advantage of using spectral colours.

Colour Kinematograph Films.—The method of producing colour kinematograph films by the 'Technicolor' process was described by Mr. Leslie Eveleigh at the Royal Photographic Society on March 30 (*British Journal of Photography*, April 9, p. 215). It is a two-colour process, using standard film, and the pictures are projected by the usual standard apparatus. The colour records are taken alternately by means of a camera that has a prism light-divider behind the lens with an orange-red filter for one and blue-green filter for the other, the two images being foot to foot; that is, the images of one colour being erect, while those of the other colour are upside down. A specially exact perforating machine has to be used to ensure a sufficiently perfect registration of the subsequently superimposed pictures. In printing, the negative is shifted two spaces and the positive one, so that only the red sensation pictures are printed, and then, on another film, the blue-sensation pictures are similarly printed. The two positives, before development, are brought back to back, the cementing liquid is sprayed on to them, and by pressure they are firmly cemented together. The compound film is then developed, washed, dried to a tacky condition, and passed over the surfaces of the necessary dye solutions, first one surface being dyed red and then the other surface dyed blue. Excess of the dye solutions is removed by suction, and when dry, both sides are sprayed with varnish, and the protection so afforded is so complete that the final film may be soaked in water for even two hours without damage. The cost is about 3*d*. a foot, while the ordinary monochrome film costs 1½*d*. a foot.

'Creep' in Metals.—Two communications to the recent meeting of the Institute of Metals deal with the subject of 'creep.' R. W. Bailey, from an examination of data obtained by several different investigators, comes to the conclusion that for most, if not all, metals the relation between the time t taken to produce a specified softening of the cold-worked metal and the temperature θ at which it occurs has the form $t = t_0 e^{-b\theta}$, b being of the order of 0·05 for a variety of metals. It is independent of the condition of the metal, but t_0 varies with the condition. The results suggest that creep should not occur under stresses below the elastic limit. H. J. Tapsell and J. Bradley experimenting with a 70 : 30 nickel-copper alloy containing 2·35 per cent. of manganese, find that this alloy, whilst inferior to an alloy of nickel and chromium gives very satisfactory results of mechanical tests at high temperatures. The limiting stress which will produce creep is in these experiments much above the elastic limit, except at high temperatures, but it is of course very difficult to decide whether creep is actually occurring when its amount is small, and experiments may measure rather the accuracy of the apparatus used than the true limiting stress. The alloy gives good impact tests even at 700° C.

Proceedings of the Optical Convention, 1926.

THE exhibition of instruments associated with the Optical Convention having been described in our issue of April 24, while the very entertaining optical illusions arranged by Sir Richard Paget and Dr. R. S. Clay were fully noticed in the lay press, the present article will be devoted to a brief review of some of the papers read during the daily sessions, which occupied two lecture-theatres at the Imperial College of Science and Technology, South Kensington, throughout the week of the Convention. As there were nearly a hundred papers in all, it is impossible to refer here to more than a few of them, but it is understood that the Proceedings of the Convention, containing the complete text, will be published in time to be available at the Oxford meeting of the British Association.

The contribution of outstanding merit was undoubtedly Mr J. Guild's "Survey of Modern Developments in Colorimetry," and the discussion of this and other topics was enhanced in interest by the presence of Mr H. E Ives, of the United States, to whose labours the science of optics is so much indebted. There are few subjects upon which textbook information lags so far behind the available knowledge as the investigation of colour, and it would be difficult to exaggerate the value of this report, which is not less remarkable for its lucidity than for the directness with which it selects for discussion topics which are of greatest practical interest. It was news to many who might be expected to know about such things that the photometry of colours has been put upon such a basis that "the luminosities of different coloured lights can be equated to one another, or added together, in exactly the same way as a gallon of oil can be equated, on a volumetric scale, to a gallon of water, and as the total volume of a gallon of oil added to a gallon of water will measure two gallons"

Various criteria for equality of brightness have been examined, and it has been found that the difficulty which is experienced in judging the equality in brightness of two dissimilarly coloured lights is due to adventitious psychological factors which can be eliminated by statistical methods Simple photometry therefore provides the basis of the modern theory, but flicker photometry can also be used as a derivative method of comparison. The paper deals very thoroughly both with the underlying theory and with the practical methods of colour measurement and specification, and shows that the whole subject is now upon the level of an exact science: colour mixtures can be specified numerically with precision. The terminology is still somewhat confused, however, and the Optical Society, following the example of the corresponding American body, is seeking information by means of a questionnaire with the view of standardising the nomenclature. The author considers that the most pressing need of the science is a statistical standardisation of the chromatic properties of the normal eye. the laws of colour mixture are subject to fluctuations, being slightly different for different individuals, and systematic experiment is necessary to ascertain the norm. The importance of experimenting under standard conditions as to the size of the visual field, the method of illumination, etc, is also insisted upon.

Another interesting paper on this subject was that by Dr. W. Peddie, dealing with the effects of fatigue on the sensations produced by colour mixtures The industrial aspect was brought out in a paper by Mr Gamble, who put forward suggestions for the standardisation of coloured inks for three-colour printing, and one by Dr. S G Barker and Mr H. R. Hirst on the work of the British Research Association for the Woollen and Worsted Industries with regard to the fading of colours.

The use of the photo-electric cell in photometry is an interesting modern development. Dr. N R. Campbell, the originator of the idea, and Mr. M. K. Freeth described an investigation, carried out by this method, of the variations in the properties of tungsten filaments in vacuum lamps. The luminous efficiency of successive samples cut from a single filament is found to vary by several parts in a thousand, and the sensitivity of the method is well illustrated by the present study of this phenomenon. The colour temperatures of the samples are compared by means of a rubidium cell, covered by a filter so as to have nearly the same colour-sensitivity characteristic as the eye, and the electrical magnitudes concerned are carefully measured; an estimated accuracy of 0·05 per cent is achieved, and it is found that more consistent results are obtained if lamps are rated by current instead of by voltage. Mr. T. H. Harrison has extended the method to the measurement of directional candle power, as distinct from the total flux from a lamp The difficulties are considerable owing to the dissimilarity in the characteristics of individual cells and to fatigue effects, but it is claimed that by means of suitable precautions an accuracy better than 0·1 per cent. can be obtained

Among the papers on ophthalmic subjects may be mentioned two, by Mr. O. Aves and Mr. W. Swaine respectively, dealing statistically with the distribution among the population of various defects in eyesight. These papers contain much information on such matters as the age and sex distribution of optical defects, the results obtained by correction, the occupations of the patients, etc. There is a tendency for women to seek the optician's aid at an earlier age than men, possibly on account of their being compelled to do needle-work · in each case the frequency-age curve shows two maxima, one in the early twenties and the other in the later forties. As regards the effect of occupation, sewing and kindred tasks claim by far the largest proportion of victims: half as many of the latter are clerks, and one quarter as many are teachers, students, etc. The subject appears to be a somewhat new one, and the authors express dissatisfaction with the material available. A standardised system of analysis also appears to be desirable.

The subject of optical glass is of great interest for those who are concerned as to the fate of the British optical industry. The matter is of wide importance; the optical industry is intimately related to the security and well-being of the nation, for on this branch of the industry all the others are dependent. It is satisfactory to know that whereas before the War only one British firm was engaged in the manufacture, that number has now been trebled. Mr W. H. Chance and Mr W. M Hampton gave an interesting account of the work of their firm, showing that the number of types of glass which it makes has increased from the pre-War figure of 26 to 112 at the present day. Glass colour filters are made in place of the former gelatine filters: a third colour, distinguishable under all conditions from green and red, has been found for railway signals, enabling home signals to be discriminated from distant signals: 'Crookes' glass has been introduced for excluding ultra-violet radiation, and 'vitaglass' for admitting it The latter has been fitted in the monkey-house at the Gardens of the Zoological Society at Regent's Park, and is said to have had a beneficial effect on the welfare of the inmates; but it seems doubtful whether the indiscriminate use by the public of lamps emitting strong ultra-violet radiation is in any degree safe.

In connexion with the subject of optical glass, considerable interest attaches to a paper by Mr. W. D. Haigh describing a method for determining the absorption coefficient of glass for light passing through it His results for British glass are confirmed by the experience of the National Physical Laboratory, and in view of this confirmation of the accuracy of the method, the author's comparison of the transparencies of British and foreign glasses is of some importance. The British glasses are on the whole considerably more transparent to light of the shorter wave-lengths, and are therefore more suitable for the construction of fast camera lenses. A paper by Lord Rayleigh was devoted to the difference in transparency between silica glasses made from sand and from rock crystal respectively, the comparative opacity of the former being attributable to the presence of bubbles.

A number of papers dealt with instrument design and manufacture, but as this aspect of the Convention has already been described in our columns, no further space need be devoted to it here, except as regards two particularly interesting papers on surveying instruments for the Colonies, by Mr. J. L. Rannie and Col. H St. G Winterbottom respectively. The first of these authors reviewed the requirements of theodolites for use in Canada, reduction in size and weight and increased speed of manipulation being the chief of these. The paper contains some valuable hints to British manufacturers, and suggests the use of aluminium alloys for the metal parts, elimination of counterpoises by suitable design, sacrifice of excessive accuracy, reduction of the number of micrometers, enlargement of the field of view to facilitate rough alignment, and other innovations. Mr. Rannie believes that definite changes along the lines which he suggests are necessary if Great Britain is to hold the Canadian market. Col. Winterbottom, on the other hand, gave an account of the experience of the Indian Survey which was somewhat more flattering to British manufacture: continental instruments fail to stand the rough conditions of transport to India, and the superior workmanship of British-made instruments is much in their favour. Indeed, it would appear from both these papers that British instruments suffer from the disadvantage (from a manufacturer's point of view) that they do not wear out. It is Col. Winterbottom's opinion that British-made instruments are the most economical in the long run, in spite of their initial cost.

C. W H.

The Sense Organs of Insects.

LITTLE is definitely known from the physiological point of view of many of the sense organs of insects Except in the case of the eyes and the tactile hairs, it is largely a matter of conjecture to classify them according to function. It is desirable, therefore, to group the various types of these organs into different categories based upon their essential structure

Most of the sense organs of insects can be classified according to the form of their external cuticular components, as was carried out by Schenk in 1903. Dr. R E. Snodgrass, in a recent valuable contribution entitled "The Morphology of Insect Sense Organs and the Sensory Nervous System" (*Smithsonian Misc. Coll.* 77, No. 8, 1926), follows in the main this same general classification. His paper commends itself to all interested in the subject, since he has brought together the chief results of the great mass of recent German work in a convenient form Dr. Snodgrass points out that, since no sensory cytons have been found in the central ganglia of insects, we have to conclude that they are represented by the sensory cells found in relation with the body-wall and alimentary canal. This fundamental conclusion contrasts with what is known concerning the sensory cytons of the vertebrate nervous system, where they are located in the spinal ganglia Furthermore, the origin and growth of the sensory nerves have not so far been traced in any insects. All we do know is that the sensory nerves of those animals terminate in the central ganglia in finely branching nerve fibrils which constitute the sensory neuropiles.

The simplest type of insect sense organ or sensillum is little more than a slender hair. Histologically it consists of a large hair-forming cell, a membrane cell, which secretes the membrane uniting the hair to its socket, and a sense cell The latter lies beneath the hypodermis and sends out a nerve process to the base of the hair. It seems reasonable to conclude that such tactile hairs were the first specific sense organs to be acquired by insects, and that from them were developed organs for perceiving chemical stimuli, sound stimuli, or whatever other stimuli are perceptible to insects. In the case of the eyes, the fundamental elements in all varieties of these organs among insects are photoreceptive cells of hypodermal origin. These cells correspond with the sense cells of other sense organs and may be termed the sense cells of the ocular sensillum. Associated with them are cells of hypodermal origin which differ greatly from the enveloping cells of the other sense organs This fact leads Dr Snodgrass to conclude that any theory which would derive an ocular sensillum from that of an original sensory hair, as was suggested by Patten in 1890, is too far-fetched to be convincing.

The cuticular part of a sense organ is adapted for the reception of a specific stimulus. In the case of a chemoreceptor the organ is somehow penetrable by odour or taste substances. The idea that such organs were perforated to allow of the substances to be perceived to come in contact with nerve-endings is not upheld. The cuticular walls of these sense organs are, in many cases, not more than half a micron in thickness, and it is reasonable to suppose that they allow of the passage of odour or taste substances. In support of this view Dr. Snodgrass quotes the observation of Vogel, who noted that the membranous cupola of a basiconic sensillum of the wasp is coloured by haematoxylin, and hence is permeable by it. There is no doubt that a better acquaintance with the physiology, the senses, and the tropisms of insects will provide an insight into how these creatures so successfully maintain their dominant place in Nature, notwithstanding man's most energetic efforts to repress them.

A. D. I.

Geophysical Observations in France.

THE third volume of the "Annales" of the Institut de Physique du Globe de l'Université de Paris and of the Bureau Central de Magnétisme Terrestre, the two institutions directed by Prof. Maurain, has been issued recently (Paris: Les Presses Universitaires de France, 1925). The volume is devoted mainly to observations made during the year 1923. The principal geophysical observatory in France is at Val-Joyeux, 24 kilometres west of Paris. For this observatory hourly values of the magnetic elements are published. Systematic magnetic observations have been re-established recently at Nantes on the lower Loire, and the results of the first complete year's work are now given. It appears that, in spite of the disturbance due to electric trams, which come within 450 metres of the Observatory at Nantes, there is satisfactory agreement between the two stations, which are in nearly the same latitude. For the year 1923 the range[1] of the mean diurnal variation of declination was 6·46′ at Val-Joyeux and 6·33′ at Nantes, the corresponding figures for horizontal force were 16γ and 16γ.

Another new departure is the organisation of regular observations of atmospheric electricity at Val-Joyeux. Potential gradient in the open is recorded directly by the method adopted by Norinder in Sweden. A radium collector is suspended about 2 metres above ground in the middle of a wire 16 metres long, and the potential is shown by a Benndorf electrograph. The difficulty in such operations, a difficulty which has made many old records of atmospheric potential useless, is to ensure good insulation. In the present instance there is no provision for warming the hut, so that the deposit of moisture on cold nights would seem to be inevitable. It is therefore to be regretted that there is nothing in M. Salles's account of the work at Val-Joyeux to show what control observations are made. The conclusions as to the average potential gradient must be accepted with some reserve; as the figures stand, they suggest that the atmosphere at Val-Joyeux is much purer than that at Kew. For Val-Joyeux the average gradients in June and December 1923 are given as 65 volts and 123 volts per metre respectively. According to Chree, the averages for Kew (covering 1898–1912) are 207 volts in June and 409 volts in December.

A résumé of the observations made with the Ångström pyrheliometer at Parc St. Maur from 1907 to 1923 is given by M. Brazier. The brightest sunshine observed was on March 26, 1915, 1·44 calories per square centimetre per minute.[2] The 'solar constant' being 1·94, nearly 75 per cent. of the solar energy was getting through the atmosphere on that occasion. The highest transmission coefficient (estimated for a vertical sun) was recorded in December, 87 per cent., whereas in the summer months no co-efficient was estimated as more than 76 per cent. This contrast is attributed to the stopping power of the excess of water vapour in the summer air.

Several sections of the volume are devoted to accounts of parts of the magnetic survey of France. The previous survey was in 1896. The interval is large enough for a diminution of declination by 3°. There is some indication of local peculiarities, but the discussion of these is reserved until the completion of the survey.

Mention must also be made of a series of articles co-ordinating all available information as to magnetic surveys of French dependencies. In the present volume maps of Indo-China and Madagascar are reproduced. The latter map is remarkable for the complexity of the lines in the centre of the island. The geological significance of the contortions has been worked out by the director of the Tananarive Observatory. These articles by Mlle. Homery will be very useful for reference.

---

[1] In each case the figure quoted is the difference between the highest and lowest of the mean hourly values for the year.

[2] The reading has been adjusted to the Smithsonian scale; the date is misquoted in the table on p. 137.

Ethnic Relations in India and the Near East.

IN a paper read before the Royal Anthropological Institute (Indian Section) on April 30 on this subject, Mr. L. H. Dudley Buxton stated that the three great regions of the eastern Mediterranean, Mesopotamia, and India have been the mothers of civilisations on which to a greater or lesser degree our own civilisations are based. In them also have arisen the three great religions of the world, Christianity, Mohammedanism, and Buddhism. Superficially their inhabitants seem to be very unlike, but a closer examination reveals many traits in common, both with each other and with the people of western Europe.

Excluding the Mongoloid peoples, who are really intruders into this region, though their arrival was probably far back in the past, we have two great groups, roundheads and longheads. Both types are found even in the earliest graves excavated up to the present. Any race which is composed of both longheads and roundheads shows considerable variety, as might be expected, both types appearing in the mixed race in each generation.

Such a mixture was found in the earliest graves so far excavated at Kish in Mesopotamia, and still continues. In India the rounder the heads of each group of people examined the more variable they are, but in the Near and Middle East the least variable are the extreme longheads and the extreme roundheads. This suggests that in India we have basic stocks who are longheads and roundheaded intruders; whereas westwards we have both types represented in a pure as well as a mixed state.

Further analysis shows that in the Near East there is a type akin to Stone Age man, such as 'Combe Capelle.' This type is probably also represented in India. There are even suggestions that a more primitive type lingered on in prehistoric times well after the Stone Age. The second type of longheads is akin to the well-known Mediterranean man. This or a kindred type is also found in India. But here we have also a more primitive type, probably specialised for life in the tropics, and akin to the very primitive Australian aboriginal. Whether this type ever occurred in the Near East is uncertain. The roundheads which are intruders in India are dominant in much of the Near East, but never succeeded in becoming more than an element in the population of the Middle East, although they can be found in units almost everywhere there.

All this elaborate racial mixing probably took place at a remote period, long before the dawn of history, and it seems difficult to identify any physical type with any known historical people. Civilisations have come and gone, especially in the land of the two rivers, but always the physical type of the people seems much the same. It is to be hoped, therefore, that some lucky chance will give us graves at the very beginning of the Bronze Age or before, so that the actual date of the invasions of the roundheads and of the later comers among the longheads may be traced.

University and Educational Intelligence.

BIRMINGHAM.—Sir Oliver Lodge will deliver the Huxley Lecture on Tuesday, May 4, at 5.30 P.M., his subject being "Difficulties about the Ether."

CAMBRIDGE.—Certain regulations which are to take effect as ordinances on the commencement of the new statutes have been promulgated. Among these are the regulations for the committee which is to superintend the Natural Sciences Tripos. There are always present among the senior members of the University a certain number who are dissatisfied with the Tripos; these will now be able to bring their theories to the notice of an official body constituted for the purpose. It is not improbable that this committee, which now seems a simple innovation, will occasionally prove to be a storm-centre of wordy warfare.

Sir John Russell and some of the staff of the Rothamsted Experimental Station are again giving a course of public lectures on the chemistry, physics, and biology of the soil. Last year the course attracted considerable attention and was an undoubted success. The lectures are being given on Tuesdays, Wednesdays, and Thursdays, at 2.15 P.M.

The Board of Research Studies has presented its annual report; the total number of registered research students shows a slight increase, for which mathematics and geology are mainly responsible. It is satisfactory to note that graduates of the University are now registering as students for the doctorate of philosophy more frequently than formerly. At present, of a total of 276 research students, 90 are from Cambridge, 89 from other universities of the British Isles, 44 from the colonies, and 37 from the United States.

An appointment will be made towards the beginning of July next to a Busk Studentship in Aeronautics. The studentship is of the value of about 150*l*., tenable for one year from October 1, and is open to any man or woman being a British subject and of British descent who has not attained the age of twenty-five years on that date. The holder of the studentship will be expected to engage in research in aeronautics, and specially in subjects such as stability problems, meteorological questions bearing on flight, or the investigation of gusts, treated either experimentally or mathematically, in which the late Edward Busk was specially interested. Forms of application can be obtained from Prof. B. Melvill Jones, Engineering Laboratory, Cambridge, and must be returned not later than May 12.

GLASGOW.—Dr. R. H. Thouless, fellow of Corpus Christi College, Cambridge, Arnold Gerstenberg and Burney student and prizeman, senior lecturer in psychology at the Victoria University of Manchester, has been appointed lecturer and head of the department and laboratory of psychology in the University, in succession to the late Dr. Watt.

A memorial lectureship and medal have been founded in the University in commemoration of the late Prof. Sir William Macewen, F.R.S. The lectureship will be biennial, and the memorial lecture will deal with advances in surgery. The first memorial lecture will be given in 1927 by a distinguished surgeon unconnected with Glasgow. The memorial medal will be awarded annually to the most distinguished candidate in the final or qualifying examinations in surgery of the year.

LONDON.—The following courses of free public lectures are announced: At the Imperial College of Science and Technology—Royal School of Mines—at 5.15 on May 3, 10, and 17, "Past Ice Ages of the World, and their Control of Animal and Plant Life, with special reference to the Australian Evidence," by Sir T. W. Edgeworth David; at King's College, at 4.30 on May 25, June 1, 8, and 15, "The Constituents and Coagulation of Blood Plasma," by Dr. J. W. Pickering; and at University College at 5.30 on May 27, 28, and 31, "The New Aspect on Strong Electrolytes," by Prof. Niels Bjerrum (of the University of Copenhagen). No tickets will be required for either course.

THERE will be an election to junior Beit Memorial Fellowships for medical research in July, and applications for the fellowships are invited. The annual value of each is 350*l*. and the tenure usually three years. The latest date for the return of application forms (which should be sent to Sir James K. Fowler, 35 Clarges Street, W.1) is June 1.

THE Council of the London (Royal Free Hospital) School of Medicine for Women invites applications for the Dr. Edith Pechey Phipson post-graduate scholarship of 100*l*. a year for not more than three years. The scholarship is open to all medical women, preferably coming from India, or going to work in India, for assistance in post-graduate study. Applications must be sent to reach the Warden and Secretary of the school, 8 Hunter Street, W.C.1, by May 31.

THE Oxford and Cambridge Appointments Boards have published reports for the year 1925 showing that the appointments obtained during the year by their candidates numbered 210 and 399 respectively. The former are classified as Government 42, educational 59, business and industrial 32, journalistic, secretarial, etc., 10, and temporary 67; the latter as Government departments (mainly scientific) 16, administrative posts in commerce and industry 81, manufacturing and technical 89, Colonial administration 37, agriculture and forestry 11, Indian and Colonial railways 16, railway traffic 4, journalism and publicity 2, publishing 2, articled clerkships 6, museums 2, architecture 1, medical 2, secretaryships 6, educational 119, miscellaneous 5. The Cambridge report says that engineering students were readily placed. Many opportunities exist for engineers with a knowledge of chemistry, or chemists with a knowledge of engineering, but candidates properly equipped on both these sides are very few. More physical chemists could have been placed. The number of candidates who registered for the first time during 1925 was 582 at Cambridge and 473 at Oxford.

HULME HALL, Manchester, announces that an examination will be held in the second week of May for Entrance Scholarships. An interesting feature of the entrance conditions prescribed alike for scholarship candidates and other candidates for admission except advanced students is a test of their "alertness, intelligence, and intellectual outlook, their personal qualities of mind and mental equipment, and their mastery of the modern standard English dialect." The test is conducted by means of a paper of general questions—historical, scientific, economic, social, political, geographical, literary, artistic, and ethical—and a *viva voce* examination, including the reading aloud of passages of English prose. The total amount of an undergraduate's annual expenditure while a member of the Hall, exclusive only of university fees (15*l*. to 40*l*. according to faculty), clothing, vacation and travelling expenses, is shown by recent inquiries among the students to average 107*l*. The Hall aims at reproducing the best features of college life at Oxford or Cambridge, an excellent summary of which is given in a leaflet circulated with its prospectus entitled "University Life: Residence in Hall or Not?"

Contemporary Birthdays.

May 1, 1852.	Prof Ramón y Cajal, For.Mem. R.S
May 1, 1866.	Sir A. Trevor Dawson, Bart., M Inst.C E.
May 1, 1858.	David Hooper, LL D.
May 2, 1868.	Prof Robert W. Wood, For Mem.R.S
May 5, 1882.	Sir Douglas Mawson, F.R.S.
May 5, 1860.	Dr Charles Chree, F.R.S.
May 6, 1866.	Sir Murdoch Macdonald, M.Inst C E.
May 6, 1848.	Dr. H. R. Procter, F.R.S.
May 7, 1863.	Sir John Rose Bradford, F R S.

Prof. RAMÓN Y CAJAL, the eminent physiologist, was born at Petilla, Spain He was Nobel laureate (with Golgi) in 1906.

Sir TREVOR DAWSON received his technical training at the Royal Naval institutions at Gosport and Greenwich. He is the inventor and constructor of many improvements relating to artillery. Sometime experimental officer to the Home Office Committee for the investigation of gas cylinders, he is a past president of the Junior Institution of Engineers.

Dr HOOPER, an authority in pharmacology and economic botany, was born at Redhill. Quinologist to the Government of Madras from 1884 to 1897, he was afterwards, before returning to England, curator of the Industrial Section of the Indian Museum, Calcutta.

Prof WOOD was born at Concord, Mass. Educated at Harvard, Johns Hopkins, and Berlin, from a post at the University of Wisconsin, he became (1901) professor of experimental physics in Johns Hopkins University, Baltimore He is specially identified with researches in optical science, in which he has shown experimental skill of a high order.

Sir DOUGLAS MAWSON is a graduate of the University of Sydney. He was born at Bradford, Yorkshire. His pioneering work in Antarctic exploration is well known. He was with Sir Ernest Shackleton in his southern expedition of 1907, and he was leader of the Australian Antarctic Expedition, 1911–14. The Royal Geographical Society awarded him its Antarctic medal in 1909, and its distinction of the Founder's medal in 1915. The president of the Geological Society (Mr Lamplugh) in handing Sir Douglas the Bigsby medal in 1919, referred to his arduous geological researches in the New Hebrides, in the Broken-Hill district, and in other regions in Australia, as well as the systematic study of Australasian minerals, in themselves a full measure of achievement.

Dr CHREE, who, after attending the Grammar School, Old Aberdeen, proceeded thence to the University of Aberdeen and afterwards to Cambridge, becoming, at the latter university, sixth wrangler. Until 1925 he was, for more than thirty years, superintendent of Kew Observatory, Richmond The relationship between solar manifestations and terrestrial magnetism has specially engaged his attention. In 1919 Dr Chree was Hughes medallist of the Royal Society.

Sir MURDOCH MACDONALD, following extensive constructional railway work in Scotland, engaged for many years in engineering schemes under the Public Works Ministry of Egypt

Sir JOHN ROSE BRADFORD, who is a Londoner, was educated at University College School. A former secretary of the Royal Society, he was recently elected president of the Royal College of Physicians.

Societies and Academies.

LONDON.

Society of Public Analysts, April 7.—H Droop Richmond and J. A. **Eggleston**: The analysis of Acetic anhydride By adding 2 c.c. of acetic anhydride to 200 c c of a mixture of 94 parts of toluene and 6 parts of aniline, and measuring the rise of temperature produced in the reaction, a determination of the strength of the acetic anhydride can be made with an accuracy comparable to that of the method of Henschutkin and Wasilieff. In very accurate work a correction is necessary for the heat evolved in the formation of aniline acetate —H Droop Richmond and Eric H **England**: The analysis of glacial acetic acid. Acetic acid is almost unique in that specific gravity falls with increasing percentage, whilst the freezing point rises Impurities, of which propionic acid is the most important, lower both specific gravity and freezing point. By calculating the specific gravity equivalent to the freezing point and subtracting from it the specific gravity found, a close approximation to the percentage of propionic acid can be obtained by dividing by 0·00135 Other impurities are aldehydes and ketones, probably chiefly propionaldehyde and homolgues —J. F. **Tocher** (1) Errors of judgment in chemical analysis. In experiments on the titration of sodium hydroxide solution with N-sulphuric acid, the mean results of successive determinations during a forenoon were of a periodic character. On an average the first two determinations were less trustworthy than the others. The variations in the personal equations of observers were independent of the apparatus and the material.—(2) Variations in the composition of milk. The percentage of butter fat tends to decrease slightly with increasing yield per milking for a particular animal, but the total amount of butter fat (and also of solids not fat) increases proportionally with increased yield. —E. R. **Bolton** and K. A. **Williams**: A test for Tung oil. Previous attempts to obtain a definite and constant petroleum spirit extract of unpolymerised matter from the residue of Worstall's test have failed owing to incomplete and uncontrolled polymerisation A definite yield of extract varying between narrow limits can be obtained under proper conditions, and adulterants are readily disclosed by the yield of extract in excess of the standard amount Most of the oils likely to be used as adulterants are completely recovered in the extract; linseed oil being an exception, in which case approximately 50 per cent. is retained in the polymerised mass

Royal Meteorological Society, April 21.—J **Glasspoole**: The driest and wettest years at individual stations in the British Isles, 1868–1924. The data have been obtained for some 250 long-period stations distributed over the British Isles as regards the driest and wettest years Thus for Camden Square (London): average annual rainfall, 24·47 in; driest year 1921, with 14·60 in. or 60 per cent of the average, wettest year 1903, with 38·10 in. or 156 per cent of the average The years 1887 and 1921 were the driest years in the series 1868–1924 over 40 and 31 per cent. of the British Isles, and the years 1872 and 1903 were the wettest years over 49 and 19 per cent. of the whole British Isles respectively. Almost every year was the driest or the wettest for one place or another in these islands.—C. E. P **Brooks**: (1) The meteorological conditions during the glaciation of the present tropics, being some remarks on the climatological basis of Wegener's theory of continental drift. The reconstruction of Permo-

Carboniferous geography given by Wegener shows a large continent formed by the union of South America, Africa, India, Australia, and Antarctica, surrounding the south pole and bearing extensive ice-sheets, while the equator passed through Europe and the United States. Recent researches have shown, however, that in the latter country also there were a number of powerful glaciers extending to sea-level. Thus there are the same climatic objections to Wegener's reconstruction as to that based on the present positions of the continents. The reconstruction of the Upper Carboniferous given by Th. Arldt ("Handbuch der Palæogeographie") is accordingly taken as a basis, and the probable distribution of warm and of cold ocean currents and of winds is discussed. A warm current would traverse the region of the coal-measures, and the American glaciation is also readily explicable owing to the neighbourhood of an arm of the Arctic Ocean, while even the glaciation of the tropics may not be a vital objection.—(2) The variation of pressure from month to month in the region of the British Isles A chart of the deviation of means of pressure from normal in any month usually shows 'centres' of maximum excess or maximum deficit. Centres of excess of pressure tend to move along fairly well-defined tracks and generally from west to east. The main track runs from Alaska south-eastward to the centre of the United States, then eastward to the Azores, north-eastward to the British Isles or Scandinavia, and again eastward to northern Russia or the Kara Sea. This would take about six months, though no single centre was found which persisted long enough to make the whole journey. Centres of deficit are more variable in their movements, but also tend to move from west to east.

Dublin.

Royal Dublin Society, March 23.—W. E. **Adeney**: On the rate and mechanism of the aeration of water under open-air conditions. The bubble method employed by Adeney and Becker for the investigation of the process and rates of solution of atmospheric nitrogen and oxygen by fresh and salt waters, affords a means of determining the rates of solution of these gases, when every part of the water is successively exposed to them in thin films, and becomes gradually and completely aerated independently of evaporation or of downward 'streaming'. The aeration of quiescent bodies of fresh water by downward 'streaming' may take place 113, 56, 245, and 185 times slower than the initial rate of solution of the surface film 0·05 cm. thick, according to the humidity of the air passing over their undisturbed surfaces. When, however, the surface of the water is kept in a continuous state of turbulent agitation, as in a bio-aeration tank for the purification of sewage liquors, the effective area of water exposed to the air becomes so much increased that the downward 'streaming' is greatly augmented, and the rate of aeration of the water may become equal to, or even exceed, that calculated from the rates of solution found by the bubble experiments for films 0·05 cm. thick, for the given depth of the water, assuming the exposed surface to remain in an undisturbed condition.—J **Bell**: The constitution of dicyanodiamide. In Bamberger's experiments on the action of nascent hydrogen on dicyanodiamide, hydrolysis to dicyanodiamidine takes place to the extent of 50 per cent. A mercury derivative of dicyanodiamide is also described.—J. **Doyle** and Miss P. **Clinch**: The pentosan theory of cold-resistance applied to conifers. The pentosans of conifers can be classed in three groups: (*a*) water-soluble pentosans, (*b*) pentosans subsequently extractable with 1 per cent. hydrochloric acid, and (*c*) pentosans still remaining and only extractable with 12 per cent. hydrochloric acid. All three classes vary considerably throughout the year, though not independently, the variation in classes (*a*) and (*b*) being reciprocal. Cupressus is remarkable in having a very high winter content of water-soluble pentosan, this class being usually present in minimum quantity during the winter months. The H-ion concentration of conifer leaves shows little seasonal variation. The leaves are distinctly acid—from *p*H 3 to 4. Cupressus is distinctly less acid than the other forms examined. No relations, seasonal or otherwise, can be established between hardiness in conifers and pentosan content.

Paris.

Academy of Sciences, March 29.—Paul **Appell**: Some formulæ relating to Euler's constant, C.—F. E. **Fournier**: General expressions of the resistance, R, of water to the translation of hulls, at all possible velocities —M. **Brillouin**: Is the moon radioactive? The hypothesis that the moon is radioactive is regarded as probable, and this radioactivity may exert a sensible action upon the earth's outer atmosphere.— — **d'Arsonval** and F. **Bordas**: The determination of the impurities in the atmosphere. Some results obtained with a modified Owens gauge in the centre of Paris —Paul **Sabatier** and J. F **Durand**: An attempt at the catalytic hydrogenation of ethylene oxide. Ethylene oxide mixed with hydrogen and passed over reduced nickel heated to 125° to 150° C. is not reduced, but is converted into acetaldehyde and condensation products of the latter.—R **Maire**: The vegetation of south-west Morocco.—Émile Forgue was elected a corresponding member for the Section of Medicine and Surgery in succession to the late M. Depage.—Walter **Saxer**: The exceptional values of the successive derivatives of meromorph functions.—I. **Karamata**: Certain limits connected with Stieltjes integrals.—Paul **Lévy**. Remarks on the methods of summation of divergent series — — **Hadamard**: Remarks on the two preceding communications —Leonida **Tonelli**: The integration of suites of functions capable of summation —Louis **Roy**: The dynamic adiabatic law relating to elastic lines — — **Amans**: The aerodynamics of windmills.—Jean Jacques **Trillat**: Researches on the phenomena of lubrication by means of X-ray spectrography. The X-ray spectra prove that as the result of friction between two surfaces the fatty layer is stratified —Michel O. **Samsoen**: The crystallisation of glycerol. In the course of some experiments on the change in the coefficient of expansion of glycerol in the neighbourhood of −62° C., it was noticed that on warming up, the glycerol always crystallised spontaneously, centres of crystallisation commencing to appear about −23° C. Unless the prolonged preliminary cooling has been carried below −40° C., crystallisation does not take place —John H. **Shaxby**: Formulæ relating to the density of a fluid and the molecular diameter —Henri **George**: The manufacture of transparent quartz glass. The difficulty of freeing fused silica from gas bubbles is well known. The author has found that a transparent fused silica glass, free from bubbles, can be obtained by simple fusion in a crucible of certain natural quartzites. These quartzites are of high purity (99·9 per cent. silica) and there are no gaseous inclusions.—J. **Hugounenq** and J. **Loiseleur**: The use of glycogen in the preparation of colloidal metals. Colloidal solution of many metals may be prepared by means of glycogen, which behaves both as stabiliser and reducer. Details are given of the preparation of colloidal silver, mercury and bismuth.—Charles **Prévost**: The catalytic dehydration of the vinylalkylcarbinols. Ethylvinylcarbinol, dehydrated by the catalytic action of alumina at 350°-365° C., gives a 60 per cent to 70 per cent yield of 1·3 pentadiene.—Ch. **Courtot** and J. **Bonnet**: Contribution to the study of the π of sulphonation.—E. **Delcambre**, P. **Idrac** and F. **Geoffre**: A new temperature and pressure recorder for the study of the higher atmosphere.—P. L. **Mercanton**: The magnetisation of the Greenland basalts.—G. **Mangenot**: The existence of a remarkable functional arrangement in the orifices of the liber sieves.—V. G. **Korneff**: Measurement of the force of suction of the soil for water.—C. **Rouppert** and H. **Jedrzejowski**: The action of the radiation of radioactive bodies on plant pearls.—H. **Hérissey**: The detection of asperuloside in plants. The extraction of this glucoside from *Galium Aparine*.—Theodor **Lipmaa**: The physical and chemical properties of rhodoxanthine.—R. **Fosse**: A new natural principle in plants: allantoic acid.—E. **Roubaud** and J. **Colas-Belcour**: The obligatory winter sleep and its various manifestations in mosquitoes indigenous to France.—**Gruvel**: The development of trout culture in Morocco.—J. **Sabrazès**: The simple and rapid coloration of the treponeme of syphilis. The comparative affinity for stains of the Spirochætes.

ROME

Royal Academy of the Lincei, February 21.—V. **Volterra**: Variations and fluctuations in the number of individuals in animal species living together.—O. M. **Corbino**: Magneto-optic phenomena in fields which are varying rapidly. Theory predicts that the Zeeman phenomenon should respond instantaneously to the changes of a field varying with the time according to any law and with any rapidity. In carbon disulphide the magnetic rotatory dispersion follows quantitatively the oscillations of a high-frequency field as far as the shortest persistent waves (300 metres) with which it was found possible to experiment.—Ferruccio **Zambonini** and S. **Restaino**: Double sulphates of rare earth and alkaline earth metals (v.). Cerous ammonium sulphate. The crystallographic and other characters of the two compounds, $Ce_2(SO_4)_3$, $(NH_4)_2SO_4$, $8H_2O$, and $Ce_2(SO_4)_3$, $5(NH_4)_2SO_4$, are described.—Umberto **Cisotti**: Resolution of harmonic problems in a plane area of indefinite extent with *n* circular gaps of small diameter.—Azeglio **Bemporad**: A new method of studying experimental results. The method recently described by Cantone has been applied to the results of astronomical measurements, and is closely analogous to the hodograph so frequently used in mechanics and other branches of mathematics.—G. **Vranceanu**: The integration of the problem of two bodies in the case in which the mass is a linear function of the time.—Emilio **Adinolfi**: The absorption spectrum of potassium and calcium permanganates.—Washington Del **Regno**: The behaviour of selenium subjected to the action of mesothorium radiations. Exposure of selenium to mesothorium radiation produces a marked variation in the electrical resistance of this element, the effect being due mostly to the β-rays.—G. **Carobbi**: The chemical composition of the orthite of Ambatolotsikely (Madagascar).—Pia **Gravino**: The antimonite of Wolfsberg (Harz).—G. R. **Levi** and R. **Haardt**: The catalytic action of metals of the platinum group and their degree of subdivision (ii.). The results already published, together with those now obtained with palladium, rhodium, iridium, ruthenium, and osmium show that, in the form of 'black,' these metals are so highly subdivided that the granules are comparable with those of colloidal metals. Measurements of the X-ray diagrams show that, within moderately wide limits, the dimensions of the granules depend on the method of preparation as well as on the nature of the metal. The fact that the granules of the spongy metals are large in comparison with those of the 'blacks' explains the practical advantage of subdividing the catalyst on a diluent material, such as asbestos or porcelain.—A. **Ferrari**: Rontgenographic investigation of the crystalline lattices of manganous fluoride and manganese dioxide. Manganous fluoride crystallises in the tetragonal system, the axial ratio being $c:a=0·675$. Its structure is of the rutile type, the dimensions of the elementary cell which contains two molecules being $a=4·865$ and $c=3·284$ Å.U.; the calculated and observed values of the density are respectively 3·97 and 3·98. The dioxide exhibits the same lattice as the fluoride, the dimensions being $a=4·380$ and $c=2·856$ Å.U., the calculated specific gravity is 5·27, whereas the experimental value is 5·08, and the axial ratio, $c:a=0·625$, is decidedly lower than that found crystallographically, namely, 0·664. The dioxide exists in only one crystalline form.—Enrico **Carozzi**: A chromiferous spessartite from St. Barthélemy (Valle d'Aosta).—Arnaldo **Masotti**: Uniform rotation of a solid cylinder in an indefinite perfect liquid. Extension of Kutta and Joukowski's theorem.

Official Publications Received.

Classified List of Smithsonian Publications available for Distribution, March 15, 1926. Compiled by Helen Munroe. (Publication 2806.) Pp. v+80. (Washington, D.C.: Smithsonian Institution.) [Corrected entry.]

Engineering Abstracts from the Current Periodical Literature of Engineering and Applied Science, published outside the United Kingdom. Published by the Institution of Civil Engineers with the Cooperation of other Engineering Societies in Great Britain and the Dominions. New Series, Nos. 26 and 27, January and April 1926. Pp. 150. (London: Institution of Civil Engineers.)

Agricultural Research Institute, Pusa. Bulletin No. 164: Standard Methods of Analysis of Fertilizers. By Dr. J. Sen. Pp. iii+14. (Calcutta: Government of India Central Publication Branch.) 4 annas, 6d.

Memoirs of the Indian Meteorological Department. Vol. 24, Part 11: Rainfall Types in India in the Cold Weather Period, December 1 to March 15. By Sir Gilbert T. Walker and Dr. J. C. Kameswara Rav. Pp. 317-354. (Calcutta: Government of India Central Publication Branch.) 4 annas, 5d.

Department of Commerce: U.S. Coast and Geodetic Survey. Serial No. 312: Terrestrial Magnetism; Results of Magnetic Observations made by the United States Coast and Geodetic Survey in 1924. By Daniel L. Hazard. (Special Publication No. 116.) Pp. 50. (Washington, D.C.: Government Printing Office.) 10 cents.

Journal of the Indian Institute of Science. Vol. 8A, Part 16: The Occurrence of Sylvestrene. By B. Sanjiva Rao and John Lionel Simonsen. Pp. 287-294. 8 annas. Vol. 9A, Part 1: Contributions to the Scientific Study of the Lac Industry. Part xi.: Early Recognition of Sex among Lac Insects. By S. Mahdihassan. Pp. 24+10 plates. 4 rupees. (Bangalore.)

Department of Commerce: Bureau of Standards. Circular of the Bureau of Standards, No. 279: Relations between the Temperatures, Pressures and Densities of Gases. Pp. 86. 25 cents. Circular of the Bureau of Standards, No. 300: Architectural Acoustics. Pp. 9. 5 cents. (Washington, D.C.: Government Printing Office.)

Bulletin of the American Museum of Natural History. Vol. 56, Art. 1: The Hemicyoninæ and an American Tertiary Bear. By Childs Frick. Pp. 119. (New York.)

Papers and Proceedings of the Royal Society of Tasmania for the Year 1925. Pp. v+252+xiv+19-36+24 plates. (Hobart.) 10s.

Department of Commercial Intelligence and Statistics, India. Agricultural Statistics of India, 1923–24. Vol. 1: Area, Classification of Area, Area under Irrigation, Area under Crops, Live-Stock, Land Revenue Assessment and Harvest Prices in British India. Pp. xi+81+7 plates. (Calcutta: Government of India Central Publication Branch.) 1 rupee, 1s. 9d.

Year-Book of the Department of Agriculture, Ceylon, 1926. Pp. iv+62+22 plates. (Peradeniya.)

Transactions of the Royal Society of Edinburgh. Vol. 54, Part 2, No. 10: Geology of the Outer Hebrides. Part iii.: North Uist and Benbecula. By Prof. T. J. Jehu and R. M. Craig. Pp. 467-489+4 plates. (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.) 4s. 6d.

Diary of Societies.

SATURDAY, MAY 1.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (South-Eastern District) (at Grand Hotel, Margate), at 1.—H. A. Borg and others: Discussion on Notes on Municipal Work at Margate.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. P. C. Buck: The Song Form in England as represented by Stanford.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—Annual Meeting.

MONDAY, May 3.

Cambridge Philosophical Society (in Cavendish Laboratory), at 4.30.—Prof. Sir J. Larmor: Insular Gravity and Oceanic Isostasy.—W. A. D. Rudge: A Mechanical Model of the Rutherford-Bohr Atom.—Miss C. A. Scott: On the Higher Singularities of Plane Algebraic Curves.—*Communicated by title only*:—Ž. Marković: Sur la non-existence simultanée de deux fonctions de Mathieu.—C. G. F. James: On the Multiple Tangents and Multisecants of Scrolls in Higher Space.—E. V. Appleton: On the Diurnal Variation of Ultra-short Wave Wireless Transmission.—R. Vaidyanathaswamy: The (2, 1) Correspondence.

Royal Institution of Great Britain, at 5.—General Meeting.

Society of Engineers (in Demonstration Room of the Science Museum, South Kensington), at 5.30.—H. W. Dickinson: Landmarks in the History of Prime Movers.

Institution of Electrical Engineers (Western Centre) (at Chamber of Commerce, Swansea), at 6.—Prof. S P. Smith: An All-Electric House.

Aristotelian Society (at University of London Club), at 8.—Prof A E. Heath: Objectivity in Science.

Royal Society of Arts, at 8.—C. R. Peers: Ornament in Britain (Cantor Lectures) (3).

Society of Chemical Industry (London Section) (Annual and Ordinary Meetings), at 8.—S. Dickson and R H. H. Stanger: Discussion on Modern Portland Cement Manufacture.

Royal Society of Medicine (Social Evening), at 9.30.—Sir Humphry Rolleston: Some Worthies of the Cambridge Medical School (Address).

TUESDAY, May 4.

Royal Society of Arts (Dominions and Colonies Section), at 4.30.—C. Ponsonby: Nyasaland.

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: Organs of Multiple Function (4): Lungs

Royal Society of Medicine (Orthopædics Section), at 5.30.—Annual General Meeting.

Institute of Marine Engineers, at 6.30.—J. A. Aiton: Steam Pipes for Super-High Pressure.

Röntgen Society (at British Institute of Radiology), at 8 15.

Royal Anthropological Institute, at 8.30.—Rev P. Schebesta: The Semang (Negrito Aborigines) of the Malay Peninsula.

WEDNESDAY, May 5.

Geological Society of London, at 5.30.—R. M. Jehu: The Geology of the District around Towyn and Abergynolwen (Merioneth).—K. A. Davies: The Geology of the Country between Drygarn and Abergwesyn (Breconshire).

Institution of Electrical Engineers (Wireless Section), at 6.—Dr. R. L. Smith-Rose and R. H. Barfield: On the Cause and Elimination of Night Errors in Radio Direction Finding.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—A Chaston Chapman: The Detection and Determination of Glycerin in Tobacco.—H. Toms. Further Notes on the Crystalline Bromides of Linseed and other Oils.—A. Bakke and P. Henegger: The Polarimetric Determination of Sucrose in Condensed Milk.—H. L Smith and J. H Cooke: The Determination of very small Quantities of Iron.—Dr W. R Schoeller: The Separation of Iridium from Iron.—Jitendra Nath Rakshit: The Determination of Total Alkaloids, Sugar and Oily Substances in Opium.

Royal Society of Arts, at 8.—C. F. Elwell. Radio: Its Past, Present, and Future.

Royal Society of Medicine (Surgery Section), at 8.30.—Annual General Meeting.—Dr. W. E. Gye: The Origin of Tumours.

Royal Microscopical Society (Biological Section)

THURSDAY, May 6.

Iron and Steel Institute (Annual Meeting) (at Institution of Civil Engineers), at 10 a.m.—Presentation of Bessemer Gold Medal to Sir Hugh Bell, Bart.—Sir W. Peter Rylands: Presidential Address.—Report on Heterogeneity of Steel Ingots. By a Sub-Committee of Committee No. 5, consisting of Dr. W. H. Hatfield, T. P. Colclough, W. J. Dawson, J. H. S. Dickenson, A. P. Hague, E. F. Law, S. A. Main, T. M Service, and J. H. Whiteley.—J. H. S. Dickenson: A Note on the Distribution of Silicates in Steel Ingots.—J. H. Whiteley Ghost Lines and Banded Structure of Rolled and Forged Mild Steels.—At 2.30.—W. H. Dearden and C. Benedicks: Magnetic Changes in Iron and Steel below 400° C.

Royal Society, at 4.30.—Prof. A S. Eddington: Diffuse Matter in Interstellar Space (Bakerian Lecture)

Royal Society of Arts, at 4.30.—Sir Frank Baines: Preservation of Ancient Cottages.

Linnean Society of London, at 5.—Capt. J. G. Dollman: Exhibition of a supposed new 'Mutation' in the Rabbit.—Dr. A. W Hill: The Genus Lilæopsis.—R. D'O Good: The Genus Empetrum.—J. T. Cunningham: On the Nuptial Pads of Frogs and Toads.

Institute of Pathology and Research (St. Mary's Hospital, W.2), at 5.—Prof. J Barcroft: Recent Work on the Spleen (Lecture).

Royal Institution of Great Britain, at 5.15.—Sir William Bragg: The Imperfect Crystallisation of Common Things (2).

Institution of Electrical Engineers, at 6.—Annual General Meeting.

Institution of Automobile Engineers (Derby Graduates' Meeting) (at Cavendish Café, Derby), at 7.30.—J. Topham: Inspection in the Building of an Automobile Chassis

Institution of Structural Engineers, at 7.45.—Annual General Meeting.—At 8.—Major J. Petrie: Some Lessons from Practical Experience, with Special Reference to Structural Work on Railways.

Chemical Society, at 8.—Dr. C K. Ingold, E. Holmes, and E. H. Ingold: The Nature of the Alternating Effect in Carbon Chains. Parts IV., V., VI., and VII.—Dr. C. K. Ingold, C. W. Shoppee, and J. F. Thorpe: The Mechanism of Tautomeric Interchange and the Effect of Structure on Mobility and Equilibrium. Part I. The Three-Carbon System.—K. E. Cooper, Dr C. K. Ingold, and E. H. Ingold: The Correlation of Additive Reactions with Tautomeric Interchange. Part V. The Structural Conditions Affecting Mobility and Equilibrium.

Royal Society of Medicine (Obstetrics and Gynæcology Section), at 8.—Annual General Meeting.

FRIDAY, May 7.

Iron and Steel Institute (Annual Meeting) (at Institution of Civil Engineers), at 10 a.m.—Announcement of the Award of the Andrew Carnegie Research Scholarships for 1926-7.—D. Brownlie: Coal Blending.—W. W. Hollings: Notes on the 'Combustibility' of Coke, and Direct Reduction in the Blast Furnace.—Dr. W. Rosenhain, R. G. Batson, and N. P. Tucker: Effect of Mass in the Heat Treatment of Nickel Steel.—G. R. Woodvine and A. L. Roberts: Influence of Segregation on the Corrosion of Boiler Tubes and Superheaters.—At 2.30.—I. G. Slater and T. H. Turner: The Hardness of Carbon Steels at High Temperatures.—A. R. Page: The Hardening and Tempering of High Speed Steel.—A E Cameron and G. B. Waterhouse: The Effects of Arsenic on Steel.—E. D. Campbell and H. W. Mohr: Specific Resistance and Thermoelectro-motive Potential of some Steels differing in Carbon Content.—R. H. Greaves and J. A. Jones: The Ratio of the Tensile Strength of Steel to the Brinell Hardness Number.—H. O'Neill: Deformation Lines in Large and Small Crystals of Ferrite.—A. Osawa: The Relation between Space-Lattice Constant and Density of Iron-Nickel Alloys.—T E. Rooney and L M. Clark: The Estimation of Phosphorus in Steels containing Tungsten.

Royal Society of Arts (Indian Section), at 4.30.—H Baker: The New Delhi.

Royal Astronomical Society (Geophysical Discussion), at 5.—Chairman: Dr. J. H. Jeans.—Dr. H E. Hurst: The Hydrology of the Nile.—H. Harries: The Relation between Barometric Pressure and Gas Pressure in Mines.—Dr H. Jeffreys: The Reflexion and Refraction of Elastic Waves. The Amplitudes of Bodily Seismic Waves.—R. Stoneley: The Effect of the Ocean on Rayleigh Waves.

Royal Society of Medicine (Laryngology Section), at 5.—Annual General Meeting.

British Institute of Philosophical Studies (at Royal Anthropological Institute), at 5.30.—Prof. E. F. Carritt: Contemporary Data for Æsthetics (Lecture)

Institution of Mechanical Engineers, at 6.—Fourth Report of the Marine Oil-Engine Trials Committee.

Society of Chemical Industry (Chemical Engineering Group) (at Florence Restaurant, 56 Rupert Street, W.C.1), at 6.30.—Annual General Meeting.

Society of Chemical Industry (Manchester Section) (at St. Mary's Parsonage, Manchester), at 7.—Prof. J. C. Drummond: Chemical Aspects of Organic Evolution.

Royal Society of Medicine (Anæsthetics Section), at 7.—Annual General Meeting.

Photomicrographic Society (at 4 Fetter Lane), at 7.—Annual General Meeting and Members' Evening.

Junior Institution of Engineers, at 7.30.—A. V. Ballhatchet: Distortion in Wireless Reception.

Geologists' Association (at University College), at 7.30.—Dr. D. R. Grantham: The Petrology of the Shap Granite.—G. W. Young: Notes on the Shoshone Valley, Yellowstone National Park, U.S.A. (Lecture).

Philological Society (at University College) (Anniversary Meeting), at 8.—Presidential Address.—Prof. D Jones: The Cardinal Vowels.

Royal Institution of Great Britain, at 9.—Sir Frederic G. Kenyon English Illuminated Manuscripts.

SATURDAY, May 8.

Royal Society of Medicine (Otology Section), at 10.30 a.m.—Annua General Meeting

Royal Institution of Great Britain, at 3.—Dr. P. C. Buck: Th Song Form in England as represented by Parry.

Royal Society of Medicine (Balneology and Climatology Section) (a Llandrindod Wells).

SUNDAY, May 9

Royal Society of Medicine (Balneology and Climatology Section) (a Llandrindod Wells).

PUBLIC LECTURES.

MONDAY, May 3.

University College, at 5.—Prof. G. Dawes Hicks: Hegel's Aesthetics

Imperial College of Science and Technology (Royal School o Mines), at 5.15.—Sir T. W. Edgeworth David: Past Ice Ages of th World, and their Control of Animal and Plant Life, with Special Refe ence to the Australian Evidence. (Succeeding Lectures on May 10 an 17.)

King's College, at 5.30.—Prof F. Delattre: La Personnalité d'Hen Bergson et l'Angleterre.

TUESDAY, May 4.

Imperial College of Science and Technology, at 5.—Dr P. Chalmers Mitchell: Logic and Law in Biology (Huxley Memorial Lecture)

University, Birmingham, at 5.30.—Sir Oliver Lodge: Difficulties abo the Ether (Huxley Lecture).

University College, at 5.30.—Prof. G. E. Moore: Universals an Particulars. (Succeeding Lectures on May 11 and 18.)

Gresham College (Basinghall Street, E.C.), at 6.—Sir Robert Arm strong-Jones: Physic. (Succeeding Lectures on May 5, 6, and 7.)

WEDNESDAY, May 5.

Lesser Free Trade Hall, Manchester, at 7.30.—Public Meeting connexion with the Manchester District Branch of the Electric Association for Women. Chairman: Principal B. Mouat Jone Speakers: Miss Ellen Wilkinson, Mr. J. A. Roberts, and Miss Haslett.

THURSDAY, May 6.

Imperial College of Science, at 5.30.—Brig.-Gen. H. B. Hartle Chemical Warfare.

SATURDAY, MAY 8, 1926.

National Eugenics.

THE first parts of the new journal of the Francis Galton Laboratory for National Eugenics[1] should remove many misconceptions concerning both the methods and utility of later developments of the science which Galton founded. The editors contribute a short foreword reviewing the reasons which have prompted them in launching another large vessel of scientific journalism. Their tone may be considered in some quarters unduly combative; but it would be difficult to point to any accusation of prejudice or ignorance, explicit or implied, not strictly justifiable. When they state that "our journal will differ from existing journals in that . . . the papers published will be the work of trained scientists rather than of propagandists and dilettanti," the scarcity of journals devoted wholly to the scientific treatment of racial problems must be borne in mind. There appears to be no need to scent a slander upon all methods but those mathematical. Heredity may be viewed from other not less 'scientific' points of view than those of statistics.

Naturally, "a journal issued by the Galton Laboratory will be sympathetic to the methods of its founder, summed up in the title of his Herbert Spencer Lecture, 'Probability the Foundation of Eugenics.'" But the harvest of other disciplines is not excluded. Every new science is an "unclean novelty," and as a field for prejudices "the study of agencies under social control that may improve or impair the racial qualities of future generations, physically or mentally"—the subject of the Galton Laboratory—has been and is singularly fruitful. If impatience with prejudice is intelligible, so is impatience with the vague and dubious expressions of much descriptive biology. Yet no one knows better than the workers of the Galton Laboratory the importance of qualitative characters and the difficulties imposed by the absence of definitions where exact measurement is impossible.

Ultimately it is to descriptive biology that the biological statistician must go for scientific data. In practice the biometrician, if he has at times found fault with what he has received, has never disdained to seek light, in sociology or in medicine, upon his problems. The biologist, secure in a formulated if not a stereotyped discipline, has found no need for statistical aid, and thus has received less pressure to inform himself of even the most elementary details of his colleague's procedure. "Obsolete lumber" or not, the biological statistician is a fairly energetic raider of the storehouses of qualitative description. What is the truth underlying the editors' assertion that "eugenics requires now, and will require still more as it advances in the future, the most highly trained scientific minds," if it is not a plain admission that their science is a discipline as well as a technique, and that the only facts they can afford to condemn or opinions to despise are those that are false?

---

[1] "Annals of Eugenics," vol. 1, parts 1 and 2. Edited by Karl Pearson, assisted by Ethel M. Elderton, 1925. (The University Press, Cambridge.) Annual subscription, 50s. net.

The present issue contains a pedigree of Epicanthus and Ptosis by C. H. Usher, a note on the correlation between birth- and death-rates, with reference to Malthus's interpretation of their movements, by Anthony B. Hill, and the first parts of two larger studies—one on the "Problem of Alien Immigration into Great Britain," by Karl Pearson and Margaret Moul, and the other on the "Relative Value of the Factors which Influence Infant Welfare," by Ethel M. Elderton, based on data provided by the Medical Officers of Health for Rochdale, Bradford, Blackburn, Preston, and Salford. Than this last it would be difficult to imagine a better illustration of the scope, methods, and difficulties of the technique adopted. The subject is essentially statistical but is complicated by all manner of circumstances from which an inquiry like that of the senior editor and his collaborator is free. For example, among the factors influencing viability, are considered the health of the parents, the habits of the parents, the condition of the home, the occupation of the father, the place in family of the child, the age of the mother at birth of the child, and the employment of the mother.

Surely it is of importance that questions of such social value should be studied and judged by methods more refined than those of casual acquaintance. It is impossible to read Miss Elderton's judicial reviews of her own results—which need not be summarised here as they are incomplete—without attaching to them a higher value than the partial results of other methods can claim. The same applies to the paper on alien immigration, the authors of which conclude that restriction is both nationally eugenic and practicable. With regard to both, some sentences in the latter paper may be quoted:

> "For the practical purposes of prognosis there does not exist in the present material any correlation of the slightest consequence between the intelligence of the child and its physique, its health, its parents' care or the economic and sanitary conditions of its home. No doubt the indiscriminative critic will assert that we advocate poor physique, carelessness in the parent, uncleanliness in the child with overcrowding and poverty in the home. The workers in the Galton Laboratory are fairly inured to that type of criticism. They hold, however, that the decencies of life are worth fighting for and obtaining for their own sake, and without an adventitious stimulus from vague assertions that their absence is the chief source of stupidity, if not indeed of mental defect, in the child. Philanthropists, seeking to reform deleterious conditions, never gain in the long run, when they proclaim, without due research, that these conditions are the unquestionable cause of all concomitant evils."

There was never such pressing need as to-day for the work of such a laboratory as the Galton Laboratory; only by the skilled and methodical sifting of facts can be reached a state of knowledge that will lead to a raising of the standard of national fitness.

The Study of History.

Geschichte der Mathematik und Naturwissenschaften im Altertum. Von Prof. J. L. Heiberg. (*Handbuch der Altertumswissenschaft.* Fünfter Band, Erste Abteilung, Zweite Hälfte.) Pp. v+121. (München: C. H. Beck'sche Verlagsbuchhandlung, 1925.) 7·50 gold marks.

THE fact is so well known that it is neither flattery nor even compliment to say that Prof. Heiberg is one of the most learned of living men. Theodore Gaza, I feel sure, knew no more Greek than he, nor can Casaubon or Selden or Bentley have been more industrious and more erudite. The booklet now before us is one of the least of Heiberg's works, but it is an astonishing performance; for he has managed to fit a real history of ancient science into its 120 pages. A reasonable share, some fifty pages, goes to the great subject of mathematics; a delightful sketch of ancient medicine occupies the last thirty pages of the book; and between the two are readable and most instructive chapters on astronomy, mechanics, optics, music, and natural science.

When Zeuthen, another very learned Dane, wrote his short "History of Mathematics," he was more concerned with the development of mathematical concepts than with the precise part in that historical evolution which A or B happened to play; his little book was not over-full, but it was the perfection of lucidity. Prof. Heiberg's book is of a different kind, for it is an encyclopædic article which he has undertaken to write. It is packed to overflowing with information, but it is still exquisitely clear; it seems to touch on everything, and to omit nothing. Short as it is, every student of the history of science will want to keep it by his side.

To epitomise the long chapter on mathematics is beyond our powers; let us glance at the shorter chapter on ancient astronomy. Anaximander comes first, disturbing the old Homeric cosmogony; the Pythagoreans, Philolaus, Anaximenes, and the rest, down to Oinopides and Anaxagoras, are next passed in review. Plato is shown to have given a firm foothold to astronomy in Athens, and we are told how the fantastic or at least poetic cosmology of the "Timaeus" and the

"Phaedo" led on to the more prosaic but more scientific work of Eudoxus and Callippus. There follows the great figure of Aristarchus (for whom we are, of course, referred to Sir Thomas Heath), and with Aristarchus we seem to have well-nigh reached to the Copernican system; Heiberg does not forget to tell us, from Plutarch, how Cleanthes abandoned Aristarchus's views as impious, and how Seleucus alone clave to him—that Seleucus who, together with Heracleides, would seem to have been the first to conceive of our universe as ἄπειρος, or infinite.

The rival theories of epicycles and of circular but eccentric orbits are next discussed, and the particular relation of the former to the cases of Mercury and Venus is shown to foreshadow the views of Tycho Brahe. Meton and Euctemon, the great Athenian calendar-makers, come next in order; and then we pass quickly to the story of the constellations, and to the popular poem of Aratus, with its many translators and commentators—that very poem which St. Paul quoted in his sermon on Mars' Hill. Hipparchus, Theon, and Ptolemy are all discussed quietly and even leisurely. Next come Proclus and the other Neo-Platonists; then the few Roman scholars, such as Varro, Seneca, Martianus Capella, Manutius and Manilius, the last of whom plays his part, with Manetho, Firmicus, and Hephaestion, in the long history of astrology. Even the Byzantines, such as that great scholar of the eleventh century, Michael Psellus, or Leon the Philosopher, or Manuel Comnenus the Emperor, are not forgotten; and who knows the Byzantines better than Prof. Heiberg? The footnotes and references to books and scattered pamphlets are very copious; and out of his vast knowledge of MSS. Heiberg points out every here and there how this or that remains to be studied: how a commentary of Michael Psellus on Ptolemy lies uncollated in Paris, how a MS. of Theodore Metochiton awaits an editor in the Marcian, or how there is still much more of Vettius Valens than Cumont or Boll have told us of.

Prof. Heiberg handles the immense literature of ancient mathematics, medicine, and the natural sciences with the selfsame ease. His story runs so smoothly it never reads like a compilation: we feel all the while that the writer is giving us only what he has made his own, that he has endless material in reserve, and that he can afford us little allusions and sidelights in plenty, which are far beyond the mere compiler's reach and ken. It is not everybody who happens to know that Jo. Philoponus and Simplicius, the Aristotelian commentators, were at daggers drawn; or that Barlaam of Calabria (who paraphrased the 2nd Book of Euclid) was the schoolmaster both of Petrarch and of Boccaccio.

D. W. T.

Photosynthesis.

Photosynthesis: the Assimilation of Carbon by Green Plants. By Prof. Walter Stiles. Pp. vii+268. (London: Longmans, Green and Co., 1925.) 16*s. net.*

A WRITER of some considerable eminence says, in prefacing his account of one of our English shires, "In the account which follows my aim has been to gather a . . . bouquet rather than to present the facts which the more practical traveller requires." Prof. Stiles is less definite in his preface to the highways and byways of photosynthesis. In his preface we find "an attempt is made to present a view of our present knowledge . . . it is intended to be more general in its scope" than an earlier account by Prof. Stiles and Mr. Jorgensen, which "was essentially a critical account of what were then recent developments of the subject." Further on we find that the present account "is not simply a critical review of recent developments." We are left in doubt as to whether our fate is facts, bouquet, or both.

We find that our guide has not stinted us of facts on the structure of assimilatory organs, the composition of the protoplasm of non-assimilatory organisms, the chemical composition of the green and yellow pigments of the leaf and how to separate them, the methods of measuring assimilation, the variation of the rate of the process with change of external and internal factors, and so on. In fact, we might almost say that the author's hope "that no important work has been overlooked" has been realised.

Bouquets are, however, subtler and personal things in more ways than one. Selection and perhaps arrangement are required. If we have all the facts it is perhaps hopeless to expect selection, but one does look for some indication of the reaction of the collector to the facts he brings together for us. Prof. Stiles usually refrains from revealing himself, and when he does make comments he is sometimes misleading. In his account of methods of measuring photosynthesis he commits himself to saying that the continuous current method is the most reliable of all methods that have been evolved for measuring photosynthesis. Apart from the facts that 'continuous current' describes the supply and removal of substances rather than their measurement, and that the reliability of the measurement is not affected by the method of supply, the subject has many aspects. What is the explanation of the low values obtained by Brown and Escombe when using this method? That these values are low is shown by the rate at which the plant increases in dry weight under natural conditions. Prof. Stiles puts forward as an objection to the eudiometric method the fact that the transpiration of a leaf into a closed space disturbs the water relations of the leaf. We imagine that disturbed water relations is the explanation of the discrepancy between the results of Brown and Escombe and those obtained by other methods. The real point is that with different technique we have different sets of conditions both external to and inside the assimilating organ, and it is not reliability of method but the type of problem tackled which usually decides the technique. The quotation of the expression

$$x_{O_2} = \left[v_G \cdot \frac{273}{T} + v_F a_{O_2} \right] \frac{P-p}{76,000} \left(\frac{b_{N_2}}{b'_{N_2}} \cdot b'_{O_2} - b_{O_2} \right),$$

used by Warburg in calculating assimilation, makes one wonder for what class of reader the book is intended.

The author is not much happier in expressing himself when he is commenting upon the experimental results recorded. In the section on the relation between rate of assimilation and the concentration of carbon dioxide, we find "Warburg selected the unicellular alga *Chlorella* because in such a minute object the concentration of carbon dioxide at the surface of the chloroplast must be in approximate equilibrium with that in the water outside so that complications introduced by the diffusion stage are practically eliminated." What the complications are is not stated, but presuming that equilibrium means equality, we think that the author might have explained how size of object came in, and referred to the importance of the medium, water or air, and the relative amounts of carbon dioxide and bicarbonate. Later we find that in the experiments of Blackman and Smith it "does not appear likely that the rate of photosynthesis might have been determined by the diffusion." Whatever the author may mean, this statement is misleading, for no matter what the nature of the organism the rate of photosynthesis *is* the rate of supply of carbon dioxide to the seat of the reaction.

It is remarks such as the above that make one feel that our author, to return to our earlier analogy, is but a hurried visitor to our shire, and that but few of our intricate scenes have bewitched him so much that he has lingered awhile, and perhaps none has returned to him in his sleep. With so much ground to cover, it would perhaps be unreasonable to expect much of a visitor

We have discovered but one error. The experiments of Willstatter and Stoll with elm leaves were carried out with a light intensity which these workers call 24,000 lux, and not 48,000, as stated on p. 181 We should also like to protest against the continued confusion of Blackman's Law of Limiting Factors and the laws of Liebig and Malthus. The first refers to rates of a process, whilst the last two refer to size of a community of organisms.

It would indeed be surprising if the first book of its type were perfectly satisfactory. Plant physiologists and others are indebted, however, to Prof. Stiles for courageously pushing on where others have hesitated. The presence of more than eight hundred and seventy references in the bibliography may give some idea of the labour involved.

G. E. B.

The Integration of Physiology.

Principles of Human Physiology. By Prof. Ernest H. Starling. The Chapter on the Sense Organs edited by Dr. H. Hartridge. Fourth edition. Pp. xiii + 1074. (London: J. and A. Churchill, 1926.) 25*s.* net.

IT is not too much to say that the "Principles of Human Physiology" forms a definite landmark in English text-books on this subject. It is not many decades since a comprehensive text-book on physiology could have been written by almost any professor of the subject. To-day, owing to the rapid growth and differentiation of the subject, for which the large amount of research work and the still larger volume of published matter are responsible, there are few of our experts who would care to attempt the task, and of these a still smaller number would have any chance of success, so difficult is it to keep in touch with the advance of a subject which avails itself of the contemporary advances in so many other branches of science.

There have been attempts, especially on the continent, to overcome this difficulty by the collaboration of several authors in the preparation of a text-book, and while it must be admitted that such a book may gain in precision, as it does in detail, yet these advantages must be in great measure offset by the lack of homogeneity from which such an effort must inevitably suffer. One even finds, in such productions, that the authors of different sections often express opinions diametrically opposed to one another. Out of a hundred readers of such a book, ninety-nine find themselves unable to form any definite opinions, while to the hundredth, himself an expert, the book is superfluous.

It is therefore a matter of the most urgent necessity to a subject like physiology that it be kept from falling to fragments, by being written up in an integrated fashion by a master hand. A book such as this serves, therefore, not only for the instruction of students, but also for the orienting of physiologists themselves in branches of their subject which they have not, by their research work, made peculiarly their own.

Aware of the magnitude of the task which the author has undertaken, we must therefore be prepared to overlook small errors of omission or commission or partiality, which are inseparable from such works, and in doing so we gain much more than we lose, for we do not think that a better balanced text-book of physiology has ever been or could possibly be written. Although much new matter has been added, the bulk of the volume has been reduced by the deletion of a good deal of the organic chemistry which occupied space in former editions. Some of the chapters might with advantage have been extended a little in order to preserve the same treatment of detail throughout; thus, the chapters on the endocrine organs might well occupy twice their present space; as it stands at present, the physiology of the pituitary body, for example, occupies less space than, say, the general biology of nitrifying bacteria. But these are small cavillings, and we must feel grateful to the author for the splendid viewpoint of physiology which he has given us.

The chapter on the sense organs has been edited by Dr. H. Hartridge, and is excellently done; it is certainly an advantage to have this specialised chapter revised by one who has devoted particular attention to the subject, and the inclusion of this chapter in no way mars the continuity of the book. Many of Prof. Starling's colleagues have assisted him in the preparation of chapters dealing with subjects which they have made heir own, and when we see how much of the matter ncorporated in the book has emanated from the aboratories of University College, London, we feel how ruly great has been the influence which Prof. Starling nd his colleagues have exercised on the recent evelopment of the science of physiology in Great Britain.

"Principles of Human Physiology" appeals most to those students who wish to get acquainted with the cientific side of physiology as it is to-day. The edical student who wishes to build a proper foundation or his clinical studies will be wise to choose it, and the cience student working for a degree in physiology nows it to be indispensable; for physiologists themelves it is too well known to need further commendation.

An Australian Encyclopædia.

he Illustrated Australian Encyclopædia. Edited by Arthur Wilberforce Jose and Herbert James Carter. Vol. 1: A to Lys. Pp. x + 768 + 26 plates. (Sydney, N.S.W.: Angus and Robertson, Ltd.; London: The Australian Book Co., 1925.) n.p.

THE first volume of an illustrated Australian encyclopædia, by Captain A. W. Jose, a well-nown Australian journalist and historian, and Mr. . G. Carter, president of the Linnean Society of New outh Wales, forms an important addition to the reference books on Australia. The work was begun as an historical and biographical dictionary in 1912, but after the War it was resumed and enlarged by the inclusion of Australian science. The volume is illustrated by numerous text figures and a series of beautiful plates, of which ten are coloured, and show characteristic algæ, insects, birds, eggs, and reptiles.

Amongst the scientific articles in this first volume are those on the aborigines, in which Mr. S. H. Ray deals with the languages, Sir Baldwin Spencer with the customs and tribal organisation, and Dr. Ramsay Smith with the origin and physical character. Dr. Smith repudiates as baseless the view that the aborigines are mentally so primitive that they are unable to count up to more than four, as some uncivilised tribes have numerical names for children up to ten; they are very quick in mental arithmetic; and he says that the "ordinary black fellow is as good at figures as his white brother," that the aboriginal children at schools can be educated like white children and to the same extent, and that the "parents object to any distinction in the curriculum or the standard." Dr. Ramsay Smith says that it is now established that the Australians are a homogeneous race of Caucasian stock. Mr. Ray, though rejecting some of the claims for the affinities of the Australian and South Indian languages, remarks that the Dravidian and southern Australian are of the same morphological type.

The article on artesian water refers to the widespread decline in yield of the Australian wells, and the view that their discharge is due to gas pressure caused by the inflow of superheated plutonic water is noticed in terms which show that the theory is regarded more seriously in Australia than when it was put forward twenty years ago.

The article on flight traces the foundation of the modern aeroplane to the work of Hargraves, and quotes the prediction by Sir Richard Threlfall, in rebuke of its local neglect, that the time would come when Sydney would be less famous for its harbour than as "the home of Lawrence Hargraves, the inventor of human flight." Two of the more important articles are those on economic geography by Prof. Griffith Taylor, and on geology by Sir Edgeworth David and Prof. Cotton. In the latter article the glacial beds of Adelaide are said to be probably Proterozoic, but possibly Cambrian, and the term Permo-Carboniferous is retained mainly as a matter of custom, with full recognition that the beds in question are Permian. The article on irrigation describes many adventurous enterprises; that on the ballot recalls its first adoption in Australia and its original name of the Australian Ballot; and that on the Labour Movement is sympathetic, but does not bring the story later than 1915.

T I

Birds of Eastern China.

A Handbook of the Birds of Eastern China (Chihli, Shantung, Kiangsu, Anhwei, Kiangsi, Chekiang, Fohkien and Kwantung Provinces). By J. D. D. La Touche. Part 1 (containing Families Corvidæ, Paridæ, Panuridæ, Sittidæ, Certhiidæ, Troglodytidæ, Paradoxornithidæ, Timaliidæ and Pycronotidæ. Part 2 (containing Families Cinclidæ, Turdidæ, Muscicapidæ and Laniidæ). Pp. 97-192+plates 4-7. (London: Taylor and Francis, 1925.) 7*s.* 6*d.* net.

TWO parts of Mr. La Touche's work on the birds of Eastern China have now appeared, and if the standard set in these two parts is maintained, a long-felt want in ornithological circles will be admirably filled. Since the appearance of Oustalet's "Oiseaux de la Chine" in 1877, no book of any importance has been written on any of the larger areas of China, although a considerable amount of work has been done, and many authors, Ricketts, Styan, La Touche himself, Jones and Vaughan and other naturalists, have from time to time published articles in the *Ibis* and other ornithological journals. The author of the present work has adopted Stuart Baker's classification as given in the "Avifauna of British India"; a classification which will make it easy for readers of oriental ornithology.

In a work of this kind there are naturally certain minor points upon which all ornithologists may not be able to agree with the author, but it is obvious that he has bestowed so much thought upon his work and has drawn his conclusions with such care and deliberation that his decisions will always have to be examined with attention before being discarded. We notice that Mr. La Touche divides *Parus major* and *Parus cinereus* into two species, although he himself admits that the two grade into one another. On the other hand, in the second portion of his work, he treats *Turdus ruficollis* and *Turdus atrogularis* as races of one species, and quotes Stresemann to the effect that these two so-called subspecies hybridise.

The majority of Mr. La Touche's new forms have already been described in the *Bulletin of the British Ornithologists' Union*. In Part 1 we have *Pyctorhis sinensis major* and *Pycnotus sinensis stresemanni*, whilst in Part 2 we have *Cynclus pallasii wilderi* and *Hemichelidon sibirica incerta*, but we would note that the types of these sub-species has not been recorded.

When we come to the field notes, we find these to be very full and most interesting, due no doubt to Mr. La Touche's long and intimate knowledge of the countries harbouring the birds he discusses. So far, no map has been given of the localities treated, but we understand that one is to be given in Part 3 of this work, and such a map will add greatly to its value.

We may congratulate Mr. La Touche on having produced a work which is not only sound from a scientific point of view but is also one of great interest. No student of oriental ornithology but will welcome its appearance, and the chance of obtaining, at so moderate a price, so excellent a work.

Our Bookshelf.

Sampling and Testing of Highway Materials. By Prof. Wm. H. Barton, Jr., and Prof. Louis H. Doane. Pp. ix+355. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 17*s.* 6*d.* net.

THE scope of this book is more extensive than its title would indicate, seeing that it includes a general treatment of cements, bricks, and aggregates, together with a variety of miscellaneous materials. The joint work of two American engineering professors, the treatment follows the usual lines of American laboratory manuals, the organisation of the testing-room being described with minutest detail and the various experiments outlined in routine form. The consequent 'cookery book' diction is necessarily pronounced; but, after all, the method pursued is possibly the best for those who are to perform the tests; while others, with laboratory experience in directing students, will appreciate the emphasis laid upon care and caution in conducting quasi-scientific tests in accordance with pseudo-empirical rules. In cement testing alone, this book will prove invaluable in the laboratories of the various colleges and departments, since it prescribes a number of tests additional to those usually recognised.

Of its nine chapters, the first three are devoted respectively to laboratory practice, sampling, and Portland cement and concrete. Even the specialist might benefit by perusal of these. Comparatively little has yet been attempted in Great Britain in regard to the standardisation of tests for hardness abrasion resistance, toughness, etc., of stones. Chap. v. appears to lack scope and system in dealing with miscellaneous materials, but these deficiencies are compensated for to a great extent by the treatment of bituminous materials in the succeeding chapter.

The thirty-six pages of Chap. vii. are devoted to specifications, mainly in accordance with the requirements of the American Society for Testing Materials The collection of diagrams and tables in Chap. viii affords a useful appendix to the book. Nine diagrams showing the effects of various factors on the strength o concrete, are included, while, additional to a number in the text, twenty-five useful tables are given of a typ rarely found in text-books. A concluding chapter "Subgrade Soils," is by Mr. J. R. Boyd, Assistant Engineer of Tests, U.S. Bureau of Public Roads Washington.

The History of Protozoology: Two Lectures delivere before the University of London at King's Colleg in May 1925. By Prof. F. J. Cole. Pp. 64+2 plates (London: University of London Press, Ltd., 1926.)

THIS little volume is based on two lectures delivere by Prof. Cole at King's College, London, in 1925. It is impossible in the small amount of space at the author's disposal to give more than a brief outline of the more important events in the history of protozoology; but it must not be assumed on this account that this has become a mere recital of dates and names. Far from it. By means of a judicious selection of the more important events in protozoological discovery and by the neglect of all matter of a controversial nature, Prof. Cole has prepared a very readable book which gives a much-needed sense of perspective to a branch of science which has been so very rapid in its growth. He emphasises the difficulties under which the pioneers worked and shows that we cannot appreciate them at their true value unless we rid ourselves of our modern bias. He illustrates "not only the importance of success, but the significance of failure. In criticising our predecessors, we must not forget that we stand on their shoulders and that we owe as much to their errors as to their wisdom."

Commencing with Leeuwenhoek, the "Father of Protozoology," the more important discoveries are indicated and their importance shown. The greater amount of space is given to the work of the past century—an era when so many brilliant discoveries in the medical and economic fields were made. The whole of the science is covered, however, not merely the economic sides, and an extensive bibliography is appended by means of which the student is encouraged to pursue further the subject to which this forms such an interesting introduction.

Air Ministry: Meteorological Office. The Meteorological Observer's Handbook. Approved for the Use of Observers by the Meteorological Office and the Royal Meteorological Society. 1926 edition. (M.O. 191.) Pp. viii + 136 + 36 plates. (London: H.M. Stationery Office, 1926.) 5*s.* net.

This work is of interest to all meteorologists without distinction of the branch of weather study in which they are concerned, and its essentials are as necessary to trained physicists as to the more ordinary observer whose work is somewhat empirical. The necessity for uniformity of practice has been kept well in view, and with regard to temperature and rainfall, details as to position and exposure are of primary importance. The decisions of international conferences are adhered to so far as practicable.

Instructions are given for making observations of the several elements, except that observations of the free atmosphere are not dealt with, this information being contained in other publications. There are copious illustrations of autographic instruments, and details are given for their management. There are also complete tables for the manipulation and correction of the various observations. With many elements where diurnal variation is concerned, summer time has to be disregarded so far as is practicable by the observer or most important defects would be the result of observation. Notes of important action should be carefully entered in the permanent register.

A new section on visibility, of special importance for navigation on the sea or in the air, has been introduced, and by its aid good observations can be made either by day or night. A number of cloud pictures are given, and the excellent representations will enable an observer to identify the various cloud forms. A study of the work cannot fail to interest an observer.

(1) *A First Course in Statistical Method.* By Prof. G. Irving Gavett. Pp. vii + 358. (New York: McGraw Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 17*s.* 6*d.* net.

(2) *Mathematics of Life Insurance.* By Prof. L. Wayland Dowling. (Modern Mathematical Texts.) Pp. x + 121. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 8*s.* 9*d.* net.

Hand in hand with the boom in industry in the United States there has been a continued spate of text-books on statistics, life insurance, and the mathematics of finance generally. The mathematical knowledge required to master these books, generally speaking, does not extend beyond elementary algebra, mainly permutations and combinations, and sometimes, but not always, a knowledge of differentiation. In the first of the above works, for example, there is a special appendix on "Derivatives and Integrals" expounding a great deal less than is known by the average schoolboy just entering a university course in Great Britain. Yet the scope of the work includes frequency, dispersion, skewness, probable error, curve-fitting, correlation and regression. It means, of course, that no time is wasted in arguing with the reader; he is just told. If he is not satisfied with this, he will find in these works numerous illustrations in which it *is* so.

The second of these books should be of value to those desiring to master the methods of calculation adopted in the many forms of insurance. It is really a book on arithmetic and algebra applied in a stimulating manner to an interesting series of special problems, and is very readable. Both works are well produced.

The Journal of the Institute of Metals. Volume 34. Edited by G. Shaw Scott. Pp. 799 + xi + 33 plates. (London: Institute of Metals, 1925.) 31*s.* 6*d.* net.

Metallographic studies of alloys of the non-ferrous metals occupy a large part of the present volume, and it is satisfactory to observe that in this field of research England takes the leading place. Such an investigation as that of Drs. Hanson and Gayler on the ternary alloys of aluminium, copper and zinc, with its extraordinarily complex equilibria, shows to what perfection the methods of study in this field have been brought. Two quite independent investigations deal with the β-brasses and their transformation at 470°, both arriving at the conclusion that a eutectoid is not formed, and that the transformation is one which is not accompanied by any change of structure. The copper-tin and copper-cadmium alloys are also studied. Two papers are concerned with the influence of time in tensile tests conducted at high temperatures, this being now a matter of technical importance, on account of the need for metals which can withstand continuous loading at high temperatures. A note on the copper objects of the American Indians before the arrival of the Spaniards will be of interest to archæologists. The objects are of pure material, apparently Lake Superior native copper. More than half of the volume is occupied by abstracts, the literature relating to non-ferrous metals having now been brought up-to-date, and covering a very wide field. This work is remarkably well done, and is worth consulting by others than metallurgists, on account of the large quantity of data brought together from many sources.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Spinning Electrons.

I UNDERSTAND that in the newly proposed spinning electron the periphery is supposed to move faster than light, and the question has arisen in some minds whether such a motion can be allowed by the relativity theory. I think an assurance can be given that the relativity theory raises no objection.

It must be remembered that the mass and energy of an electron are considered to reside in the electromagnetic field outside its boundary. Whether the electron spins or not, this field is steady, so that there is no question of any transport of mass or energy with speed faster than light. It is only when *energy* or *signals* are alleged to go faster than light that the relativity theory is moved to intervene. Further, the spinning electron represents a state of the world-distribution of charge-and-current vector—which, while differing from that of an electron at rest, is nevertheless equally static and unchanging. It seems almost an abuse of language to apply the term velocity in connexion with a structure which is perfectly stationary; but the description in terms of spin may be held to serve its purpose since it leaves no doubt as to the structure intended.

The mathematical definition of velocity (dx/dt) contains no special reference to motion in a dynamical sense, x is merely the co-ordinate of a selected succession of world-points, and there is in the definition no guarantee that dx is traversed by anything except the thought of the mathematician. In describing the electron as spinning, what happens is that, faced with a hitherto unimagined structure, we make our thought skip faster than light round its boundary, and by so doing succeed in seeing a correlation with a more familiar structure, namely, that of an electron at rest. The correlating velocity has no more physical existence than has the factor $\sqrt{-1}$ used to correlate the structure of the four-dimensional world to the more familiar structure of a four-dimensional Euclidean space. In a deeper analysis we should not speak of a moving charge-element but of a charge-and-current vector, motion being attributable only to boundaries or analogous features of charge distribution—not to *charge*, but to *a charge*. When in the cruder description the charge moves faster than light, the charge-and-current vector J^μ becomes *space-like*. (In ordinary macroscopic phenomena J^μ is always *time-like*.)

It may be interesting to recall that the conclusion that the electron contains a space-like J^μ was already reached tentatively from a study of the interrelation of the electromagnetic and gravitational fields (see my "Mathematical Theory of Relativity," p 211). It is deduced from Weyl's action-principle. So far as I can make out, Weyl himself reached a different conclusion, but it seems a straightforward result from his theory. From the action-principle a formula was obtained connecting mass-density with the electric vector ($\rho_0 = -(\beta^2/12\pi)J^\mu J^\mu$) and the conclusion was—"Since the density of matter is always positive, the electric charge-and-current inside an electron must be a *space-like* vector, the square of its length being negative. It would seem to follow that the electron cannot be built up of elementary electrostatic charges but resolves itself into something more akin to magnetic charges." A. S. EDDINGTON.

Observatory, Cambridge,
April 24.

I FEEL that there are serious arguments against the two objections raised by Mr. Kronig (NATURE, April 17, p. 550) to the view that the electrons in the atom possess an inherent magnetic moment, a view which Uhlenbeck and Goudsmit have shown to have important spectroscopic consequences. I will consider first the second objection, which seems to me to involve implicit assumptions about the structure of the atomic nucleus which go far beyond our present knowledge of the facts or even of the probabilities. I am prepared to follow Mr. Kronig to the extent of believing that if an electron has a quantised spin when in a Bohr orbit, an electron which has the privilege of taking part in the building up of an atomic nucleus will have the same property of possessing one or more units of angular momentum or of magnetic moment. But it seems to me improbable that the electron after it has entered into the composition of the nucleus will be able, as an individual electron, to retain this angular momentum. The 'dimensions' of the nucleus are not very much greater than those of an electron, and as the nucleus may contain a very considerable number of electrons and protons, it must be a highly interlocked structure of a kind which scarcely seems likely to afford opportunity for the ordered spinning contemplated.

I suggest that what is more likely to happen is that the electron gets rid of this angular momentum in the process of nucleus formation either by passing it on to the nucleus as a whole or else by radiating it away. If the angular momentum is transferred to the nucleus as a whole, its magnetic effect becomes negligible owing to the much higher moment of inertia of the rotator; so that in either event the nucleus would have no appreciable magnetic moment. That the nucleus as a whole does possess a quantised angular momentum is shown by the mechanical gyromagnetic anomaly, as I showed in 1922 (*Roy. Soc Proc.*, A, vol. 102, p. 538), and also, though less directly, by the corresponding and similar spectroscopic anomaly. In any event the magnitude of the mechanical gyromagnetic anomaly makes it necessary to admit the existence of a quantised spin of the nucleus, a structure the 'dimensions' of which are not much greater than those of an electron.

As regards the first objection, the statement as to the foundation of the Bohr magneton resting on the orbital motions of electrons which can be treated solely as point charges moving with velocities small compared with that of light, seems to be too narrow. If it is assumed that an electron is a sphere of radius R carrying a charge e and that the inertia is entirely electromagnetic (these are the simplest assumptions which can be made), the application of the quantum condition $\int pdq = nh$, where p is the angular momentum, requires that for any rotation the magnetic moment of a spinning electron should be $n \cdot eh/4\pi cm$ where n is an integer and the other factor is the magnitude of the 'Bohr magneton.' O. W RICHARDSON.

King's College,
Strand, W.C.2.
April 19

IN view of the letters recently published in NATURE upon the subject of rotating electrons, it may be o interest to mention some attempts made four years ago to use this idea in explaining the stability of the nucleus. It is common knowledge that the fact that nuclei can exist despite their excess positive charge cannot be explained without introducing hypotheses outside the classical electrodynamics. Whilst the electrostatic attractions which would lead to collapse of matter may be balanced by the centrifugal acceleration of the particles on stationary quantised orbits, no inertia effect can compensate the electrostatic repulsion which should lead to the explosion of the nucleus.

The idea, which was not pursued as it did not seem susceptible of quantitative examination, was to assume that protons and electrons are rotating at speeds given by the usual quantum condition. It is at once evident that one cannot go very much further without making some arbitrary assumption—

1. About the distribution of electricity and mass in the proton or electron, if indeed either term has any meaning when referred to part only of a particle.
2. About the force holding the proton or electron together if the parts repel one another as they would if the ordinary laws of electrodynamics apply to them
3. About the magnetic field of a rotating proton or electron.

This much, however, is clear, that if the effective radii are of the order usually assumed, the peripheral speed would in either case approach the velocity of light and that the peripheral speed of the proton would approach it somewhat more closely than that of the electron. If anything like the ordinary laws hold, this means that protons and electrons will have intense magnetic fields, almost, but not quite balancing their electrostatic fields at distances of the order of their radii, the magnetic field of the proton being somewhat greater than that of the electron. At greater distances, of course, the magnetic forces would disappear compared to the electrostatic forces, since their value decreases more rapidly than with the square of the distance.

With such particles it is clear that stable nuclei can be built up, for the magnetic forces can be arranged all to support cohesion, whilst, of course, only the excess positive charge is available to cause disruption. Since the positive particle with its greater mass has the greater peripheral speed and magnetic field, an excess positive charge can be accommodated. It is possible to make fairly plausible assumptions which explain the stability of the simpler nuclei, but as it is impossible to base them upon any exact calculation without making hypotheses about the internal forces, they are scarcely worth recording.

F. A. LINDEMANN.

Clarendon Laboratory,
Oxford, April 23.

IN a recent letter to NATURE (February 20, p. 264), Messrs. Uhlenbeck and Goudsmit have shown how the theory of the spinning quantised electron can be applied to the problem of the multiplet structure of spectral lines and that of the anomalous Zeeman effect. In both cases the theory gives excellent results, if the ratio m/M of the magnetic moment to the mechanical one is identified with the corresponding ratio for the orbital motion ($e/2cm_0$, where e is the charge and m_0 the mass of the electron) in the former case, and to the double of it in the latter.

The following is a brief account of a solution of this paradox on the basis of the special relativity theory (the fuller publication being reserved for the *Zeitschrift fur Physik*).[1]

Without entering into the consideration of the spinning motion of the electron and into speculations about its 'inner structure,' we shall treat it merely as a point, associated with a vector $\mathbf{m}$, corresponding to the magnetic moment, and possessing a mechanical moment $\mathbf{M}=\frac{1}{\kappa}\mathbf{m}$. From the point of view of the relativity theory, a three-dimensional vector quantity must be considered as the space part either of a four-dimensional vector with four components or of an antisymmetrical tensor with six components. Now, the magnetic intensity $\mathbf{H}$ represents, as is well known, the space part of the electromagnetic field antisymmetrical tensor $F_{\alpha\beta}=-F_{\beta\alpha}\ (\alpha,\beta=1,2,3,4)$ the 'time part' of which corresponds to the electric intensity $\mathbf{E}$, according to the Minkowski substitution.

$$\begin{pmatrix} F_{23}, & F_{31}, & F_{12}, & F_{14}, & F_{24}, & F_{34} \\ H_1, & H_2, & H_3, & -iE_1, & -iE_2, & -iE_3 \end{pmatrix}.$$

It appears necessary, therefore, to introduce as the four-dimensional extension of $\mathbf{m}$ an antisymmetrical 'moment tensor' $\mu_{\alpha\beta}=-\mu_{\beta\alpha}$:

$$\begin{pmatrix} \mu_{23}, & \mu_{31}, & \mu_{12}, & \mu_{14}, & \mu_{24}, & \mu_{34} \\ m_1, & m_2, & m_3, & ip_1, & ip_2, & ip_3 \end{pmatrix},$$

the 'time part' $\mathbf{p}$ of which is a three-dimensional vector analogous to the electrical moment of a dipole.

The corresponding extensions for the three-dimensional magnetic energy $-\mathbf{m}\,.\,\mathbf{H}$ and torque $\mathbf{m}\times\mathbf{H}$ with components $m_\alpha H_\beta - m_\beta H_\alpha$ are then easily seen to be $U=-\frac{1}{2}\mu_{\alpha\beta}H_{\alpha\beta}$ (the summation sign for equal index-pairs being omitted), and $f_{\alpha\beta}=m_{\alpha\gamma}F_{\beta\gamma}-m_{\beta\gamma}F_{\alpha\gamma}$ Denoting the electron's 'proper time' with τ, we then get the following equations for the 'spinning motion,' that is, the rate of change of $M_{\alpha\beta}$:

$$\frac{1}{\kappa}\frac{d\mu_{\alpha\beta}}{d\tau}=\mu_{\alpha\gamma}F_{\beta\gamma}-\mu_{\beta\gamma}F_{\alpha\gamma}, \quad . \quad . \quad . \quad (1)$$

which are equivalent to

$$\frac{1}{\kappa}\frac{d\mathbf{m}}{d\tau}=\mathbf{m}\times\mathbf{H}+\mathbf{p}\times\mathbf{E},\ \frac{1}{\kappa}\frac{d\mathbf{p}}{d\tau}=\mathbf{p}\times\mathbf{H}-\mathbf{m}\times\mathbf{E}. \quad (2)$$

These equations are, however, strictly valid in that case only, when no *a priori* relation between $\mathbf{m}$ and $\mathbf{p}$ exists. In the case under consideration these vectors are connected with each other by the invariant relation

$$\mu_{\alpha\beta}\dot{x}_\beta=0\ \left(\dot{x}_\beta=\frac{dx_\beta}{d\tau}\right), \quad . \quad . \quad . \quad (3)$$

that is

$$\mathbf{p}=\frac{1}{c}\mathbf{v}\times\mathbf{m}, \quad . \quad . \quad . \quad . \quad (4)$$

expressing the fact—or rather the *assumption*—that in a co-ordinate system, in which the electron's translational velocity $\mathbf{v}$ is zero, the 'electrical moment' $\mathbf{p}$ must vanish. In order to account for this restriction one must replace the energy function U by $U'=-\frac{1}{2}\mu_{\alpha\beta}F_{\alpha\beta}-A_\alpha\mu_{\alpha\beta}\dot{x}_\beta$, where A_α are the components of an indefinite vector multiplier, and accordingly replace the equation (1) by

$$\frac{1}{\kappa}\frac{d\mu_{\alpha\beta}}{d\tau}=\mu_{\alpha\gamma}F_{\beta\gamma}-\mu_{\beta\gamma}F_{\alpha\gamma}+A_\gamma(\dot{x}_\alpha\mu_{\beta\gamma}-\dot{x}_\beta\mu_{\alpha\gamma}). \quad . \quad . \quad (5)$$

By means of the relation (3) and $\dot{x}_\alpha\dot{x}_\alpha=-c^2$ the following expression is found for A_γ:

$$A_\gamma=\frac{1}{\kappa c^2}(\kappa F_{\gamma\beta}\dot{x}_\beta-\ddot{x}_\gamma). \quad . \quad . \quad . \quad (6)$$

A more rigorous deduction of these equations, as well as of the corresponding equation for the translatory motion of the spinning electron, is achieved by means of the Hamiltonian principle $\delta\int L d\tau=0$, with the two accessory conditions $\dot{x}_\alpha^2 = -c^2$ and $\mu_{\alpha\beta}\dot{x}_\beta = 0$, the Lagrangian function having the form $L = \frac{1}{c}\phi_\alpha\dot{x}_\alpha + T + \frac{1}{2}\mu_{\alpha\beta}F_{\alpha\beta}$, where ϕ_α is the electromagnetic potential and T the 'kinetic energy' of the electron's spin. This quantity as well as $\mu_{\alpha\beta}$ must be regarded as functions of the 'angular velocity' $\omega_{\alpha\beta} = -\omega_{\beta\alpha}$, their variations being expressed by $\delta T = \frac{1}{2\kappa}\mu_{\alpha\beta}\delta\omega_{\alpha\beta}$ and $\delta\mu_{\alpha\beta} = \mu_{\alpha\gamma}\delta\Omega_{\gamma\beta} - \mu_{\beta\gamma}\delta\Omega_{\gamma\alpha}$ $(d\Omega_{\alpha\beta} = \omega_{\alpha\beta}dt)$.

---

[1] This question has been already treated on different lines by Dr. Thomas, of Copenhagen I am indebted to Dr W. Pauli for the possibility of taking notice of Dr. Thomas' paper before it was published, and also for valuable suggestions in the course of my own investigation.

Omitting the deduction (which will be found in my *Z. f. Phys.* paper), I shall give here but the final equations, which are (5), (6) and

$$\frac{d}{d\tau}(\lambda\dot{x}_\alpha + A_{\beta}\mu_{\beta\alpha}) = \frac{e}{c}F_{\alpha\beta}\dot{x}_\beta + \frac{1}{2}\mu_{\beta\gamma}\frac{\partial F_{\beta\gamma}}{\partial x_\alpha}, \quad . \quad (7)$$

where the factor λ differs very little from the 'rest-mass' m_0:

$$\lambda = m_0 + \frac{U}{c^2} = m_0 - \frac{1}{2c^2}\mu_{\alpha\beta}F_{\alpha\beta}. \quad . \quad . \quad (8)$$

By applying these equations to the motion of a spinning electron about a fixed nucleus, it appears possible to get *with the same value of the ratio*, $\kappa = m/M = \frac{e}{cm_0}$, a correct representation both of the multiplet structure and of the (anomalous) Zeeman effect. For example, in the absence of an external magnetic field ($H = 0$) we find from (5) the following approximate equation for the *secular variation* of $\mathbf{m}$:

$$\frac{1}{\kappa}\overline{\frac{d}{dt}\mathbf{m}} = \frac{1}{2}\mathbf{m}\times\overline{\left(\mathbf{E}\times\frac{\mathbf{v}}{c}\right)} = \frac{1}{2}\mathbf{m}\times\overline{\mathbf{H}}', \quad . \quad . \quad (9)$$

where $\mathbf{H}' = -\frac{\mathbf{v}}{c}\times\mathbf{E}$ is the mean magnetic intensity in a co-ordinate system where the electron is momentarily at rest (the mean being taken for the undisturbed orbital motion). This equation differs from that of Thomas by the fact that it refers to the *secular mean* and not to the true motion; it corresponds to an apparent ratio between the magnetic and mechanical moment of the electron's spin, which is exactly equal to one half of the actual one κ, that is, coincides with the corresponding ratio for the orbital motion.

Hamburg, March 25.

Transmission of Stimuli in Plants.

SNOW[1] has confirmed my discovery that the propagation of stimuli in the stem of the so-called Sensitive Plants is due to the transport of a hormone in the water of the tracheæ.[2] He, however, comes to the conclusion that in the leaves there is another and more rapid means of conduction of stimuli. This function he provisionally assigns to protoplasmic processes.

The idea that the same end is attained in the stem and in the leaves by two entirely different processes is difficult to accept. At the same time Bose's[3] view, which attributes the propagation of stimuli in both these organs alike to protoplasmic processes is negatived by the experiments of MacDougal, Cunningham,[4] and myself. In my own experiments especially it was rigorously proved that propagation took place across zones in which there were no living elements. Bose's statement that he cannot repeat my experiments, which were contrary to his own conclusions, may be put aside, inasmuch as my results have been confirmed by Snow and others.[5]

It is true that my experiments were principally carried out on stems. Nevertheless, two series were carried out with leaves, and proved conclusively that in these organs also the propagation of stimuli is due to the transport of hormones in the water of the tracheæ. However, when Snow brought forward new facts and interpreted them in support of his view that there are two distinct means of propagation, I determined to make a further study of the matter, as I thought it of the highest biological importance to determine whether the propagation of stimuli in plants took place by a means comparable to nervous transmission in animals, or whether it is simply and solely due to the transport of hormones.

My complete work on this subject will not be ready for publication for some time. Consequently, this is a short account of my experimental results without critical discussion. Meanwhile, I would merely state that the cohesion theory of Dixon and Joly appears to me to afford the explanation of the water movements which cause the propagation of stimuli.[6]

In 1924 I carried out the following experiments: I stripped the middle region of the pinnæ of a leaf of *Mimosa spegazzinii* of a number of its pinnules; leaving only about six pairs at the base and six at the apex. On the intact pinna there were about thirty pairs. Then one of the pinnæ was cut off and supported obliquely in a vessel of water close by the pinna still attached to the plant. When the remaining pinnules of each pinna had reopened I applied a small heat stimulus to the apical pinnules. The basal pinnules of the attached pinna quickly closed, and the stimulus often passed on to other leaves, but in the severed pinna the basal pinnules did not close, although the applied stimulus was no less; indeed, it was often intentionally greater. Similar results were obtained with *Mimosa pudica*.

Last summer I made experiments on the basipetal propagation of stimuli through a region of a petiole which had been killed. A jet of steam applied for about 10 or 15 minutes was used to kill a length of 5 mm. of the petiole. After the pinnules had reopened, a stimulus was applied by burning the apical third of a pinna—sometimes somewhat more. In every case the stimulus was transmitted to the primary pulvinus and nearly always could be traced beyond that by the responses of other leaves. Snow, who failed to get this result, assigns the success of Haberland[7] and Fitting[8] in similar experiments to the transport of sap from the killed cells, and considers this type of transmission quite different from that occurring in normal leaves. This interpretation is negatived when one compares the velocities found in normal leaves, which have been selected as being as similar as possible to the experimental leaves. In the first column of the following table are shown the velocities (in cm. per min.) of propagation in these experimental leaves compared with the velocities observed in the similar normal leaves. In the second column the velocities of propagation of the stimulus in the stem after it had passed from the killed portion of the petiole, compared with that observed in the stem supporting the normal control leaf, are entered

Table.

	Velocities in Leaf.	Velocities in Stem
Experimental Plants	93, 75, 48, 65, 90	9, 3, 3, 3, 15
Normal Controls	96, 102, 80, 110, 160	6, 4·5, 6, 7·8, 24

Here it is evident that the velocity in the experimental and normal leaves are of the same order, while those observed in the stem are much smaller. This difference finds full explanation in the difference of the cross-section of the conducting wood in the two organs. The fact that the velocity in the leaves having killed zones in the petioles is generally less than that observed in the normal ones may be explained as due to changes brought about in the wood by the application of the steam. Probably the most important of these changes is the development of water vapour in some of the tracheæ.

Snow found that the velocity with which colouring matters rise in the stem corresponds fairly with that of the propagation of stimuli. Last autumn I also carried out similar experiments with *M. spegazzinii*, making use of eosin. When cut branches are transferred from water into a solution of that dye, the colouring matter rising in the stem acts, in most cases, as a stimulus, and it is possible to follow its rise by the consecutive fall of the leaves from the base to the apex of the stem. In a dozen cases immediately as a pulvinus responded I cut it across and found the eosin already arrived. This method is not applicable to tertiary pulvini, which are in general less sensitive to eosin. In order to meet this difficulty, I added a good stimulant (an extract of the long shoots of *Stigmatophyllum littorale*) to the eosin solution, making up the concentration of the latter to 5 per cent. This solution was applied to the cut end of a branch, and usually the lowest leaf of this branch was the subject of these observations. As soon as the topmost pinnules of a pinna of this leaf had closed, I cut off the terminal portion (4-10 mm.) of its rachis with a scissors and examined it to see if the colouring matter had reached it. At the same time stop-watch observations gave the velocities of the propagation in the stem, the leaf, and the pinna. The results showed clearly that the stimulus is transmitted, alike in the stem and the leaf, by means of the water current. Out of 37 experiments, in one only was the eosin not found in the tip of the pinna. In all the other 36 cases a simple lens was sufficient to show the eosin on the cut surface of the apex of the pinna. Among these there were cases in which the pinnules from the base to the apex closed in 5, 4, 3½, 2½, 2 min. In these cases, whether one applies cutting or heating as the stimulus, the tension previously existing in the water of the conducting tracts must disappear owing to the rapid motion of the liquid. The neutralisation of the tension must follow the immission into the waterways of the sap of the responding cells, namely, those of the tertiary pulvini of the pinnules which close one after the other. The coloured liquid containing the hormone is present effectively in the tracheæ of the leaves even beyond the level of the motor organs which have responded, as other experiments demonstrated to me; and, in certain cases at least, the sap expelled by the responding pulvini, containing in all probability the hormone, helps in the propagation of the stimulus.

In another set of experiments I bent down a piece of a branch supporting a leaf into a shallow vessel of eosin solution. I then cut across the petiole under the liquid. At the moment of the closing of the topmost pinnule, I cut off a small apical portion (4-8 mm.) from its rachis. Of 12 such experiments, 11 showed the eosin present in the cut surface of the apical region. For this experiment I used a more concentrated eosin solution to allow for dilution caused by the exudation from the cut 'Schlauchzellen.'

In other experiments I bent down the tip of a leaf very gently into a solution of eosin and then cut it while submerged. Microscopic examination then showed that the eosin arrived at the base of the last pinnules as they closed. Sometimes the presence of the dye in the transverse section of the rachis of the pinna might be observed with a simple lens, but sometimes it required a compound microscope to reveal it. By using a more concentrated eosin solution (30 parts in 100) it was possible, in nearly every case, to demonstrate that the eosin arrived simultaneously with the stimulus, at the bases of the pinnules of the adjoining pinna.

Experiments in the Shaping of Wood with Flint Implements.

The discovery (Nature, January 9, 1926) made during my archæological excavations in 1925 of an ancient wooden structure, induced me to carry out some experiments in the shaping of wood with flint implements. So far as I can ascertain, this matter has not been investigated extensively, and the results of my work may therefore be of some interest. The flint implements used in these experiments were flaked by me with a quartzite hammer-stone, and comprise—an axe (Fig. 1, B), planes (Fig. 1, A and D), a pointed specimen (Fig. 1, C), and a flake with thick back, and more or less straight cutting edge. The axe was mounted[1] along the dotted line shown in Fig. 1, B, in a split stick about two feet in length, and I found that with this weapon I could detach branches up to three inches in diameter from trees without any great difficulty. The axe is flaked on one side only. On the side not figured, unflaked

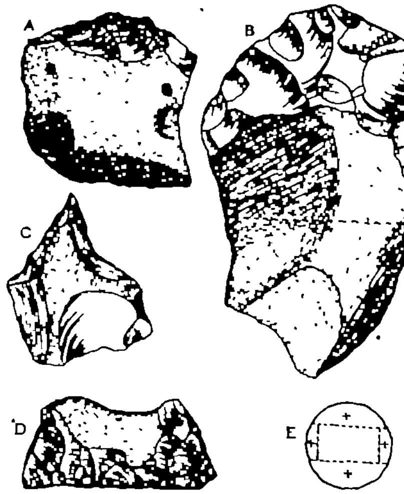

Fig. 1.—Flint implements made by Mr J. Reid Moir and used in the experiments described. A and D, planes; B, axe which was shafted along the dotted line; C, point used for boring; E, section of branch from which specimen shown in Fig. 1, C, was formed; the continuous and dotted lines, enclosing crosses, indicate the four pieces which were split off the original branch. Reduced to ½.

---

[1] The stone was kept in position by string tightly bound round the split portions of the stick.

cortex is present, but this fact made, apparently, little or no difference to the cutting powers of the edge.

The specimen shown in Fig. 2, B, is part of the branch of an apple-tree which was detached with the axe described, and shaped roughly to the form of a pointed stake, such as was found supporting the wooden structure above mentioned (NATURE, January 9, 1926). It will be remembered that this structure was formed of two pieces of oak, of plank-like form, evidently split off from a trunk of considerable size, and I was anxious, therefore, to see if it were possible to produce, with flint implements, a piece of wood of plank-like form, from a branch with a more or less rounded section. The result of my attempt to do this is illustrated in Fig. 2, C, and it will be seen that I was successful in my efforts. The branch was first of all split longitudinally four times with the axe, so that the outer, rounded surface was removed (Fig. 1, E), and the specimen thus caused to assume an approximately plank-like form, oblong in section. The wood, which is part of the branch of an apple-tree, was then further modified to the desired shape by means of the planes shown in Fig. 1, A and D, which were also used in smoothing down the point of the stake illustrated in Fig. 2, B. The piece of deal (Fig. 2, A) was perforated by means of the pointed implement (Fig. 1, C), the operation being carried out from both sides of the wood alternately, while the specimen shown in Fig. 2, D, represents a branch of an elm tree which was sawn through with a flint flake, the cutting edge of which I did not provide with 'teeth.' With the exception of the axe, which was mounted, all the other flint implements were held in the hand when in use.

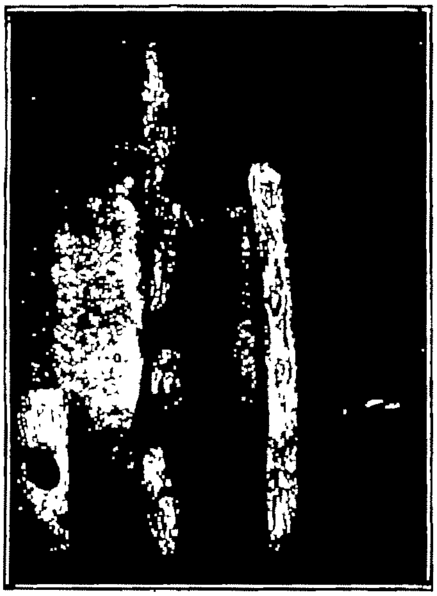

FIG. 2.—Specimens of wood shaped with flint implements. A, piece of deal perforated by flint point; B, branch of apple tree pointed—note cut indicated by arrow; C, apple wood shaped to a plank-like form from a more or less circular branch; D, branch of elm sawn through with a flint flake. Reduced to about ¼. Photograph by the Curator, Ipswich Museum.

The simple experiments I have been able to carry out have convinced me that with suitably shaped flint implements it is possible to do most things in the rough shaping of wood that can be done with steel tools. Further, it appears to me at present very difficult to distinguish, in the majority of cases, between wood thus cut by flints, and that which has been roughly shaped by steel. In this regard I would direct attention to the cut (indicated by an arrow) in Fig. 2, B, and resulting from a blow with the flint axe (Fig. 1, B). This incision is, however, so narrow and 'clean' that I cannot see how it is possible to differentiate between it and a cut produced by a sharp steel hatchet. I found that the shaping of these pieces of wood, though not actually difficult, was nevertheless a very slow process, as may be judged from the fact that it took me about half an hour to perforate the piece of deal shown in Fig. 2, A.

It would seem probable that prehistoric man, from the earliest times, utilised wood for making into implements and weapons, but it is only under exceptional geological conditions that any examples of this material would be preserved till the present day. The experiments I have carried out have demonstrated to me that very many of the ancient flint implements, referable to every phase of the Stone Age, which have been found, are admirably adapted for the shaping of wood and similar material, and I feel that these practically indestructible flint implements represent, as it were, merely the 'insoluble residue' of prehistoric industries, of which the other and more friable artifacts have disintegrated and disappeared during the great periods of time that have elapsed since they were made. If this surmise is correct, then the flint implements of ancient man give us, perhaps, but a very small and imperfect picture of his state of civilisation.

J. REID MOIR.

One House, Ipswich.

Relation of Weight to Height during Adolescence.

MY friend, Mr D. Caradog Jones, who during his stay in Manchester was my collaborator in the anthropometric work which has been carried on at the Manchester Grammar School for so many years, has directed my attention to his contribution to NATURE of April 10, and has asked me to make some further comments. I gladly do so, partly as an acknowledgment of the help which he so unstintingly gave me and partly because I am also indebted to Prof. Dreyer for the interest he showed in 1921 in the work at the Grammar School, and the help I have gained from his numerous attempts to connect body measurements with accepted standards of body metabolism.

The formula to which Mr. Jones directs attention was first brought before my notice by Dr. James Kerr of the London School Board in 1911, when he was searching for a method of expressing mathematically the degree of nutrition of young children which was noticeable to the eye of the medical observer. Mr. Jones has applied this formula to adolescent children, among whom Livi claims that the result becomes constant for the 'mean' boy. It is, however, evident that the constant which Livi obtains is somewhat different from the constant obtained from the Grammar School boys. In studying the application of various formulæ I have felt to an increasing extent that the greatest difficulty in accepting any special one is due partly to the fact that the human body is built to do several entirely different kinds of work and that it develops therefore in a different way under different conditions. The apparent uniformity that is obtained by Livi's formula may be due to the fact that only two factors are taken into account, and that other factors, however essential to school anthropometry, are left out of account, particularly chest circumference, on which Dreyer himself lays stress in his "Assessment of Physical

Fitness," which affords information both of body build and respiratory reservoir.

I am by no means certain, however, that the physical framework and the mechanical output which fit a boy to be a long-distance runner is the same as those which fit him to be a good swimmer or a good gymnast, and there is good ground for believing that the good scholar in any given population is better, physically as well as mentally, than the poor scholar in the same population, but that this superiority may not be so manifest when we are dealing with another population. Even the accepted constant relation between body surface and body mass that is adopted for basal metabolism provides us with only a limited basis for judgment when we consider the metabolism of different forms of active life We find that the area of the body surface, even as calculated from the mass, affords only a limited knowledge of the function of the skin and its capacity for heat radiation or the elimination of perspiration. All that one can hope from any of these formulæ is a basis for calculating variations in a particular population. They do not, I think, provide a standard of proper growth suitable for all conditions, nor do I think any uniform standard can be found applicable to all classes and races after adolescence is established.

So long ago as June 1899, NATURE published some very remarkable grading charts of a group of public school boys of an earlier generation by Mr. Cecil Hawkins, which enabled one to calculate the relative variations from the 'mean' of different boys in height, weight, and chest girth at successive ages Graphs based on these illustrating special types of physical development were given in an article in the *School World* in August 1903. Mr Hawkins' grading tables were in use at this school from 1909 until 1921, and have proved of inestimable value in studying the growth of individual boys in different directions With the help of similar tables applicable to more recent conditions, but based on expected time increments of growth, which Mr Jones has drawn up for Grammar School boys from figures calculated by Matthew Young, I have been able to compare the body build and the body metabolism as indicated by vital capacity of boys distinguished in different forms of athletic exercise, *e.g.* long-distance running, sprinting, swimming, gymnastic competition, high scholarship, and also a group of boys of retarded scholarship, and I think this method of comparative or composite graph affords us the basis for a convenient expression of our judgment of any particular boy. With the help of Dr. P. Brooke Mumford I am now organising at Manchester Grammar School schemes for the differentiation of the degree of development of the heat-eliminating powers and response of the skin to timulation, and the relation of these powers to physical build and to output of activity. I hope to publish a complete statement of the anthropometric research done at the Grammar School since 1909 during the coming autumn.

The Use of Arcs and other Fluctuating Sources in Photoelectric Photometry.

IN his paper on the registering microphotometer, P. Koch (*Annalen der Physik*, iv. 39, p 705, 1912) escribes an arrangement consisting of two similar hotoelectric cells connected to an electrometer, both luminated by the same source, but through different ptical paths The arrangement described has the advantage of being independent of intensity fluctuations in the source (provided that these are uniform over the area of the source), since the electrometer reading depends only upon the *ratio* of the intensities falling on the two cells. An example is given in which a change from 10 to 100 in the light intensity of the source produced only a 1 per cent. change in the electrometer deflexion. However, it remained impossible to use arcs, or other light sources which not only fluctuate in intensity but also flicker or change their position ; for since the two beams come from different parts of the source, and traverse different optical paths, flickering changes the ratio of their intensities, as well as the absolute values.

It is the purpose of this note to point out that in most cases the optical paths to the two cells may be made practically identical by using a partially reflecting plane mirror to divide the beam The arrangement is shown in the diagram below (Fig 1). S is the source (a carbon or mercury arc, for example) ; the purpose of the lenses L and L' is obvious , TR represents an optical train of any kind (lenses, prisms, filters, polarisers, etc) , M is the partially reflecting plane mirror, C_1 and C_2 the two similar cells, and, before C_1, F, the filters, photographic plates, crystals, analysing nicols, etc , the variable transmission or absorption of which it is desired to measure (The electrical connexions of the cells and the electrometer, etc., are not shown , they are described in detail by Koch, *l.c*) Under these conditions flickering and wandering of the light source will alter both intensities in the same ratio, provided that the variable absorber F takes the full beam of light; that is, requires no further diaphragms. This will be true, for example, in measuring the absorption of filters, large crystals, large areas of a photographic plate, etc.

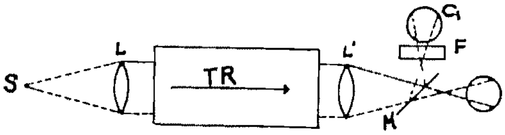

FIG. 1

If the variable absorber F requires a diaphragm, troubles may arise, due to the fact that fluctuations may change the distribution of energy over the cross-section of the beam of light. The intensity of the beam diaphragmed out may then change, whereas that of the full beam going to C_2 does not There are then two alternatives : if the diaphragm in F may be removed some distance from the absorber, the dividing mirror M may be placed between the diaphragm and the absorber; but if, as in the microphotometry of spectral lines, the diaphragm must be very close to the object the transmission of which is to be measured, an attempt must be made to diaphragm the beam going to C_2 in an exactly similar manner, so that the two diaphragms or slits are situated at corresponding points of the cross-sections of the beams (which, fortunately, are themselves similar). How well this compensation will succeed depends on the fineness of the slits, on the optical system, and on the constancy of the light source.

The proper ratio for the intensities of the two beams is determined by the experimental conditions. It can be altered at will by interposing a uniform filter before either cell. One must of course take precautions to ensure that the variations in the intensity of the source are not too great. From Koch's data, and from results obtained in testing the present modification, variations of even several hundred per cent are permissible.

Thus it is possible to use arcs and similar light sources giving high intensity in all regions of the spectrum for a large number of problems involving photoelectric photometry.

International Phenology.

THE list of thirty-one plants given in NATURE for March 20, p. 413, for which observations are requested, is singularly unfortunate for the British Isles, as fifteen are cultivated or alien; these, though four trees may be approved, are thus prejudiced for real scientific use.

It seems regrettable also that a list should be launched for scientific use that ignores botanical nomenclature and relegates a small letter to the specific or trivial name of those plants in which the former generic name is preserved; there are twelve such errors, besides two for insects.

F. A. BELLAMY.

28 Polstead Road,
Oxford.

MR. F. A. BELLAMY'S letter directs attention to a point which might be considered a weakness in our selection of flowering plants for international phenology; but for this there was a reason which seemed prepotent.

Forty-six plants were first selected and their presence on the lists from the ten countries carefully compared. With very small exception these lists include a heavy proportion of cultivated plants. In one it was almost entirely so.

Of the eleven selected from the chief list in our own schedule (observed systematically for thirty-five years) there is only one, the horse chestnut. (By a printer's error its asterisk was transferred to the lilac.) Numbers 1 to 3 come in our supplementary list. Hence we felt compelled, in selecting the balance of seventeen, to consider our colleagues abroad by including ten further cultivated or alien kinds, making a total of fourteen out of the thirty-two.

The intentional omission of capital letters for all specific names, even where originally generic, was perhaps open to criticism. But is there not a growing tendency to adopt this simplification?

I am glad to have the opportunity of correcting an error in the reference to the "late" Prof. Vanderlinden in the letter in NATURE of March 20. Fortunately, Prof. Vanderlinden is still alive and active.

Transfer of Excited Energy from Ozone to Hydrogen and Nitrogen.

RESULTS have been obtained by Venkataramaiah (*Jour. Am. Chem. Soc.*, 45, 261, 1923) which show that hydrogen is activated by continuous burning of oxygen in hydrogen. He considers that the reaction activates the hydrogen. Probably electrons of high kinetic energy, capable of ionising the hydrogen, are emitted by the reacting molecules. In considering this theory further it seems probable that ozone might play a part in this reaction as ozone is formed in flames, and also decomposing ozone emits radiation of very short wave-length as shown by Stuchety (*Zeit. w. Photochem.*, 19, 161, 1920). The energy corresponding to the radiation emitted is greater than the energy of ozone decomposition.

It has been shown by Grubb (NATURE, 111, 671, 1923), and Venkataramaiah (NATURE, 112, 57, 1923), that active hydrogen produced by electrolysis will combine with molecular nitrogen with the formation of ammonia. If ozone emits energy enough upon decomposing to activate the hydrogen, then in the presence of nitrogen we might expect that the active hydrogen would combine with nitrogen to form ammonia.

To test this, the following investigation was carried out. A solution of sulphuric acid, sp. gr. 1·213 at 15°, was electrolysed using a current of 6·2 amperes. The drop of potential across the electrodes was 9 volts. A piece of platinum foil 5 sq. cm. in area served as a cathode. The anode was a platinum wire 0·5 mm. in diameter and 35 mm. in length. A stream of ammonia-free hydrogen and nitrogen at atmospheric pressure, mixed approximately in the ratio of three to one respectively, and at a velocity close to eight litres per hour, was led directly down over the anode at which the ozonised oxygen evolved at a very rapid rate. The escaping gas mixture passed through a tube two feet long and was washed with ammonia-free water in an extremely efficient absorption bulb. Runs of fifteen minutes' duration were made. Then upon Nesslerising the absorbing liquid a heavy precipitate was obtained. To obtain a quantitative estimate an aliquot part of the absorbing liquid was taken for Nesslerisation. If the velocity of the hydrogen-nitrogen mixture was increased, less ammonia was formed. A further study is being made of some of the factors involved.

Domestic Heating.

IT is curious that a lady of Dr. Marie Stopes's scientific eminence should not have taken more trouble to inform herself upon this subject before writing upon it in NATURE (March 6 and April 24). In the first place, the difference in tonnage of coal used in domestic fires (40 million) is not insignificant in relation to that used in industry (100 million), and in the second place (apart from Dr. Stopes's personal sensations) the radiant efficiencies of electric radiators, gas fires and coal fires are, according to Dr. Margaret Fishenden, in the ratio of 5 : 3 : 1 For my sitting-room I prefer to use coke, and in the bedroom gas fires or electric radiators, all of which are smokeless—a very desirable matter.

Low-temperature coke is not yet a commercial success though it may become so. Meantime, are we to continue to pour out literally many millions of tons of filthy soot into the atmosphere which cannot but affect the health of every town dweller because Dr. Stopes believes "a glowing coal fire gives out something subtle, yet intensely 'nourishing' to the system"?

Radio Communication and Imperial Development.[1]

By Dr. W. H. ECCLES, F.R.S.

THE British Empire is a medley of fragments spread as if by blind chance over the habitable portions of the globe. Looked at in Mercator's projection, it is like a broken potsherd on the floor—a collection of large pieces and small pieces, at all distances apart. Yet, scattered as they are, these pieces of earth bear populations which instinctively turn to the mother country as the centre of that world which lies beyond their immediate interests. This is as true of the large pieces as of the small.

For so dispersed a family, the problem of telegraphic communication is important and difficult. Until the year 1902, long-distance telegrams were all carried by cables, under the sea or under the ground, and by wires on poles; and the task of serving sparsely populated and distant regions required capital outlay beyond reason. But between 1902 and 1904, in a series of bold experiments, Marconi proved that messages could be conveyed thousands of miles by telegraphy without wires. Then he and many others showed that electric waves can pass over mountain chains, and even far round the bend of the globe, at any rate at night, and that they could be picked up simultaneously in all directions round their source. Here obviously was a heaven-sent gift to the British Empire, for by wireless telegraphy we might now hope to communicate, simultaneously if desired, with a thousand places to which cables and wires could never be run.

Quite early in the development of wireless telegraphy, the principal nations began to apply it and to regulate ts employment. Indeed, control was compelled, in the armed camp that Europe then was, by the consideration hat, when war came, wireless would be useful to fleets and armies and dangerous in the hands of spies. In peace time, even, some degree of control was called for to reduce interference, especially between powerful ong-range stations. Each such station ought, in fact, o transmit on a different wave-length from other tations; and once a wave-length is assigned to a particular long-range station, it should not be given to any other. In other words, the grant of a wave-length o a powerful station is equivalent to giving a right-of-way to that station. For all these reasons the Imperial Conference of 1911 declared that wireless communication within the British Empire should always be regulated with especial care, and that, in the main, the necessary stations should be State-owned and State-perated.

This decision being given, it only remained to erect the stations. In 1912 Parliament approved a contract which the Post Office had made with the Marconi Company for the erection of a British Imperial chain of ix stations. This contract was, however, modified fter a technical inquiry, and a new contract was ratified y the House of Commons in 1913. But the engineers ad barely time to erect a few masts at Leafield in Oxfordshire and at Abu-Zabal near Cairo, when the ontract was dissolved, principally on account of the advent of war. In contrast with our inaction, the United States had meanwhile pressed on with the construction of several large government stations, and France and Germany made great progress with their respective colonial plans. Perhaps we could afford to delay. Compared with Germany, for example, we possessed elaborate cable communications, and were more confident about defending them in every sea than Germany could be. But the result was that when war broke out in August 1914, no unit of the much-discussed British wireless chain had been erected.

Germany, on the contrary, had made great strides with her colonial communications between the years 1912 and 1914. She had established thoroughly modern stations in Togoland, in German East Africa, in German South-West Africa, and in the Pacific. The three African stations could inter-communicate with one another, and, to a limited extent, with the great station at Nauen, near Berlin. The Pacific station was at Yap in the Caroline Islands. It was a noteworthy coincidence that all these stations were completed just before the War began. I remember hearing the early trial signals from Yap while I was sailing across the Pacific in July 1914. No doubt this station was intended to receive instructions from Berlin, and retransmit them to island possessions, such as Apia in Samoa, and to naval and mercantile vessels in the Pacific and the China Seas. It may be of interest to recall the fate of Yap; it is wrapped up with the story of the German Pacific fleet commanded by Von Spee, which, months later, met Cradock at Coronel and Sturdee at the Falkland Islands. I remember some of the story because I was called from Sydney to Melbourne by the Australian Government to help in an advisory way with an interesting application of wireless. At this moment the German fleet was cruising to the north of Australia and was in nightly touch with Yap. As soon as this was observed, each of the small shore stations along the Australian coast was instructed to listen for the signals of the German fleet, to record the strength with which the signals were received, and to report daily to Melbourne. From these reports, by a process resembling triangulation, an estimate was made in Melbourne of the changes of position of the fleet. Meanwhile a British naval force had set forth with the object of destroying the wireless station at Yap. This was duly accomplished, and for days afterwards the Germans, unaware of the disaster, continued to call the dead station, in vain. These continued calls, by helping us to keep track of the fleet, eased the anxiety of those who knew that the New Zealand expedition was then well on its way to capture Samoa. Thus ends the story of Yap; that of the other German colonial stations was similar.

During the War our wireless energies were deflected from the building of great stations to producing relatively small outfits for fighting purposes. War telegrams were handled sufficiently well by the cables and the wireless stations of the Admiralty, and the War closed without any progress in imperial wireless. Meanwhile the French government had erected powerful stations at Nantes, Lyons and Paris, and smaller stations in their African territories; the Italian government had erected a large modern station at Rome;

---

[1] From a Friday evening discourse, entitled "Wireless in the Empire," livered at the Royal Institution on April 30

and the United States government had completed half-a-dozen big stations, together with a magnificent one near Bordeaux which was afterwards purchased by the French government. But the governments of the British Empire, at the close of the War, stood possessed of only one fairly large wireless station among them—that at Windhuk in German South-West Africa—captured by the forces of the Union of South Africa under General Smuts. Thus at the end of 1918 the British Empire was far behind most other great Powers as regards government-owned stations, and, by the way, equally far behind as regards powerful commercial stations.

At this time Lord Milner took up the cause of Imperial communications. Lord Milner appears to have been the only elder statesman of that day convinced of the imperial value of widespread communications, and aware of our national backwardness. But he looked for much more than mere duplication of cable- and land-line services. He envisaged the possibility of radiating daily from England and other great centres news and opinions of imperial interest in such a form that they could be picked up, perhaps after re-transmission by outpost stations, anywhere. He thought it wrong to continue to leave a large proportion of the population of the British Empire as isolated as if cast away on a raft in the ocean. I believe he thought that wireless would be as useful for the cultivation of mutual understanding as for strategy and commerce. In other words, he realised fully the importance of propaganda, and holding these views, advocated government expenditure on improving radio communications.

Within a year of the conclusion of the War, Lord Milner appointed a committee, under the chairmanship of Sir Henry Norman, to investigate afresh the problem of establishing a comprehensive wireless network. The committee found that the progress made in wireless during the War had completely changed the outlook. Plant was now available of at least double the effectiveness of the pre-War wireless chain proposals. Accordingly the Norman committee recommended that wireless stations of about 250 kilowatts power, giving 120 kilowatts of continuous wave power to the antenna, should be erected in Egypt, East Africa, South Africa, India, Singapore, Hong Kong and Australia, with, possibly, similar stations in Canada for trans-Atlantic and trans-Pacific communication; and that a station of double the power of the others should be erected in England. Stations such as these, it was thought, would each be able to communicate at all hours with its nearest colleague even under the very bad conditions that afflict wireless reception in the tropics; and each would communicate with its most distant colleague during at least a few hours daily. The scheme ensured that each point would communicate with every other at all times; directly when conditions were good, indirectly—that is, by the relay or passing-on principle as used in cable telegraphy—when conditions were bad. The English station being the most powerful of the network would have the maximum amount of direct communication with all. Besides this, the scheme would enable the Admiralty to transmit instructions from Whitehall to ships afloat anywhere, a requirement included in the terms of reference of the committee.

At this date there were no wireless stations in existence as powerful as those recommended, and, therefore, it was difficult to forecast what their performance would be. Moreover, the committee recommended that the stations should be equipped with thermionic valves. Now the largest valve station then known was of less than 20 kilowatts output, so the recommended English station was to be more than twelve times as powerful as its largest predecessor. The report was, clearly, somewhat ahead of its time, but not, I think, too far ahead. For by the year 1925, only five years later, the Post Office station at Rugby has been built with thermionic valves yielding double the output recommended by the committee. The Rugby station has shown besides, during the tests of the past few months, what the Norman committee's stations could have done. For example, the station recommended for South Africa would have communicated direct with England, Australia and India many hours each day, and the English station would have worked direct to the antipodes more than twelve hours daily.

Lord Milner on receiving the report was, I believe, especially pleased that stations were proposed for some of the dependent Colonies, such as East Africa, Singapore and Hong Kong; not merely because they would serve at times as telegraphic links between England and some of the great Dominions, but as ends in themselves. These intermediate stations would bring great areas of new country into closer touch with all other parts of the Empire. Lord Milner was convinced that the dependent Colonies had for many years past been neglected, and that wireless telegraphy would help to alter this state of things. So at the end of 1920 the Cabinet appointed the Wireless Telegraphy Commission, of which Lord Milner became chairman and officially assigned to it the task of getting as much done as it possibly could.

As no station could be erected until the requirements of all parties could be co-ordinated, the first task was to obtain unanimous consent to the scheme or a modification of it. It was unfortunate that Lord Milner retired from political life before any decisions were reached by the Dominion Governments. As it turned out, each Dominion Government held a differen view about Imperial wireless, partly as to the financing and management of it, partly about the technica requirements and possibilities. The only common element was that they each desired to communicate with England without intermediate steps. Thus a fast as each Dominion settled its policy, a new compromise had to be framed for the Cabinet's approval. Finally, when Mr. Amery was chairman of the Imperia Communications Committee in 1923, Empire wireless took a new spring. The Government decided to erec in England without further delay a wireless station powerful enough to transmit almost continuously to all the Dominions and dependent Colonies, and to all ships of the navy and the mercantile marine whereve they might be.

The time of waiting had not been lost. The Commission had proceeded a long way with the plans o a large station, and the Post Office engineers ha gained much experience by equipping with up-to-dat plant the medium power stations at Leafield and Ab Zabal, remnants of the old Imperial scheme of 191 As a consequence the erection of the Rugby station the most powerful in the world, has gone forward with exemplary smoothness and without accident or failure of any kind. The Rugby station when in full swing will probably be able to transmit simultaneously three long-distance telegrams and a telephone message. The ultimate aim of the telephone section is to connect any telephone subscriber in Great Britain to any subscriber in the United States and Canada. By aid of the telephone circuits already constructed between England and the Continent, it may be found possible later to connect any one in western Europe to any one in North America through Rugby.

When it is realised that this multiple service station has cost only about half what the single service station near Bordeaux cost in 1919, one appreciates the great strides that wireless design has made during the past few years. Rugby, in fact, has cost about 400,000*l.*, much less than even the new stations at St. Assise near Paris and on Long Island near New York. Further, as the Leafield station began to earn, within a year of its opening, more than covered its working expenses, so we may reasonably look forward to the Rugby station soon becoming a profit-earning concern.

It has always been obvious that the telegraphic traffic to and from the centre of the British Empire will be greater than that to and from any of the Dominions; for the centre has to deal with all the Dominions, all the dependencies and with distant shipping. The spokes all meet at the hub of the wheel. Therefore Britain must make much greater provision than even the largest Dominion, perhaps tenfold. Definite recommendations for the erection in England of stations additional to Rugby were made in the report of the Imperial Wireless Telegraphy Committee, February 1924, presided over by Sir Robert Donald. An opportunity of meeting the recommendations came in the summer of 1924, when the British Government, finding the majority of the Dominions would probably agree to use the Marconi beam system, made a contract with the Marconi Company which will result in the establishment of duplex beam circuits between Canada and England, Australia and England, South Africa and England, and India and England. The arrangement promises a happy solution of many long-standing difficulties. These beam stations are now nearly completed. A transmitting station at Bodmin serves Canada and South Africa, and a station at Grimbsy serves both Australia and India. Corresponding stations are being erected in the four Dominions.

The beam stations may claim to send their messages straight to the desired objective since the guaranteed angle of concentration of the waves is 30°. There is the additional advantage that little power is consumed, partly because of the concentration and partly because short waves are used. This again implies small capital outlay, so at first it was thought that suitable beam stations would be very inexpensive. In practice the engineers met many snags, and it is probable that the English beam stations for communicating with four Dominions will cost altogether about half as much as Rugby. For this expenditure good communication is guaranteed for a daily average of 18 hours with Canada, 7 hours with Australia, 11 hours with South Africa, and 12 hours with India.

It has been suggested that beam stations may some day supersede the wireless stations which send their waves all round. This kind of controversy is always going on in wireless and other progressive sciences, and sometimes tends to cripple action to-day by promising cheaper alternatives to-morrow. As an example, when the motor-car gained its first successes we were told that railways were obsolete; but one can still travel by train from London to Edinburgh more comfortably, more cheaply, and more quickly than by car. As regards the wireless problem, the present beam stations are the first of their kind and have not yet been operated. We only know enough to say that both systems will be useful, and that each can do something the other cannot.

Before the end of this year the long-range wireless transmitting equipment of the British Empire will include—

(1) The multiple station at Rugby, comprising:
  (*a*) Long wave plant of world-wide range.
  (*b*) Long wave plant of medium range.
  (*c*) Short wave plant of world-wide range.
  (*d*) An experimental telephony plant of range 4000 miles.
(2) Medium power stations using long and short waves at Leafield, Oxfordshire, and at Abu Zabal, Egypt.
(3) Four duplex beam circuits for communication between England and the four largest Dominions.

Thus by the efforts of the engineers of the Post Office and the engineers of the Marconi Company, the British Empire will shortly possess the most up-to-date wireless equipment in the world.

So far I have dealt with things nearly completed, but now I must indicate briefly what has yet to be attempted and is within reach. In the first place, there are important communities still unprovided with long-distance wireless; for example, New Zealand. This urgent necessity was emphasised in the report of the Donald committee. In the second place, preparations ought to be made to utilise fully the new facilities. For example, twice a day Rugby transmits a summary of news prepared by the Foreign Office, and conceivably other news services may be arranged. If I were a settler in Uganda or the owner of a remote sheep station in Australia, I should install a simple receiving set and so keep in touch with the world. But this implies learning the morse code, not so hard as learning to use a typewriter, but still a difficulty; and therefore in small communities where there is a local news sheet, it would be more practical to organise a receiving service by paying an operator to listen regularly and decode the messages for the printer. In the British Empire there are innumerable remote settlements to which the cabled news messages leak very slowly, and there are many which depend entirely for their news on the occasional visit of a ship. All such outposts can now, by the aid of a simple receiving set, be made to feel that they are within five minutes of Fleet Street. Moreover, if these stations were registered, messages could be specially addressed to them from England just as telegrams are addressed from Rugby to-day to ships on distant oceans.

Another method of distributing the morse messages from home when received, say in New Zealand, is to announce them, after decoding, through the local broadcasting stations. In each of the Dominions such stations are growing in numbers, and by their aid messages could be distributed promptly to millions of listeners-in. Of course it may some day be possible, after further invention and development, for speech and music from England or other centres to be put on to every local broadcasting station in the British Empire.

This does not exhaust the possibilities now arising. During the past two or three years wireless amateurs have succeeded in transmitting signals and even speech across vast distances with tiny apparatus. The plant used is so small that it could be installed in a drawing-room. If only we could rely upon plant of this size getting through for days instead of hours, then there would be no need for high-power stations. Even so it is easy to imagine how such glimpses of intercommunication might be made use of in the elaboration of Empire wireless.

The chief results expected from all these efforts to establish an Imperial wireless network can be put in two sentences. Firstly, mutual trade will be facilitated by rapid and cheapened communications, and finance will benefit by a shortening of credit such as followed the introduction of the cables. Secondly, the interchange of opinion between all sections of the British Empire will become fuller; and just as wireless on the small scale has become, in the shape of broadcasting, an important social influence in Great Britain, so wireless on the large scale will have a similar influence in, and strengthen the unity of, the British Empire.

Segregation and Related Problems.

THE laws of evolution and heredity have generally been regarded as universal in their application both to plants and animals. The various theories of evolution have been held by their authors to apply indiscriminately to both kingdoms, and the same has been true of theories of heredity and, with certain limitations, of cellular structure and mitotic division. But there are signs in the more recent developments of genetics that these general resemblances, fundamental as they are, have been over-estimated. In the future, we may expect to see greater emphasis laid on the distinctions, many of which are also fundamental, between animal and plant structure, especially as they affect variations and hereditary behaviour.

The tendency to recognise a divergence between plants and animals in certain aspects of their genetical and evolutionary behaviour has become increasingly evident, both on the breeding and on the cytological side. This tendency is well exemplified in the recent paper on segregation, by Bateson (*Journ. Genetics*, vol. 16, No. 2), the last, unfortunately, which he published before his lamented death. It was the Leidy Memorial Lecture delivered at the University of Pennsylvania in 1922, and in it the greatest biologist, perhaps, of his generation discusses the nature of segregation and the various problems connected with it. In recent years the Merton Laboratory had made extensive studies of variegation in many plants and of various forms of somatic segregation, especially from root cuttings. These in Bateson's hands furnish the basis for a consideration of the nature and significance of the many forms of segregation observed. The fact emerges that not only are most of these forms known only in plants, but also that somatic segregation when it occurs in animals is usually quite different in genetic behaviour and significance.

The term *anisogeny* is introduced for the numerous cases now known in Matthiola, Oenothera, Linum, Campanula, Begonia, and other plants, in which the male and female gametes are carrying separate factors, and it is not clear that this is always due to the loss of one class of gametes after segregation in meiosis. Not only does the place of segregation vary in the many kinds of somatic segregation now known, but also it has been shown by Miss Andersson in the variegated hart's tongue fern that all the 64 spores of any sporangium are alike in the form of plastid they transmit, this depending only in part on the plastid characters of the vegetative tissue from which the sporangium arises. The well-known experiments with rogue peas, made by Bateson and Punnett, Miss Pellew, and others, indicates that here is an orderly type of progressive somatic segregation occurring from below upwards in the plant and accompanied by anisogeny.

Bateson returns to the presence-absence hypothesis and makes out a case for it, based particularly on the interpretation of multiple allelomorphs; for example, the yellow 'eye' series in *Primula sinensis* and the colour series in rabbits. These, as he points out, characteristically form a plus or minus quantitative series as regards one character. The quantitative interpretation of a multiple allelomorphic series is very probably correct; but even so, any advantage of the presence-absence conception appears to be merely a matter of convenience in symbolism. It is, of course, possible that all variations are in essence quantitative. We seem to be arriving at a position in which no essential difference remains between the presence-absence conception and that of each pair of allelomorphs as the result of a germinal change.

In the same number of the *Journal of Genetics*, Castle, Punnett, and Pease continue their discussion of the various types of 'Dutch' rabbits, which have taken the place of the hooded rat as material for the explanation of an apparently continuous series of variations. Castle contends that Self, Dark, and White Dutch form an allelomorphic series, together with modifying factors, while Punnett argues that Dark Dutch is the basic condition, which becomes self-colour through the addition of modifiers. It would follow that an allelomorphic series is not involved in this case; but to settle the matter finally a further study of the linkage relations may be required.

It is clear that segregation remains the central conception in modern genetics, the science which Bateson founded. But it takes a great variety of forms, particularly among plants. Their further elucidation will lead us into new fields.

R. Ruggles Gates.

New Foreign Members of the Royal Society.

LAST week the Royal Society proceeded to the election of eight foreign members, men of science distinguished in various departments. Their inclusion fills a series of vacancies, occasioned by deaths, which had arisen since 1921.

In the early days of the Society's history, it was the custom, on the election of specially notable philosophical inquirers and workers, not of English birth, to send them an ornate diploma carrying the Society's seal. Birch, the historian, records that, in 1680, "Dr. Gale was called upon for the diploma to be sent to Mr. Leewenhoeck, and it was ordered that the society's seal should be affixed to it, and that a silver box should be provided for it."

Subjoined are the names of the newly elected members with some details of their respective careers.

PROF. MARTINUS WILLEM BEIJERINCK.

Prof. Beijerinck is regarded as the foremost bacterial physiologist of his time. He was the first to isolate in pure culture the bacteroids of the Papilionaceæ and to study filter-passing viruses of plant. He began in 1884 an important series of memoirs, which were published by the Amsterdam Academy of Sciences. They dealt with photogenic bacteria, anaerobes, and kindred subjects. Two of his papers may be cited: (1) "Die Bacterien det Papilionaceen-Knöllehen" (*Botanische Zeitung*, 1888), (2) "Les expériences sur les bactéries lumineuses" (*Journal de Micrographie*, 1891).

PROF. NIELS BOHR.

Born at Copenhagen in 1885, Prof. Bohr received his academic training at the Universities of Copenhagen, Cambridge, and Manchester. At the last named he spent four years working with Sir Ernest Rutherford. Returning to Copenhagen in 1917, he gathered round him a band of helpers in attacking the complex problem of atomic structure from the spectroscopic side. Author of the conception to which the name Bohr-atom has been attached, he has made fundamental advances in interpreting spectroscopic phenomena in terms of quantum dynamics. He was Hughes medallist of the Royal Society in 1921, and received the Nobel Prize for Physics in 1922. Prof. Bohr delivered the seventh Guthrie lecture of the Physical Society, in 1922, on "The Effect of Electric and Magnetic Fields on Spectral Lines."

PROF. ERNST COHEN.

Born at Amsterdam in 1869, Prof. Cohen was formerly occupant of the chair of physical chemistry in the University of that city. He is now professor of physical and general chemistry and director of the Van 't Hoff Laboratory in the University of Utrecht. He has published many chemical memoirs through the Amsterdam Academy of Sciences and in the *Zeitschrift für physikalische Chemie*. He is distinguished for his researches on the allotropic states of the chemical elements. As a pupil and follower of Van 't Hoff, chemists owe much to him for methods by which sound foundations have been laid for physico-chemical theory. Prof. Cohen recently was elected president of the International Union of Pure and Applied Chemistry.

PROF. WILLEM EINTHOVEN.

Born at Semarang, Java, on May 21, 1860, and educated at Utrecht, Prof. Einthoven has been, since 1886, professor of physiology in the University of Leyden. Early in his career he was an assistant of Donders. He is LL.D., Aberdeen, and in 1924 was the recipient of the Nobel prize for medicine. Prof. Einthoven has devised instruments specially adapted to the study of physiology, as well as those suitable in high degree for physical researches. Important papers have illustrated and illuminated his procedure. One memoir of his may be cited, namely, "On the Theory of Lippmann's Capillary Electrometer" (1900).

PROF. KARL E. RITTER VON GOEBEL.

Born at Billigheim, Baden, in 1855, von Goebel was educated at the Universities of Tübingen, Würzburg, and Strasbourg. He is a foreign member of the Linnean Society. Elected to the chair of botany at Strasbourg in 1881, he later occupied posts at Rostock and Marburg, down to the time when he became professor of botany at the University and director of the Royal Botanic Gardens, Munich. An authority on the mosses and liverworts (Bryophyta), some of his work has appeared in English under the title "The Organography of Plants" (Oxford, 1905). He is an honorary LL.D. of the University of St. Andrews.

PROF. HENRY FAIRFIELD OSBORN.

Born at Fairfield, Connecticut, in 1857, Prof. Osborn graduated at Princeton University, U.S.A., holding there (1880–91) the assistant professorship of comparative anatomy. Afterwards (1891–1910) he occupied the chair of zoology in Columbia University, New York, and is now research professor of zoology there. Prof. Osborn is among the most distinguished palæontologists of our time. His first publication (1883) dealt with the structure of the brain in amphibia; later memoirs dealt mostly with fossil vertebrates. One of the results of his work is the more precise determination of the relative ages of the extinct mammals of North America. As director of the American Museum of Natural History, Prof. Osborn has made the institution world-famous. He has had distinctive influence in establishing a school of younger palæontologists. In 1918 he was Darwin medallist of the Royal Society. In our recent special issue relating to the centenary of Huxley (May 9, 1925), Prof. Osborn contributed an interesting article entitled "Enduring Recollections."

PROF. MAX PLANCK.

Prof. Max Planck was born at Kiel in 1858. Formerly a professor in the University of Kiel, he is now professor of mathematical physics and director of the Institute of Theoretical Physics in the University of Berlin. His outstanding achievement has been the foundation of the quantum theory—Planck's constant is now considered to be one of the fundamental constants in Nature. Planck first discovered the true law of black body radiation; then showed how this could be satisfactorily explained in terms of a system of dynamics. From this the modern quantum theory has grown, with all its far-reaching developments.

PROF. ARNOLD SOMMERFELD.

Prof. Sommerfeld was born at Konigsberg in 1868, and was educated there and at Gottingen. Formerly holding professorships at Claustal and Aachen, he is now professor of theoretical physics in the University of Munich. His book "Atomic Structure and Spectral Lines" (English edition) contains an account of mathematical work on the structure of the atom, his own contributions being of very high value.

Obituary.

ADMIRAL SIR JOHN FRANKLIN PARRY, K.C.B.

ADMIRAL SIR JOHN FRANKLIN PARRY, K.C.B., whose death occurred at Harrogate on Wednesday April 21, had a long and distinguished record in H.M. Navy, principally as a hydrographic surveyor and as Hydrographer of the Navy.

Born on August 15, 1863, Parry joined the Royal Navy in 1877, being promoted to lieutenant in 1885, commander in 1899, captain in 1905, and rear-admiral in 1916. He first joined H.M. Surveying Service in April 1884, being appointed to H.M.S. *Triton*, surveying on the east coast of England. After a short period in that ship he was appointed to H.M.S. *Rambler*, where he served from November 1884 until March 1889 in the Red Sea and Far East, receiving the Egyptian Medal and Khedive's Bronze Star for the part he took in the naval and military operations at Suakin in 1884–1885. In 1888 he was landed in command of a party at Mempakol, British North Borneo, to protect the Resident Commissioner from an attack by hostile natives. His next ships, all employed on hydrographical surveying, were the *Penguin*, *Triton*, and *Dart*, and whilst in the latter as senior executive officer he succeeded to the command of her, after two years' service, in 1897. He remained in command carrying out important surveying work in Australian waters until the middle of 1900.

From August 1900 until February 1903 Parry held the important post of Chief Civil Assistant to the Hydrographer (Admiral Sir William Wharton, K.C.B., F.R.S.), and from that post assumed command of H.M. Surveying Ship *Egeria* surveying in British Columbia, where he remained until 1906. He was then appointed in command of H.M. Surveying Ship *Merlin* surveying in the Red Sea and north-west coast of Borneo, but only remained until the end of that year, being incapacitated through sickness. He was appointed to H.M. Surveying Ship *Egeria* again in 1908, remaining with her surveying in British Columbia until April 1910, when he completed his hydrographic work afloat.

As Assistant Hydrographer from April 1910 until August 1914, Captain Parry carried out much important work in connexion with hydrography and allied subjects. Amongst other positions he represented the Admiralty on the Board of Trade Committee on Derelicts in 1912, and on the conference on the subject of the Atlantic ice patrol following the loss of the *Titanic*. He was also British delegate to the French conference on the use of wireless telegraphy in connexion with time and weather, and served as chairman of the important Admiralty Committee on the re-organisation of British Admiralty charts.

Appointed Hydrographer of the Navy on September 1, 1914, Captain Parry held this post throughout the War and until August 31, 1919. During this period the work of his Department was very largely increased to meet war requirements, and although the surveying ships employed were necessarily reduced to a minimum, the surveyors' activities afloat, and in connexion with the Hydrographer, were very much increased, and under his direction the numerous and varied calls for new forms of charts and other technical hydrographic publications were fully met. His last important work, before retiring as Rear-Admiral and from being Hydrographer, was to preside over the International Hydrographic Conference in London in June 1919, when forty-five delegates, representing twenty-five nations, met to discuss the standardisation of hydrographic charts and publications, and kindred subjects.

After retirement as Hydrographer, Sir John Parry was employed as a member of the International Hydrographic Bureau Committee until June 1921, when the Committee was dissolved; then becoming, by election, senior director of the International Hydrographic Bureau, Monaco, which post he held to the day of his death. During 1920 he was also employed by the contractors for the Crown Agents for the Colonies in making an examination of a suitable locality on the Gold Coast to determine the best site for a deep sea harbour. Sir John Parry undertook the sole charge of this expedition, and the valuable work therefrom resulted in Takoradi Bay being chosen, where the building of the new port is now well advanced.

In recognition of his services Parry was made C.B. in 1916 and K.C.B. in 1919. He also received the Cross of Commander of the Legion of Honour (France) and the Distinguished Service Medal (U.S.A.). He was a fellow of the Royal Geographical Society, being elected in 1917. He was promoted to Vice-Admiral on the Retired List on November 25, 1920, and to Admiral on November 24, 1925.

MR. F. C. L. WRATTEN.

IT is with much regret that we learn from the *British Journal of Photography* of April 16 of the death of Mr. F. C. L. Wratten at the age of eighty-six years. Mr. Wratten came from Hellingly, Sussex, when he was twenty-one, and became a clerk in the photographic firm of Solomon's of Red Lion Square. In 1877 he entered into partnership with Henry Wainwright (who died in 1882) and established the well-known firm of Wratten and Wainwright in Great Queen Street, London.

As soon as gelatine was shown to be a possible medium for photographic plates and to offer advantages that collodion does not possess, Mr. Wratten took up the matter, and as a result of his experimental investigations was one of the very first (1877) to put gelatinobromide dry plates upon the market. These "London" plates were remarkable for their fine quality although made entirely by hand.

Mr. Wratten was also a pioneer in 'instantaneous' photography by taking advantage of the superior sensitiveness of gelatine over collodion plates. In 1882 he photographed the University boat race, and he was the first to photograph the Derby. As soon as gelatine plates became fairly well established, Mr. Wratten started a plate factory at Croydon, and he lived there for the last forty-six years of his life. In 1896 the shop and premises in Great Queen Street were closed. In 1906 Dr. Kenneth Mees joined the firm, and in 1912 the Kodak Company bought the business. Dr. Mees went to Rochester, New York, to establish and conduct the research laboratories there, and Mr. Wratten's son, Mr. S. H. Wratten, became the head of a technical department of the Kodak Company.

News and Views.

ON March 9 Dr. Arthur Wade read a paper before the Institution of Petroleum Technologists in which he embodied the results of his experience of oil exploration in Australia and Papua. As he pointed out, in no part of the world have the Government and people of a country been more anxious to obtain indigenous supplies of petroleum than in Australia, but so far this natural desire has not been realised. Many geologists have concluded, and with good reason, that owing to the fundamental character of the Australian continent, and its similarity to the great Archæan shields of the earth's surface, it lacks either the marine sedimentary cycles or the tectonics with which one associates the main oilfields of the world; hence the chances of locating large oil-pools are remote. The author felt that this was a dangerous generalisation for a continent, though he admitted that very large areas in Australia were distinctly unfavourable to the occurrence of oil; he stated "the close study of a few areas of comparatively limited extent leads one to the conclusion that commercial pools of oil do occur elsewhere in association with conditions . . . (characterised by) . . . the presence of abnormal factors which operate locally and are not usually active in productive oilfield areas."

DR. WADE dealt with the various direct and indirect indications of oil in the continent of Australia, but it cannot be said that in any one instance these amount to much: South and Western Australia have nothing to offer which can be construed as being in the slightest degree favourable. Of the Northern Territory he says: "Copper, gold and tin are more certain of providing the prospector with adequate returns for his work than is petroleum." The possibilities of Queensland seem to be based on the historic find of natural gas in a water-well at Roma in 1897; but subsequent drilling has not proved successful. In New South Wales an application of the American 'carbon-ratio' hypothesis has directed attention to the Sydney coal basin; but the author himself dispelled optimism in prospects here by his careful scrutiny of the data, though he considers the chances of locating natural gas favourable. In other parts of the continent very little is known of the geological conditions, save in broadest outline, though there is apparently little to commend them as potential oil-producing areas. With regard to Papua, geological circumstances are entirely different from those of the Australian continent, and chances of locating commercial pools are much more favourable; conditions of exploration and operation are extremely difficult in this territory, but past developments have not been without some success, and now that the Government has recently abandoned its monopoly to drill, private enterprise may well be productive of satisfactory results in the course of time.

SIR JOSEPH THOMSON gave the Kelvin Lecture to the Institution of Electrical Engineers on April 22. He chose as his subject the mechanics of the electric field, a subject, he said, which was never long absent from Kelvin's thoughts. He pointed out that the ordinary laws of electro-magnetism and of the dynamics of the electric field merely represent the relations between averages taken over a time which, though small, is finite and comparable with the times that occur in the atom. These relations, however, are meaningless when times less than the times for which the averages have been taken are considered. When considering the orbits of electrons, the principle of the conservation of energy holds only when taken on the average. When electric waves are generated by an electron in an atom, the time constant of the force increases as the force becomes weaker. When the field is very intense, the time constant is very small and the ordinary equations hold. When electric radiation becomes weaker and weaker, a place is reached where the time constant is comparable with the period of vibration; when this occurs the radiation is reflected. It will not go out into space. The waves coming back to the electron will restore the energy to it which they originally received. This can be applied also to an electron revolving in an orbit and leads to a corpuscular theory of light. In this theory, light is regarded as travelling out in bundles, the energy in each bundle diminishing as it goes through space. Sir Joseph is of opinion that the isolated positive hydrogen atom may be capable of producing vibrations which are very short even when compared with the vibrations of Röntgen rays.

THE Perthshire Natural History Museum, which ranks high amongst local institutions of its kind, has been busy setting its house in order as regards its collection of Mollusca. Mr. Henry Coates has been occupied for some years past in amalgamating the interesting and important collections presented at different times by various donors, in arranging them for exhibition, and in preparing a catalogue, which is now published in the *Transactions of the Perthshire Society of Natural Science* (vol. 8). Mr. Coates has prefixed a brief history of the collection, the extent of which may be gauged by the fact that the catalogue occupies some 75 pages in 8vo. In common with all curators he complains of the great difficulties encountered in the matter of classification and nomenclature, and bewails the lack of a thoroughly comprehensive book giving a complete survey of the Mollusca, which, as he remarks, has still to be written. Among the old and new authorities cited as consulted we should have thought that Pelseneer's volume in the Oxford "Treatise on Zoology" and Fischer's "Manuel" ought to have found place. Illustrations of the exhibition cases, explaining the structure and development of the Mollusca, are given and show how admirably this feature has been carried out. The legends to the plates, however, are not quite correct. It might have been expected that the home industry carried on at their very doors would have received special treatment; but though illustrations of the old and present methods of fishing for the pearl mussel in the Tay are given, no exhibit of the growth and development of the mollusc is mentioned, an omission which certainly should receive prompt attention, since, as Dr. Boycott pointed out in these columns (Nature, vol. 114, 1924, p. 276), there is a gap in our knowledge thereof which requires filling, and, if anywhere, it could be made good at Perth.

The fourteenth International Geological Congress will assemble at Madrid on May 24-31. The principal subjects to be discussed are: (1) phosphates and pyrites, (2) geology of the Mediterranean, (3) Cambrian and Silurian fauna, (4) geology of Africa and its relation to that of Europe, (5) Tertiary vertebrates, (6) Tertiary Foraminifera, (7) Hercynian folds, (8) metallogeny, (9) vulcanism. There will be excursions before the meeting to the Straits of Gibraltar, the Mountains of Ronda, Linares and Huelva, the Guadalquivir, the Sierra Morena and Sierra Nevada, Burgos, the Canaries; during the meeting, to Almaden, the Guadarrama Mountains, Aranjuez; and after the meeting to the collieries of Asturias, the iron deposits of Bilbao, Catalonia and the Central Pyrenees, Catalonia and the Eastern Pyrenees, and the Balearic Islands. Any one desiring to take part in the Congress must apply to the Secretary of the Executive Committee of the Fourteenth International Geological Congress, Escuela de Minas, Calle de Rios Rosas, 5, Madrid, Spain, and enclose a remittance of 30 pesetas. A deposit is also required from those taking part in any of the excursions. Arrangements have been made for reduced railway fares to and from Madrid for members of the Congress on the Spanish railways, on the production of a special certificate issued by the Congress.

The issue of the *Journal of the Royal Society of Arts* for April 2 contains a paper on domestic heating by Dr. Margaret Fishenden, of the Fuel Division of the Research Department, in which the relative costs of different systems of heating are compared. Taking good household coal at 50*s*. a ton, coke at 40*s*, coal-gas at 10*d*.; a therm, and electricity at 2*d*. a unit, the prices of a therm are, for coal, 1 9*d*; coke, 1 7*d*.; gas, 10*d*. and electricity 59*d*. For central heating, coal and coke appliances have an efficiency of 50 per cent., while gas and electricity appliances have 100 per cent. The costs of the same amount of heat effect are therefore in the ratios 1 : 0 9 : 2 6 : 15·5, and coke is the most economical. For heating by radiation from a body at high temperature, open fires have an efficiency of about 25 per cent., gas fires about 50 per cent., and electrical radiators nearly 100 per cent. The relative costs of equal heat productions in a room are coal, 1*d*.; coke, about 0·75*d*.; gas, 2*d*.; and electricity, 7*d*. Labour-saving, cleanliness, intermittent use and comfort have to be considered in addition to cost, and in the discussion it was stated that for one person using fires intermittently, gas is as cheap as coal.

Southport meteorological observations for the year 1924 have recently been published by the Southport Corporation and the Meteorological Office, Air Ministry, the Fernley Observatory being now auxiliary to the Meteorological Office. Observations at Southport have been continuous for more than fifty years, so that the averages of temperature and rainfall are excellent for a health resort, and the observer, Mr. Joseph Baxendell, who is meteorologist to the Corporation, ranks amongst the foremost observers in meteorology, and commonly introduces material of much value into his annual report. The outstanding feature of 1924 is said to be a record frequency of southerly winds, and in consequence the year was very dull, decidedly wet, and fairly warm. The only months noteworthy for trying 'cold' winds were February and March. Due northerly winds were of less than normal frequency in every month except February. December was one of the mildest ever experienced. Though 1924 was wet it was less so than in many districts; there have been quite a number of wetter years and several more dull since observations were established in 1871; five of the twelve months were drier than usual, the run of rainy weather from July to October being very unfortunate. Only three months were brighter than is customary, almost the whole of the year's large shortage of sunshine occurring during the summer half year. In the appendix to the report for 1924 the periodicity for a small number of years is given from the harmonic analysis of 53 years' records of Southport rainfall. This is rather bold for a health resort. July and September of 1926 are both approximate dates of maxima rainfall, the earlier of periodicity 2·85 years, the later 2·19 years; the value of the forecast can soon be proved.

At a meeting of the Illuminating Engineering Society on April 29 a paper on "School Lighting (Modern Requirements and Recent Progress)" was read by Dr. James Kerr, who is chairman of the Joint Committee formed by the Society to inquire into this subject. Since the reports issued by this Committee in 1913, substantial progress in illuminants and lighting appliances has been made. The importance of adequate access of daylight has been emphasised by the recent recognition of the part played by ultraviolet radiation in sunlight in relation to health. For artificial lighting the Committee originally recommended a minimum of 2 foot-candles. Dr. Kerr suggested that in view of recent progress a value of 5-7 foot-candles should now be aimed at. He also emphasised the desirability of extra lighting of the blackboard, and proposed a general recommendation that sources within the direct range of vision should be toned down to 3 candles per sq. in. Dr. Kerr mentioned favourable experience with a local lamp equipped with daylight-glass so as to remove excess of red-yellow light, and he suggested that the use of suitable light-filters in schools for myopic children deserved investigation Dr. E. H. Nash (Medical Officers of Schools Association) presided. Various representatives of educational bodies took part in the discussion, in which the importance of adequate lighting, both natural and artificial, in schools was strongly emphasised.

A LECTURE given by Mr. C. E. R. Sherrington on "Rail Transport Systems of the United States" has been published in the March number of the *Journal of the Institute of Transport*. The lecture is a useful one, as it emphasises the great difference there is between rail transport in Britain and in America. With the exception of rubber and coffee the United States is practically self-supporting. Its trade is therefore mainly internal. But in order to benefit by large-scale production in steel and similar industries where overhead charges form a large fraction of the total, the surplus is exported abroad. This has the effect of cheapening transportation and tends to concentrate large-scale industries. The opening of the Panama Canal and the agricultural depression had serious effects on the Chicago to Pacific coast lines. The Chicago, Milwaukee and St. Paul Railway was forced into receivership. This was unfortunate, as this road had electrified 648 miles of its main line through the Rockies down to the Pacific coast in 1920, and to opponents of electric traction the effect produced seems to be due to this cause. In reality the traffic through the north-western States did not warrant the building of three trans-Rocky mountain lines. Electrical engineers are studying closely the working of the new Diesel electric engines. If these prove satisfactory they will serve as a deterrent to further electrification.

THE report for 1925 of the Director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington records a fruitful year's work The Department has co-operated with other American research institutions in the investigation of the conducting layer in the upper atmosphere by means of reflection of wireless waves, and the results obtained seem to be in accord with those obtained in Great Britain by Appleton and Barnett, and Smith-Rose and Barfield. In co-operation with the Carnegie Institution Geophysical Laboratory, work is being done on the effect of pressure on the critical temperature of magnetisation, the results to date are confined to nickel, using pressures up to about 2000 atmospheres, but the effects seem to be very small: the research is of interest in connexion with the depth to which permanent magnetisation of ferrous rocks in the earth's crust can exist. The reduction of the observations of atmospheric potential gradient, made on the various cruises of the *Carnegie*, has made it possible to attempt, for the first time, the construction of isoelectric charts for the greater part of the earth's surface—the oceans. Several questions of purely atomic physics, not at present obviously related to geophysics, have also been investigated under the auspices of the Department. Much observational work in terrestrial magnetism and electricity has also been accomplished, particularly at the two observatories of the Department—at Watheroo, Western Australia, and Huancayo, Peru.

THE Report of the Marlborough College Natural History Society contains its usual lists of observations in natural history, meteorology, etc. A list of about 113 fungi of the district is given by C. P. Hurst and twelve flowering plants are added to the hand-list. The permanent record of the risings of the Rockley Bourn with a graph of the last twenty-four years is due to L G. Peirson, it is a 'winterbourn' or 'hungerbourn,' a stream appearing in normally dry valleys in chalk country. Brentnall's account of the local Manor of Rockley is charming and quite suitable. A quite important and well illustrated paper on Cyclops, by A. G Lowndes, records seventeen of the thirty British species in correlation with the pH value of the water in which they lived, and describes three forms; such systematic research should be published in a regular biological journal, or it will be missed by most workers.

DR. A. DAUVILLIER, of Paris, is to deliver the seventh Mackenzie Davidson Memorial Lecture before the Röntgen Society and the Electro-Therapeutics Section of the Royal Society of Medicine on May 20 at 8.15 P.M., taking as his subject "The Measurement of X-ray Dosage." The lecture will be delivered at the Royal Society of Medicine.

AT the annual meeting of the members of the Royal Institution, held on Saturday (May 1), the following officers were elected: *President*, The Duke of Northumberland; *Treasurer*, Sir Arthur Keith; *Secretary*, Sir Robert Robertson.

THE International Association for Psychology and Techno-Psychology (*i.e.* Industrial Psychology) began its official activity on March 15. Fifteen European countries are represented in the Association, the administrative headquarters of which are at Riga, under the direction of Dr Moeller. In England the Association is represented by Prof. T. H. Pear, University of Manchester, and its department of Techno-Psychology by Dr. C. S. Myers, National Institute of Industrial Psychology. The first publication of the Association will be "A Survey of the Organisation and Position of Techno-Psychology."

We regret that by a slip in our note on the explorations in Derbyshire caves (Nature, April 24, p. 598), the name of the archæologist by whom the investigations are being carried out, was wrongly given. The work is in charge of Mr A. Leslie Armstrong.

Applications are invited for the following appointments, on or before the dates mentioned:—A professor of pure mathematics and a professor of chemistry in the Egyptian University, Cairo—The Director, Egyptian Education Office, 39 Victoria Street, S.W.1 (May 14). A public analyst for the Metropolitan Borough of Bethnal Green—The Town Clerk, Town Hall, Bethnal Green, E.2 (May 17). A head of the department of mechanical engineering and a lecturer in the department of civil engineering, architecture and building in Bradford Technical College—The Principal of the College (May 19). Junior assistants at the National Physical Laboratory with good honours degree and, if possible, research or technical experience in one of the following subjects: physics, electricity, metallurgy, engineering, aeronautics, naval architecture—The Director, National Physical Laboratory, Teddington (May 22). A professor of physics at the School of Engineering, Giza, Cairo—The Minister of Education, Cairo (May 30). An analyst in connexion with the Dairy Produce Act, 1924, in the Department of Agriculture, Irish Free State—The Secretary, Civil Service Commission, 33 St. Stephen's Green, Dublin (May 31). A bacteriologist in connexion with the Dairy Produce Act, 1924, in the Department of Agriculture, Irish Free State—The Secretary, Civil Service Commission, 33 St Stephen's Green, Dublin (June 30). A director and an assistant director of the Research Association of British Paint, Colour and Varnish Manufacturers—Mr. J. B. Graham, 8 St Martin's Place, W.C.2. A lecturer in geography and nature study at the Bedford Training College—The Principal. A resident tutor in geography at the Borough Road Training College, Isleworth—The Principal. A head of the chemistry department of the Huddersfield Technical College—The Director of Education, Education Offices, Huddersfield. A principal of the Derby Technical College—The Secretary, Education Committee, Becket Street, Derby.

Our Astronomical Column.

Investigation of Transits of Mercury.—Prof. Newcomb was the first to suggest that the unexplained fluctuations of the moon might really be fluctuations in the earth's rate of rotation. The suggestion can be tested by studying other heavenly bodies with rapid motion, notably Mercury and the inner satellites of Jupiter. Newcomb himself discussed transits of Mercury up to 1891, but failed to obtain definite confirmation of variation in the earth's rotation. *Union Observatory Circular* No. 65 contains a new investigation by R. T. A. Innes; he has repeated Newcomb's work, correcting a few minor errors, and has included the four recent transits of 1894, 1907, 1914, 1924, all well observed. The semi-diameters deduced for the sun and Mercury at unit distance are 959″·48 (0″·15 less than that of Auwers) and 3″·08. The latter is undoubtedly less than the real semi-diameter of Mercury, owing to irradiation.

A diagram is given of the time-residuals of the transits from 1677 to 1924; they are compared with Newcomb's diagram for the moon, and there is a certain similarity between them. Both have maxima near 1680 and 1885, and a minimum about 1780, the curve for Mercury between these limits is much more undulating than the lunar one. Jupiter's satellites I, II, are also used for the last thirteen years, and accord well with the Mercury curve in showing a rapid downward movement.

There is therefore a fair case for ascribing the errors in position of the different bodies to a common cause, namely, changes in the earth's speed of rotation. Dr. Innes seems to be in error in one point. He mentions the error of the equinox as due to a similar cause. But a shift of the sun along the ecliptic does not affect the position of the intersection of ecliptic and equator.

Masses of Stars of Types F to K.—*Astr. Nach.* No. 5434 contains an article on this subject by B. P. Gerasimovic. He points out how few stellar masses are accurately known, and how useful it would be to find a general method of obtaining them in the case of stars without visible companions. Two methods have been suggested; first, that of the equipartition of energy, which if established would correlate mass with velocity, secondly, Pannekoek's method from comparison of trigonometrical parallaxes with spectroscopic ones. The latter method is complicated by the effect of radiation pressure in diminishing gravitation, especially in the hottest stars.

The author bases his work on the Victoria parallaxes, and the masses of binaries with well-developed orbits. The equipartition principle is first tested; the quantity (mass) × (velocity)^2 is formed for a large number of stars of types F, G, K. The mean values of the product for the three types are 3·47, 3·45, 3·59, in good agreement with Seares's value 3·57 obtained in quite a different manner. It is concluded that both the equipartition theory and Pannekoek's principle are sound, and can be applied statistically, though there may be large deviations for individual stars.

Prof Eddington's proposition of correlation of mass with absolute magnitude is then tested, graphs being drawn for the different types. They show large departures from linearity, there being evidence of discontinuity between M = 2·0 and M = 3·5, about the region of demarcation between giants and dwarfs.

The paper concludes with a list of deduced masses and densities of 74 stars with parallax 0·07″ or greater. The five largest masses are 61 Ursae Maj. 4·1, δ Eridani 3·7, 61^2 Cygni 3·5, η and γ Cephei each 3·0. 61^2 Cygni is given the great density 31·8, that of Arcturus is only 0·0005, its mass being 1·6. These data are only provisional, but they give hope of future increase of knowledge in this very important but difficult field.

Research Items.

CAPSIAN AFFINITIES OF THE LATER STONE AGE CULTURE OF SOUTH AFRICA.—The possibility of connexion between the Stone Age cultures of North and South Africa was discussed with some precision by Mr. A. J. H. Goodwin of the Cape University, in a paper presented to the South African Association for the Advancement of Science in 1925 and now published in vol. 22 of the *South African Journal of Science*. Of the three industries forming the later Stone Age in South Africa, one is the pygmy industry, a second has been named the Smithfield industry. The characteristics of the pygmy culture are scrapers, points, the geometrical pygmy implements, ostrich shell beads, bone implements, paintings on walls or stones, possibly stone palettes, and the habit of eating snails. The Smithfield industry includes duck-bill scrapers, of a type larger than the pygmy, and shading to the circular scraper, blades and tanged points. In North Africa in the late Capsian is found a culture with end-scrapers, blades, points, tanged arrow-heads, crescents, ostrich egg-shell beads, and bone awls exactly similar to those of the pygmy and Smithfield cultures of South Africa. There is also the possibility that the North African Capsian may be connected with paintings. It is concluded, therefore, that the later Stone Age of South Africa is an offshoot from the Capsian culture.

MENDELIAN HEREDITY AND RACIAL DIFFERENCES.—Prof. R. Ruggles Gates points out in a communication appearing in vol. 55, Pt. 2, of the *Journal of the Royal Anthropological Institute*, that although innumerable peculiarities and abnormalities are found to be inherited in man as simple Mendelian differences dominant or recessive to the normal or sex-linked in various ways, anthropologists have not yet generally recognised the wide spread of Mendelian inheritance in man. Data relating to such characters as eye colour, stature, and cephalic index, however, are rapidly accumulating. The known facts do not justify the distinction sometimes made that Mendelian inheritance applies only to abnormalities, and that racial differences follow other rules and do not segregate. Eye colour was the first character in man to be recognised as Mendelian in its inheritance. It is well known that it segregates in families. Segregation also occurs in inter-racial crosses. There is nothing at present to indicate that its inheritance in such crosses differs from that within a single race. As regards stature, while it is characteristic in many races, it is clearly not a unitary thing but the result of many diverse elements acting under a particular set of environmental conditions. In the case of the cephalic index it is clear that brachycephaly and dolichocephaly are not determined by a simple Mendelian pair of factors. The work of Fritz, Hildén, and others indicates that the cephalic index may be determined by several cumulative polymeric factors, *i.e.* genetic factors, each of which produces a certain transition from dolichocephaly towards brachycephaly. It appears that such "racial" characters as stature and cephalic index do not differ in their hereditary behaviour from size and shape differences generally, and have no special virtues as being "racial" distinctions. But there is great and urgent need for accurate observations on the results of inter-racial crosses in mankind.

EFFECTS OF THYROID ADMINISTRATION.—Prof. Ercole Giacomini gives an account in the *Rendiconto della R. Accademia delle Scienze dell' Istituto di Bologna* of the interesting results observed on the administration to fowls of thyroid, which produces marked changes in their metabolism and influences more particularly the development, appearance, and colour of the plumage. Ingestion of fresh ox thyroid by young or old fowls of either sex infallibly determines a pronounced stimulus to the production of feathers. In some cases the old feathers are made to fall in a manner so rapidly that in a few days the body may become almost bare, being covered only by the germs of the new feathers, which are surrounded by horny sheaths and resemble short prickles. Moreover, with birds having coloured feathers there takes place an alteration in colour, usually a depigmentation, the extent and intensity of which are enhanced if administration of the thyroid is continued. In certain instances, however, but never with white fowls, the opposite phenomenon occurs, increased formation of black pigment being observed in the feathers on some parts of the body. Similar but less pronounced changes follow the use of dried thyroid.

GENETICS OF LOCUSTS.—Continuing his genetic experiments with grasshoppers, Nabours (*Kansas Agric. Sta.* Bull. 17) has published the data from twelve years' breeding of the grouse locust, *Apotettix eurycephalus*. Eleven different colour patterns of this locust, all found wild, have been bred with the 'normal,' to which they are all more or less dominant, and with each other. More than 134,000 individuals were examined in the experiments, and the patterns of a large number of specimens are permanently preserved in alcohol. By means of the crossing-over data and other hereditary behaviour, all these factors are mapped as belonging in a single linkage group (or chromosome), and nine of them form three groups of multiple allelomorphs containing respectively three, four and two factors. With certain factors, the percentages of coupling and repulsion obtained were quite different. These and certain other inconsistencies are attributed to the highly variable conditions under which the experiments were conducted. Very interesting phenomena of parthenogenesis were obtained in some of the females.

AGE AND GROWTH OF HADDOCK AND WHITING IN ICELANDIC WATERS.—Bjarne Saemundsson writing in *Meddelelser fra Kommissionen for Havundersøgelser, Serie : Fiskeri*, Bind viii, Nr. 1, 1925, states that the haddock has long been one of the favourite food-fishes of the Icelanders. It has also been cured (split and salted) on a large scale for export, being formerly second only in importance to the cod, although it now occupies third place as an article of export, having given place to the herring. From his study of the scales, Saemundsson concludes that the growth of the Icelandic haddock follows a similar rule to that of the cod : "It is most rapid on the south and the west coast, and gradually decreases as we turn to the right round the country, being slowest on the east coast." This decline in growth is attributed to the fall of temperature in the said direction, an influence which also prevents the spawning of cod, haddock, and many other fishes. In comparison with other regions, the rate of growth of the Icelandic haddock is only surpassed by that of the Faeroese ; while the size attained is also very large compared with that in more southern waters, so that ages 9-14 years commonly occur. As with the cod, there is a noticeable difference in the size of the sexes, the males being the inferior in size for corresponding age. Sexual maturity is first reached when the fish (both sexes) is four years old and about 47 cm. long. It is significant that the majority of haddock caught in Icelandic waters, particularly in shallow inshore areas, are young immature fish, but the 5-yearly means of the catches from 1897 to 1919 do not indicate that there has been any decrease in stock as the result. Unlike the haddock, the whiting gives rise to no special or important fishery. This fish is also able to grow to a much larger size in Icelandic waters than in neighbouring seas, and, as with the cod, the female is larger than the male, and probably reaches a higher age. A common feature of the scales of whiting is the presence of a considerable number of narrow rings within the first summer-zone. These narrow rings are only separated from the centre by two or three broad summer-rings, and although they assume the appearance of a normal winter-zone, their position seems to render this interpretation untenable. Saemundsson suggests that this false ring may be looked upon as a consequence of some change in the life of the fish, *e g.* moving from shallow to deeper (cooler) water, or the transition from pelagic to bottom life.

Chromosomes of Hyacinth.—The chromosomes of the hyacinth and two related genera have been studied by Mr. C. D. Darlington (*Journ. Genetics*, vol. 16, No. 2), *Hyacinthus orientalis* and *Scilla nutans* having 8 chromosomes, while *Bellevallia romana* has 4. But Hyacinthus is not strictly tetraploid, because one of the four long chromosomes has a constriction which is not found in the other three chromosomes. In Scilla the chromosome sizes and constrictions are different from those of the hyacinth, and neither condition is directly derivable from the diploid Bellevallia, owing to differences in the constrictions and sizes of the chromosomes It is concluded that the constriction is not necessarily at the point of application of the force which moves the chromosome, and that the centre of attraction of the chromosome is not strictly localised. The latter conclusion is contrary to some previous evidence.

New Technique with Fossil Plants.—Mr. T M. Harris describes in the *New Phytologist* (vol. 25, No. 1, 1926) a new method for examining plant remains in shale, by which the whole of the more resistant plant material is rendered available, and not merely plant impressions exposed on split surfaces. The shale is first immersed for some days in strong nitric acid containing about 5 per cent. potassium chlorate; after washing in running water it is then placed in dilute sodium hydroxide, in which it breaks down into a fine mud from which resistant fragments of cuticle, and sometimes of other tissues, can be strained off by wire gauze. These fragments are finally cleaned in 25 per cent hydrofluoric acid. A great number of leaf fragments, small seeds, bird scales, etc., were thus obtained, together with two characteristic megaspores of *Lycostrobus Scotti* Nath., of which only one other specimen is known. From a piece of shale consisting mainly of *Sagenopteris Nilssoniana* (Brongn) Ward., pollen grains, anthers, and seeds were obtained which were scarcely distinguishable from those described by Dr. H. Hamshaw Thomas for the Caytoniales. As these organs were not found in other shales, this strengthens the evidence for Dr. Thomas' view that the leaves of the Caytoniales were of the Sagenopteris type. By this method Mr. Harris has been able to study about one-half of the total number of species (106) now known of the early Mesozoic flora from the Rhaetic bed of East Greenland.

Determination of the Salinity of Sea Water.—Prof. Giral discusses in "Quelques Observations sur l'emploi de l'eau normale en Oceanographie" (*Publication de Circonstance No. 90*, International Council for the Exploration of the Sea, Copenhagen) the source of error in calculating the total salts content or salinity of sea water from the chloride content as determined by titration. Although the salts occurring in sea water are present in almost the same proportions in the open oceans, slight variations are known to occur which renders the calculation 'conventional.' The various errors occurring in the usual titrimetric determination of salinity are considered, from which Prof. Giral concludes that these prevent an approximation closer than the first decimal place per kilogram of sea water in all determinations of chlorides and salinity.

Long-range Forecasting.—Sir Gilbert Walker gives a summary in the *Meteorological Magazine* for March of some recent papers by W. Wiese. It is mentioned that there has of late been considerable meteorological activity in Russia, and amongst this is the work of Wiese upon conditions in the North Atlantic considered in the light that it may throw on English weather. Associated with years of much ice in the Barents Sea, there is in advance a south-eastward displacement of the axis of the trough of low pressure off the west coast of Norway. An attempt is made to associate ice in the polar seas and the general circulation of the atmosphere extending the connexion between the Arctic and Antarctic, but it is pointed out that this appears to be unproven. There seems to be a close relationship between Barents ice and air temperature in Europe The influence of the mean air temperature in spring in N Iceland on the mean air temperature of the following winter in Europe is dealt with. Other meteorological correlations are referred to. In summing up Wiese's work, Sir Gilbert remarks that while conditions in the Barents Sea do not exercise a profound influence on the conditions of the Southern hemisphere, they are of importance in a fairly wide region of the northern hemisphere.

Gold in the Dartmoor Granite.—In the *Mineralogical Magazine* for March, Dr. A. Brammall describes his investigation of the modes of occurrence of gold on Dartmoor. Detrital gold was first identified in samples of stream-sand and 'head.' A gold-bearing pegmatite on Bittleford Down was then found, and described in collaboration with Dr. H. F. Harwood. Since then gold and silver have been detected in the normal grey biotite-granite at various localities on the Moor. The gold is found as inclusions, sometimes visible, in both quartz and felspar, and together with silver in biotite. The evidence is conclusive that the two metals are primary products of crystallisation from the granitic magma. Careful examination of vein-quartz, and assays of pyrites and of pneumatolysed rock showed that the gold-silver content of the granite cannot be attributed to either pneumatolytic or hydrothermal processes. Similarly occurring primary gold has already been recorded from granites in California and Nevada.

Kames and Drumlins in Scotland.—Prof. J. W. Gregory defines 'kames' as ridges of fluvioglacial or glacieluvial sand and gravel, deposited along the margin of a glacier during some halt in its retreat, where the ice front was bounded by water (*Trans. Roy Soc. Edin*; vol. 54, pt. 2, No 7, 1926). As a result of an extensive study of the distribution and structure of the Scottish kames he concludes that they have all the characteristics of marginal formations, like the majority of Irish eskers, and that they give no support to the view that they were formed along the course of sub-glacial rivers. The term 'kame' has been applied to various formations in Scotland, including moraines, denudation mounds, and even rounded hills of slate. After eliminating these, the typical true kames that remain number only a score, nearly all of them being in the east near the foot of the Highlands. On the west the glacial deposits were laid down as moraines rapidly dumped from melting ice. In a further paper (*Ibid.* No 8) Prof. Gregory discusses the origin of 'drumlins.' He argues that the trend of the Scottish drumlins shows that they have been moulded mainly by sub-aerial erosion guided by the wind.

ISOSTASY IN NORWAY.—An important paper by W. Heiskanen on the reduction of gravity observations in Fennoscandia has been published as No. 5 of the *Veröffentlichungen des Finnischen Geodätischen Institutes*, 1926. It is shown that in southern Norway the adoption of the Pratt-Hayford hypothesis of isostasy points to a depth of compensation at 80 km., while the Airy hypothesis leads to the deduction of an outer crust having a thickness averaging 37 km. Which of the two rival views is more in accord with the actual results is difficult to determine, but the author favours the Airy hypothesis as being equally well supported by the residual anomalies, and more in accordance with geological and geophysical probabilities. Reference is made to Gutenberg's estimates of the thickness of the earth's crust: under Eurasia (55-60 km.), America (*ca.* 50 km.), the Atlantic (*ca.* 25 km.) and the Pacific (0-5 km.), and these are compared with other determinations based on the Airy hypothesis: in the Alps (41 km.), North America (50-60 km.), and the Caucasus (77-104 km.). The Airy hypothesis thus appears to receive a certain amount of direct support, but it must be admitted that the apparent concordance of some of the figures means very little. Stoneley and Jeffreys have recently pointed out a fundamental source of error in Gutenberg's work, due to the effects of dispersion of seismic waves having been overlooked. The necessary correction reduces the thickness of the continental *sial* layer to about 15 km This does not, however, invalidate the Airy hypothesis, for the depth of compension need not be identical with that of the *sial* layer. It is interesting and significant that in Europe opinion is steadily veering away from the somewhat artificial Pratt hypothesis followed by Hayford and still adopted in the official American work on isostasy.

COLOUR OF THE ALKALI METALS.—In a short paper communicated to the Vienna Academy of Sciences on February 4, 1926, Prof. Przibram gives an account of the "Interpretation of colour changes in salts." He detects a progressive change in the direction of longer wave-lengths of the absorption produced by atoms of metal in the lattice of a salt at low temperatures, at high temperatures, with a distorted lattice (*e g.* the colour produced by exposure to radium of salt which has been fused with a small percentage of boric acid), in glass, in colloidal coloured crystals, colloidal solutions, and finally in the vapour. These colour-changes are attributed to a progressive relaxation of the forces which are imposed on the atoms of the metal by the lattice of a salt-crystal; for example, a crystal of rock-salt which is coloured yellow by the presence of traces of the free metal.

ESTIMATION OF ANTI-TETANIC SERUM.—In the 1923–1924 volume of the *Rendiconto della R Accademia delle Scienze dell' Istituto di Bologna*, Prof. Plinio Bardelli gives the results of a series of experiments showing that the antagonistic behaviour of anti-tetanus serum towards strychnine is determined by the same anti-body as neutralises the tetanus poison. It is therefore suggested that strychnine be used as a means of evaluating anti-tetanic serum. It is true that, in so far as chemical constitution is concerned, there is a wide difference between strychnine and the tetanus toxin, but the effects resulting from the administration of strychnine follow the same course as tetanus, whereas this is not the case with the arbitrary antigen used in the diagnosis of syphilis. Further, the use of strychnine obviates the serious difficulties contingent on the qualitative and quantitative differences of the toxins derived from different strains of the tetanus organism.

AIR/GAS RATIO IN GAS BURNERS.—The subject of the aeration of upright and inverted lighting burners is discussed in the thirteenth Report of the Gas Investigation Committee of the Institution of Gas Engineers. A rapid increase in the degree of aeration accompanies an increase of the gas supply pressure up to 2·5 in. of water, above which any further increase of aeration is relatively small. The amount of air injected as primary air, when the burners are in normal operation, is slightly less than half that required for complete combustion of the gas The air to gas ratio of the mixture produced by the injection is higher for the upright than for the inverted burner, the burners being adjusted for best illumination. This air/gas ratio is materially reduced as the burner becomes heated, but is not appreciably altered by the use of a chimney. The differential-pressure column method of the Fuel Research Board (Technical Paper No. 5) for the determination of the specific gravity of gases is shown to be accurate to within 0·002 when applied to the ordinary grade of towns' gas supply (specific gravity about 0·5). The fourteenth Report is devoted to a description of an experimental carbonisation plant, comprising settings of two horizontal retorts and two vertical retorts, and the usual condensing and purifying plant, erected at the University of Leeds as a memorial to Sir Corbett Woodall.

HIGH TEMPERATURE STANDARDS.—The issue of part 4 of the *Abstract Bulletin of the Nela Research Laboratory* completes vol. 1 of the Bulletin Part 4 contains Abstracts 99 to 138 on pp. 523-737 of the volume. The researches to which they refer were carried out under the late Dr. E. F. Nichols, of whom a portrait is given. Many of the abstracts cover papers which have appeared at various times in the scientific and technical press and sum them up in a compact form. Thus abstract No. 108 condenses into 14 pages the results published by the Nela Laboratory in seven different periodicals during the past seven years on the subject of optical pyrometry. One of the most important abstracts deals with an intercomparison of high temperature scales in use at the Nela Laboratory, the Bureau of Standards, the National Physical Laboratory, the University of Wisconsin, and the General Electric Company's Research Laboratory. The temperatures of the filaments of seven incandescent electric lamps run at stated currents were measured at each laboratory and the results compared. Three of the laboratories take the melting-point of gold, 1336°, on the Kelvin scale as the standard temperature, while two others take the melting-point of palladium, 1828° K and 1822° K respectively. The temperatures estimated by the latter laboratory are all 10° to 20° higher at about 2000° K than those of other laboratories, which agree with each other to within 10° at 2700° K.

Application of Subatomic Thermodynamics to Astrophysics.

THE presidential address to the Mathematics and Physics Section of the thirteenth Indian Science Congress held at Bombay on January 4, by Prof. M. N. Saha, contains a résumé of the work of the last few years on the physical interpretation of stellar spectra. We are unable to find space to reproduce the whole address, but the following summary and extracts include some of the main subjects surveyed.

Since the foundations of astrophysics were laid by Kirchhoff in 1859, the spectroscopic survey of the heavens has been carried on with great vigour by many workers, and the spectra of more than 200,000 stars have been classified at the Harvard College Observatory. In the interpretation of the spectra, however, two difficulties have arisen. First, there are several elements, common on the earth, which are not represented in the spectra of the stars; secondly, the elements represented in the stars are not all the same, but vary from one star to another in such a way that a continuous sequence of spectra can be arranged corresponding to a sequence of colour from blue-white through yellow to red. The character of the spectral change along the sequence is that in going from blue to red stars the spectral lines indicate a gradually decreasing excitation stimulus.

Lockyer long ago explained the phenomena by supposing that a spectrum was an indication of temperature, and that in the high temperature blue stars the elements were dissociated into simpler forms. This hypothesis offered a sufficient explanation of the facts, but was unwelcome on account of its revolutionary character. In recent years, however, this criticism has ceased to hold good, and in Prof. Saha's address an "attempt has been made to show how modern discoveries have led us to a complete justification of the main ideas of Lockyer."

When a gas is raised to a high temperature, the violence of the atomic collisions is conceived to result in the detachment of electrons from atoms. At any temperature a state of statistical equilibrium is reached, in which the rate of ionisation is equal to the rate of recombination. The gas then consists of ionised atoms, neutral atoms, and electrons, and at each recombination of an electron with an ionised atom, radiation is emitted. The fraction (x) of dissociation can be calculated in terms of temperature (T) and pressure (P), and is found to be given by the equation:

$$\log \frac{x^2}{1-x^2} \cdot P = -\frac{U}{2 \cdot 3RT} + \frac{5}{2}\log T - 6 \cdot 5 = K,$$

where U is the ionisation potential of the atom and R is the gas constant. The formula, as Russell has shown, needs modification when more than one element is present—a statement confirmed by both experiment and observation—and, further, represents only an approximation to the complexity of an actual case, since the various excited states of the atom have not been distinguished, but it is sufficiently exact to explain the main details of the spectral sequence.

From the observed positions in the sequence at which particular lines appear or disappear (which we may take to indicate the conditions under which the appropriate atoms begin or cease to be capable of emitting the respective lines), the above equation, combined with spectral data, gives a relation between the temperature and pressure in the stellar atmosphere. Assuming a likely value for the latter, the temperature can be estimated, and is found to agree fairly well with the photospheric temperatures measured by direct experiment. This constitutes a justification for the view that ionisation in stellar atmospheres is a function of temperature and pressure. It has long been an unsettled question whether temperature alone can stimulate radiation, but recent experimental evidence indicates very definitely that it can do so. The theory under consideration not only provides for this, but also shows that the failure of earlier experiments was due to the choice of elements having high ionisation potentials, which, according to the equation, require high temperatures for ionisation or excitation. The implication that the degree of ionisation is increased by lowering the pressure is also borne out by experiment. The theory further explains the apparent absence of certain elements from the sun and stars by the argument that their chief spectrum lines under the conditions existing in the atmospheres are outside the range of observation.

Prof. Saha, to whom the theory in the above form is due, points to further evidence of thermal ionisation in the fact that the electrical conductivity of heated gases depends on their ionisation potentials. This at once follows from the theory if the conductivity is due to the presence of free electrons, for it must then be dependent on the percentage of ionisation, which is a function of the ionisation potential.

Later developments of the theory are mainly indebted to applications of subatomic thermodynamics to the problem. Following the lines of Ehrenfest's re-examination of Planck's thermodynamics, Fowler and Milne, Becker, Saha and Sur, have been the chief workers in this field.

"The scope of Fowler and Milne's work will be realised from the following brief summary: As mentioned above, when an original mass of calcium is heated, the products of decomposition are not only ionised calcium atoms and electrons, but also calcium atoms in the excited states, which, being unstable, give rise to the line spectrum of calcium. As the spectrum of calcium is rather complicated we shall take a simpler case, namely, hydrogen. The products of decomposition are then H⁺, electrons, H-atoms in 2_1, 2_2, 3_1, 3_2 . . . states, radiation $\nu = R\left(\frac{1}{1^2} - \frac{1}{n^2}\right)$ constituting the Lyman series, the lines $\nu = R\left(\frac{1}{2^2} - \frac{1}{n^2}\right)$, constituting the Balmer Series, etc. . . . In the simple theory sketched above, we neglected these intermediate orbits on the ground that even at the highest temperatures, their proportion calculated according to Maxwell's theorem is small.

By applying Ehrenfest's method (which has been improved on mathematical points), Fowler obtains the equation:

$$\log \frac{x^2}{1-x^2} P = K - \log b(T)$$

in place of the original equation. The function $b(T)$ represents the occurrence of the intermediate orbits

$$b(T) = g_1 + g_2 e^{-\frac{U_2}{kT}} + \ldots g_n e^{-\frac{U_n}{kT}} + \ldots$$

where g_n is the intrinsic weight of the nth intermediate orbit, U_n its energy. According to Bohr $U_n = R\left(1 - \frac{1}{n^2}\right)h$, ($R$ = Rydberg number), and $g_n = n(n+1)$ (according to Herzfeld and Epstein).

It may be mentioned here that $b(T)$ is divergent, and in order to get over this difficulty, Fowler thinks that $b(T)$ ought to be limited to a finite number of terms. He argues that as the nth orbit has a radius of a_0n^2, the series cannot be developed when the distance between two atoms is of this order, for the electron then passes into no-man's-land. As was pointed out in a note to NATURE, there is strong experimental evidence for believing that the development of higher orbits depends upon pressure (one has to think of Wood's method of getting higher lines of the Balmer series), and this is also supported by astrophysical data (see Miss C. Payne's "Stellar Atmospheres," page 48). Urey has recently shown that $b(T)$ becomes convergent when the finite volume of molecules is taken into account.

But the weak point in the argument is the assumption $g_n = n(n+1)$, and it seems to be unsound on physical grounds.

The conclusions which Fowler, and Fowler and Milne (*Month. Not. R.A.S*, vol 83, page 403) have drawn are, however, largely independent of the form of $b(T)$, and are of the greatest importance. It will be recalled that many elements, for example, mercury, have to be detected by subordinate lines, while others like calcium can be detected by principal, as well as subordinate lines Fowler and Milne discovered a very remarkable difference between the behaviour of the principal and subordinate lines in stellar sequence. They found that while principal lines are most intense at the lowest temperatures, and gradually weaken in the higher classes, the subordinate lines are at first faint, then increase in intensity, reach a maximum, and then die out The explanation is as follows: At the lowest temperature, all atoms are in the lowest state. Subordinate terms come out only at higher temperatures. But when the temperature is very high, the atom begins to get ionised, and hence the proportion of atoms in the subordinate states begins to fall off A maximum must have been reached in the interval

When the above ideas are translated into mathematical language, and conditions for maximum concentration of subordinate levels applied, we get a relation connecting the electron pressure and the temperature in the reversing layer. In fact

$$P_e = \frac{0\ 332}{b(T)} \cdot \frac{U_r + \frac{5}{2}RT}{U_1 - U_r} T^{5/2} e^{-\frac{U_1}{kT}} . \quad . \quad . \quad (1)$$

For example, the Balmer-lines of hydrogen arise from the 2-orbit, and they reach their maximum in the A-class. The temperature of these stars lies between 10,000° K to 12,000° K Substituting these values in (1), we obtain $P_e = 1{\cdot}31 \times 10^{-4}$ to $3\ 07 \times 10^{-4}$ atmospheres.

Fowler and Milne have thus found a very elegant method of determining the pressure. This is in itself a result of the first magnitude, for ionisation depends very largely on pressure, and after Einstein's discovery of the shift of lines towards the red by gravitational potential, the older values which were based on pressure-shift of lines have been rendered obsolete

Values of P_e have been calculated from considerations of the maxima of several elements, and they invariably give a range of pressure varying from 10^{-3} to 10^{-5} atmospheres These values recall the statement of Jewell; 'The whole mass in the reversing layer of the sun can be contained in a thimble' . . .

Prof. Milne has recently given an entirely new method of dealing with thermal ionisation of gases. In contradistinction to the thermodynamical method hitherto used, this method may be called the kinetic method. These two methods find their parallel even in the study of chemical equilibria. Let us represent a typical homogeneous equilibrium by the equation

$$mA + nB \rightleftarrows pC + qD.$$

Then according to the thermodynamical method we put

$$mS_A + nS_B - pS_C - qS_D = \frac{U}{T},$$

where S's are the entropies, and U is the heat of reaction.

In the kinetic method, the rate of change from left to right depends on the number of times m molecules of A come into contact with n molecules of B. The velocity of reaction $V_{AB} = K_1 C_A C_B$, and $V_{CD} = K_2 C_C C_D$. In the equilibrium case

$$V_{AB} = V_{CD}, \text{ hence } \frac{C_A C_B}{C_C C_D} = \frac{K_2}{K_1} = \text{constant}.$$

By using this method, Boltzmann gave a formula for molecular dissociation, which has the same form as that derived from thermodynamics.

Thermal ionisation of gases is only a particular form of chemical dissociation with the difference that the details of the mechanism are much better understood in the former case. Hence it is expected that the kinetic method would be very fruitful here.

Every kinetic method depends upon a closer treatment of the mechanism of reaction. The reaction in the present case is decomposition of M into M^+ and e (electron), and this can take place in various ways. To any one of these processes there is an opposite process resulting in recombination of M^+ and e to M. A pair of such oppositely directed processes has been called by R. H. Fowler 'a unit mechanism.' Each one of these unit mechanisms, by itself and without the aid of any other process, would give us some fundamental laws of general validity. This is known as the 'principle of detailed balancing.'

The ionisation of M-atoms placed in a thermal enclosure can occur:

(*a*) As a result of collision of two H atoms; the rate of ionisation is then proportional to the square of pressure.

(*b*) As a result of absorption of radiation by H atoms, normal as well as excited.

Thus, according to Bohr's theory, radiation of frequency higher than $\nu = \frac{R}{1^2}$, when falling on the normal hydrogen atom, would completely ionise it If the electron is in the 2-state, radiation shorter than $\nu = \frac{R}{2^2}$ would ionise the atom. Such a process of ionisation may be called photoelectric ionisation. This is true of every element, and in the case of alkalies it has been definitely proved that their vapours are ionised by radiation shorter than that corresponding to the limit of the principal series.

The reverse processes are:

(*a'*) Process (*a*), ionisation by collision is radiationless. The reverse process of capture when M^+ and e come together must also be radiation-less Hence when M^+ and e combine together, the energy set free must be carried away by a third body. Hence the reverse process to (*a*) is a three body encounter between M^+, e, and M (or e), the energy liberated being carried off by M. The unit mechanism (*a*), (*a'*) has been studied by R. H. Fowler in an extension of the ideas of Klein and Rosseland on the so-called collisions of the second type.

(*b'*), the reverse process to (*b*), must naturally be the capture of an electron by the ion M^+, with liberation of radiant energy. But Milne finds that (*b*) and (*b'*) together do not give the law of reaction isochore. So he postulates that electrons may be captured even under the influence of radiation. This last process is analogous to Einstein's 'Negative Einstrahlung' or stimulated emission. Thus we may write—

> Rate of photoelectric ionisation = Rate of capture with emission + Rate of capture under the influence of radiation.

Compare this with Einstein's well-known method of deducing the law of black body radiation:

> Rate of absorption of light = Rate of spontaneous emission + Rate of emission under the influence of radiation.

With the aid of certain assumptions, Milne calculates the rates of free and stimulated captures and equates it to the number of photoelectric ejections. The equation may be used in two ways. It may be employed to evaluate the degree of ionisation, in which case some further assumptions are necessary. Conversely, assuming the thermodynamic formula for ionisation, it can be used for finding out the law of probability of electron capture. In this way Milne arrives at the conclusion previously reached by Eddington in his study of opacity of stars, namely, that the electron is captured only when it actually hits the nucleus. Probably a more rational way of expressing the result would be: Only one in 10^8 collisions results in a capture.

Applied to hydrogen, calcium, and mercury, Milne's method furnishes values of absorption coefficients which are in general agreement with experimental values.

It is yet too early to predict how far Milne's method in its present form will be able to advance the theory of thermal ionisation. The great difficulty which is encountered in the development of these methods is due to the absence of any suitable quantum theory of absorption of lines. The present theories are a sort of half-hearted compromise with the old Lorentz theory which ascribes absorption to damping produced by collision."

The Sea-Urchins of New Zealand.

By H. FARQUHAR, Wellington, N.Z.

THE following notes were written some time since, but were held back until Dr. Mortensen had published his zoogeographical notes on New Zealand echinoderms (*Vidensk. Medd.*, Bd. 79, 1925). They are now given here because the subject is approached from a different point of view; namely, that of the New Zealand biological region; and also because I find myself obliged to differ from him on some points. For example, Dr. Mortensen believes that Wegener's hypothesis of continental displacement "gets support also from the study of the New Zealand Echinoderm fauna"; while I am of the opinion that the evidence of our fauna and flora at large, including the littoral, is strongly against Wegener's hypothesis as regards Australia and New Zealand; and that it mainly agrees with the evidence of the micro-Lepidoptera as stated by Mr. E. Meyrick in NATURE of May 30, 1925. The more I have learnt of the New Zealand fauna and flora in general, and particularly of several small groups, the more I have been impressed by the great fundamental differences between the faunas and floras of the two regions; and, as Meyrick says, "The amount of community shown here is then no greater than might be expected if the conditions had always been as at present," etc. When we remember, moreover, that the New Zealand land-area was greatly elevated and extended far to the north-west in early Tertiary times, and, again, to a less extent perhaps, later, we may well be surprised that the affinities are not much stronger.

Reasons for the recognition of the New Zealand area as a primary zoological region were set forth in NATURE of January 11, 1900. Objections by Mr. Wallace were given in the issue of January 18, and support by Prof. Alfred Newton and Mr. Hedley in the issue of January 25, and April 19, respectively. In a letter to me, at that time, Prof. Newton wrote, "I have no doubt that the littoral marine fauna has also an exceedingly interesting story to tell"; and as the several groups of the littoral come to be worked and revised the more distinctly and clearly does this "interesting story" become known. In the preface to his "Manual of N.Z. Mollusca," 1880, that keen and indefatigable observer, the late Capt. Hutton, said, "The better the fauna of New Zealand becomes known, the more prominently does it stand out distinct from that of any other country"; and this is now being verified by all New Zealand naturalists. What makes the history of our plants and animals especially interesting and important is that this area is a *biological* region of primary rank (Holloway, *Trans. N.Z. Inst.*, vol. 55, p. 67; Cockayne, "New Zealand Plants and their Story," etc.), for here and here only the botanical region is coterminous or almost coterminous with the zoological region; and the evidence of the botany, zoology, geology, palæontology, the physical conditions of the land, and the form of the sea-bed all harmoniously contribute to the wonderful past history and present status and character of this remarkable region.

Of course the littoral marine fauna does not speak so clearly and forcibly as the land fauna, for species of some of the groups (hydroid zoophytes, mollusks, echinoderms, etc.) have recently been widely spread by oceanic currents, but the evidence, in the main, agrees with that of the terrestrial plants and animals.

The New Zealand sea-urchins have been recently revised and the number of known forms increased by Dr. Mortensen of the Copenhagen Museum (*Vidensk. Medd.*, Bd. 73, 1921); and Dr. H. L. Clark of the Museum of Comparative Zoology has given an excellent classification of the group, based upon all the light of recent research, in his "Catalogue of the Recent Sea-urchins in the British Museum," 1925. The littoral forms are those which inhabit the area lying between high-water mark and the hundred-fathom line (the continental shelf). Large portions of this zone are entirely unknown, and many more species will by-and-by be added to our list, which at present consists of 22 forms:

1 *Goniocidaris umbraculum*, Hutton
2 *Austrocidaris benhami* (Mortensen)
3 *Cidaris sp.* (Young), Mortensen
4 *Araeosoma thetidis* (H. L. Clark)
5. *Amblypneustes ovum var pachistus*, H. L. Clark
6. *Holopneustes inflatus*, A. Agassiz
7. *Pseudechinus albocinctus* (Hutton)
8. *Pseudechinus novaezealandiae* (Mortensen)
9. *Pseudechinus huttoni*, Benham.
10. *Pseudechinus variegatus*, Mortensen.
11. *Pseudechinus grossularius* (Studer)
12 *Evechinus chloroticus* (Valenciennes)
13 *Heliocidaris tuberculata* (Lamarck)
14 *Clypeaster virescens*, Doderlein
15 *Arachnoides zelandiae*, Gray
16 *Peronella hinemoae*, Mortensen.
17 *Laganum depressum*, Agassiz?
18 *Echinocyamus polyporus*, Mortensen.
19 *Apatopygus recens* (Milne-Edwards).
20 *Brissopsis zealandiae*, Mortensen?
21. *Spatangus multispinus*, Mortensen
22. *Echinocardium cordatum* (Pennant)

The three known species of the first order of Echini (Cidaroida) appear to be endemic. *Goniocidaris umbraculum* is nearly related to the two Australian forms, *geranioides* and its variety *Kubaria*, of this small, southern, littoral genus, as now restricted. The three species belong to closely allied genera of a widespread, very ancient group, the Cidaridæ. The young Cidaris described by Dr. Mortensen may be the young of a known form, but is more likely that of an undescribed species

Of the second order (Diadematoida) there are ten known forms. The first of these, *Aræosoma thetidis*, which occurs also off the south-eastern coast of Australia, is a species of a prosperous, widespread genus, the home of which is in deeper water. The specimens were obtained from 70 fathoms, and it is evidently a migrant from the continental slope. The two forms *Amblypneustes ovum* var. *pachista* and *Holopneustes inflatus* belong to a very interesting but difficult group (the Temnopleuridæ). These two genera are wide-ranging and closely related; and both species occur freely on the eastern and southern coasts of Australia; and have doubtless come thence. The next group consists of five endemic species of the essentially New Zealand genus Pseudechinus. Only one other species is known (*P. magellanicus*) from the southern coasts of South America, the Crozet and Marion Islands. It is closely related to *P. albocinctus*; and it has no doubt drifted from New Zealand. All its stations are in the area of distribution of the seaweed *Macrocystis pyrifera*. Hawkins has noted that two species, *P. albocinctus* and *P. novæzealandiæ*, have been found in raised beaches of probably Pleistocene age. *Evechinus chloroticus* is the commonest New Zealand urchin; and the genus is monotypic and endemic. The other species of the family Strongylocentrotidæ, *Heliocidaris tuberculata*, is a warm-water form, a migrant from the north, which occurs freely on the north-eastern coast of Australia and at the Kermadecs.

Of the third and last order, the irregular urchins (Exocycloida), nine species have been found in New Zealand. *Clypeaster virescens* belongs to a large genus, widely spread in the Indo-Pacific region. The specimens were collected north of New Zealand, and it is evidently a migrant from the north. *Arachnoides zelandiæ* is an abundant, endemic, rather ancient (Pleistocene) form; and the only other living species of the genus, *A. placenta*, is widely diffused in the Indo-Pacific region. Of the two species of the Laganidæ, *Peronella hinemoæ* is endemic, and closely related to a Japanese species,[1] *P. pellucida*; and the other has been referred to *Laganum depressum*, an Indo-Pacific species, but its identity is doubtful. *Echinocyamus polyporus* seems to be a rare species of a northern genus, which has been found in Cook Strait and at the Kermadecs.

We come now to the most interesting of all the New Zealand echinoderms, *Apatopygus recens*. It occupies in the littoral much the same position as the Tuatara (*Sphenodon punctatus*) in the land fauna; being the only living representative of a group which was abundant and widely distributed in Mesozoic times. Prof. Hawkins has examined specimens, and he tells us that "the original contention that '*Nucleolites*' *recens* is a latter-day survival of the essentially Mesozoic Nucleolitoida is perfectly justified. . . . Save for its ambulacral plating *Apatopygus* would not have been out of place on a Middle Jurassic beach" (*Geol. Mag.*, 1920, vol. 57, p. 396).

Of the three Spatangoids, *Brissopsis zealandiæ* may be endemic, but its identity is doubtful. *Spatangus multispinus*, an endemic species, belongs to a widespread, northern genus; and *Echinocardium cordatum* is interesting on account of its remarkable discontinuous distribution. It occurs freely, and is widely spread in the littoral of both the northern and southern temperate zones. The only other echinoderm which has a similar distribution is the little brittle-star *Amphipholis squamata*.

The facies of the New Zealand littoral echinoid fauna is then eminently Neozealandian, with a strongly marked distinctive character.

---

[1] There is a considerable element in the New Zealand littoral marine fauna nearly related to that of Japan; and one of the extremely interesting questions to be decided by future research, is how this has come about.

Annual Meeting of the British Science Guild.

THE annual meeting of the British Science Guild was held at the Mansion House, London, on April 29 The Right Hon. Lord Askwith, president of the Guild, who opened the proceedings, moved the customary resolution that the Right Hon. the Lord Mayor of London be elected a vice-president of the Guild

Sir Richard Gregory, chairman of the executive committee of the Guild, then moved the adoption of the annual report, and directed attention to some of its salient features Reference was made to the establishment of the Norman Lockyer Lecture as an annual event. The first lecture, delivered by Sir Oliver Lodge on November 16, 1925, dealt with "The Link between Matter and Matter" It was mentioned that a supplement to the "Catalogue of British Scientific and Technical Books" (a second edition of which was published in June 1925) is in preparation. Further progress has been made, in collaboration with other bodies, with a Science Publicity Service scheme, which has now been confided to a representative committee. It is hoped to report on the cost of establishing and maintaining the service, and the prospective revenue to be derived from endowment or payment for contributions, at an early date, at a further conference of representatives of leading scientific and technical societies. A memorial was forwarded to the Board of Trade during the past year referring to the importance of scientific qualifications for a Comptroller of H.M. Patent Office. It may be permitted to hope, that this memorial, signed by many who are well known in pure and applied science, had some influence in deciding the recent appointment to this important post. Additions to the membership of the Guild have been encouraging, and useful work has been carried out by the South Australian Branch during the past year.

The resolution was seconded by Mr. F. Twyman, who alluded to important recent developments in pure science in Great Britain, and to the growing recognition of the value of applied science, as illustrated by the public interest aroused in the recent Optical Convention.

This resolution having been declared carried unanimously, Sir Richard Redmayne spoke on "The Future of the Coal Mining Industry." After pointing out the vital importance of devising a satisfactory scheme for the maintenance of this national key-industry, Sir Richard paid a tribute to the valuable summary of the position contained in the recent report of the Royal Commission. He pointed out that the depression in the coal industry is universal Germany is experiencing bad times. In the United States—which produced annually 500 million tons of soft coal (nearly twice the amount obtained in Great Britain) and where the output per man is four times what it is here—the position likewise gives ground for concern. On an average, the miner worked for only 179 days of the year during 1923 There are about 14,000 mines worked by more than 12,000 corporations or individuals.

In this depression the competition of oil-fuel is only a minor factor. It has been shown that the present methods of conducting the industry are unscientific, that selling, organisation and transport are too complex, and that many undertakings are using obsolete and inefficient machinery. Such changes as the wider use of electricity and the burning of low-temperature coke in grates can only be expected to effect partial relief. The real remedy lies in consolidation and scientific organisation of the industry, and the elimination of present wasteful methods. As an illustration of what organisation can accomplish, Sir Richard quoted the experience of the United States Steel Corporation, which by making use of the economies and possibilities of scientific method arising from consolidation, has raised the American steel industry from a position of great depression to one of great prosperity. The formation of this 'trust' has not prevented friendly rivalry between its constituents, and has led to much better relations between management and employees, who are given opportunities of taking up common stock in the concern on favourable terms.

Sir Richard therefore suggested that the solution of the problems of the coal industry lay in consolidation, involving the closing of inefficient pits and the general introduction of better organisation and more scientific methods; the industry should be controlled by an executive council, meeting daily, on which there should be workers' representatives appointed Methods of profit-sharing for the benefit of employees should be introduced, and the Government might arrange a loan, under the Trades Facilities Act, to tide over the period of reorganisation

Dr E. F Armstrong then spoke on "Dyestuffs." He recalled that the first synthetic dyestuff was an English discovery. The development of the industry in Germany was due to the fact that commercial leaders, having scientific training, encouraged the application of scientific methods and results. The War demonstrated the importance to Great Britain of maintaining an organic chemical industry. Considering the circumstances, the progress so far made in the dyestuff industry in England has been a real achievement. A highly technical industry had to be built up from the beginning To-day by far the larger portion of the hundreds of known dyestuffs are manufactured here in adequate quantity, and the standard reached is higher than that of the Continent in pre-War days. Economic difficulties have to be contended with, but substantial improvement is expected in the near future. Apart from the production of colours, described as "a miracle of applied science," manufacturers maintain a complete technical service to aid users in their application.

Capt. P. P Eckersley, who discussed "Broadcasting and the Electrical Industry," remarked that science must be applied on a scientific method. If wisely used it is of priceless benefit to mankind; if wrongly used it may prove a curse. The electrical industry presents many examples of science properly applied. British engineers combined ingenuity and solidity in their work. He agreed that we are apt to be conservative in regard to consolidation, and referred to the British broadcasting service as a shining example of the benefits of judicious amalgamation. Ninety per cent of people in the British Isles can listen to programmes with the help of inexpensive sets. The smoothness with which programmes are conducted, the manner in which an address by a public man in any part of the country can be broadcast at short notice, and the quality of the programme, are due to the consolidation of all interests in the public service. In the United States, where private interests may dominate broadcasting in some areas and disagreement between competitors may arise, the conditions are less perfect from the point of view of the public Whatever change may be made in the control of the B B.C. the fundamental methods will remain the same as at present.

A vote of thanks to the speakers, and to the Lord Mayor for the use of the Mansion House for the meeting, was proposed by Lady Lockyer and carried with acclamation Lady Lockyer mentioned that meetings had been held in the Mansion House for the last eleven years, each Lord Mayor in turn being elected a vice-president of the Guild.

University and Educational Intelligence.

CAMBRIDGE.—It is announced that Prof. E. T. Whittaker, of Edinburgh, will on May 10 deliver a lecture on "The Present State of the Theory of Light."

A change in the scheme of studies qualifying students for the Ordinary B.A. degree is proposed; by it the much-debated subsidiary subjects should be rendered more effective than at present.

The Board of Extra-Mural Studies is proposing to add to the status of the lecturers and tutors who give instruction on its behalf at various centres throughout the country The proposals recommend that such persons shall in future be appointed by grace of the Senate on the nomination of the Board, and further, that they shall come under the contributory pensions scheme for university officers. These proposals should lead to the strengthening of the position of these teachers and would be one step in the advancement of extra-mural work, an activity of the University with which the Royal Commission has shown much sympathy.

Two Robert Blair fellowships of 450*l* each are being offered by the London County Council to adult students of British nationality They will enable the holders to go abroad for a year for advanced study or research in scientific and manufacturing processes. Applications should be made to the County Hall, Westminster Bridge, London, S.E 1.

APPLICATIONS are invited by the Salters' Institute of Industrial Chemistry for a limited number of fellowships for chemists of post-graduate standing who are desirous of adopting a career in industrial chemistry. The normal value of each fellowship is from 250*l*. to 300*l*., but applications for grants of a higher value would be considered. The latest date for the receipt of applications is June 1. They should be addressed to the Director of the Institute, Salters' Hall, St. Swithin's Lane, E.C.4.

IN the University of Dacca, which was opened on July 1, 1921, the principles of a number of the recommendations made by the Calcutta University Commission of 1917–19 have been subjected to the test of practical application; with what success may be gathered from a farewell address delivered by Sir

Philip Hartog, the first Vice-Chancellor, at a meeting of the University Court last November. Chief among these principles is the residential organisation combined with a tutorial system. At Dacca three halls have been established on the lines, so far as possible, of the Oxford and Cambridge colleges, and in each of them have been started literary and debating societies, athletic societies, and social service leagues. Later a University Union was created. Whilst these halls and societies form valuable schools for character training and citizenship, the most important new element on the teaching side is the tutorial work, with the corresponding practical work supervised by the teachers in the laboratories. Much attention has been devoted to the physical welfare of students, and the executive council has decided that physical exercises ought to be compulsory for all students who are not medically unfit. There has been a notable increase in the number of Mohammedan students, from 170 out of a total of 1075 in 1921, to 353 out of a total of 1487 in 1925. The institution of the Dacca Board of Secondary and Intermediate Education, in accordance with the recommendations of the Calcutta University Commission, has not, so far, led to as much improvement as was expected. Experience has shown the need of a practical test at the intermediate examinations in science, but its introduction has been postponed *sine die*. Sir Philip Hartog remarks that the Board should be so constituted that the financial stability and progress of the educational institutions with which the members are connected would not depend on the passing of any particular number of candidates.

THE United States Commissioner of Education's report for 1924–25 concludes a tale of varied and multitudinous activities with the statement that the Commissioner travelled 43,444 miles and made 157 addresses before audiences aggregating 87,410. Specially impressive is the list of publications of the Bureau of Education, comprising, in addition to fifty-eight bulletins and the periodical *School Life*, numerous special series of leaflets relating to city schools, commercial education, health education, home economics, home education, industrial education, and other matters, library leaflets, reading courses, rural school leaflets, etc The Commissioner devotes a large share of his attention to rural education, and undertook during the year in this connexion a new type of activity, namely, co-operation on an extensive scale with selected educational organisations for the co-ordination and conduct of educational research studies. In addition, he caused a large number of special studies to be made of various aspects of the work of rural schools. His Home Education Department conducts reading courses with the co-operation of State universities or the State library commission or State normal college. The scope of the work seems to be very much on the lines of that of the National Home Reading Union in Great Britain; 1522 readers were enrolled during the year, and the number of readers who have at some time enrolled exceeds 18,500. In view of the notoriety of Tennessee's legislation on the subject of the teaching of the doctrine of evolution, it is interesting to note that a report of a survey by the Bureau's Division of Higher Education directed attention to the low proportion of the college population in that State, the inadequate financial support of the colleges, the lack of co-operation between colleges conducted under the auspices of the same Church denomination, low rates of tuition, inadequate preparation of the faculties of some institutions, and the small attendance of students from counties difficult of access

Contemporary Birthdays.

May 8, 1858.	Sir Bertram C. A. Windle, F.R.S.
May 9, 1877.	Sir James C. Irvine, F.R S.
May 13, 1854.	Dr. Marie Yves Delage.
May 13, 1857.	Sir Ronald Ross, K C.B., F.R.S.
May 13, 1851.	Sir Horace Darwin, K.B.E., F.R.S.

Sir BERTRAM WINDLE, professor of anthropology in St. Michael's College, University of Toronto, was educated at Repton and the University of Dublin Before his activities were transferred to Canada, he was professor of anatomy and anthropology in the University of Birmingham; afterwards president of University College, Cork, and whilst resident in Ireland, was much concerned with schemes of Irish education. Apart from scientific memoirs, Sir Bertram is the author of many informing books in general archæology and anthropology, including "The Romans in Britain" (1923).

Sir JAMES IRVINE was educated at Allan Glen's School, Glasgow, and the Universities of St. Andrews and Leipzic. Formerly professor of chemistry and Director of the Research Laboratory at St. Andrews, he is now Principal and Vice-Chancellor. He is an authority on the constitution and chemistry of sugars. Continuing the researches of Emil Fischer, and in collaboration with the late Prof. Purdie, he evolved new processes of investigation relating to these important natural products. Sir James was awarded the Royal Society's Davy medal last year in recognition of his work.

Dr. YVES DELAGE, professor of zoology in the Faculté des Sciences, Paris, and director of the Marine Biological Laboratory at Roscoff, was born at Avignon. He is an Officer of the Legion of Honour and a member of the Paris Academy of Sciences. Leaving teaching work at Caen (1886) he succeeded the late Prof. Milne Edwards in his professorial chair. Dr. Delage is the author of numerous monographs in experimental and general biology.

Sir RONALD ROSS, director of the Ross Institute and Hospital for Tropical Diseases, Putney Heath, received his medical training at St. Bartholomew's Hospital. Qualifying in 1881 for the Indian Medical Service, he served until 1899. It was a period fruitful in biological achievement. Following up some suggestions offered by the late Sir Patrick Manson, investigations were begun by Ross in 1895, in India, with the view of determining the life-history of the parasite of malaria (discovered by Laveran) and the transmission of infection. Ross was able to indicate the cycle of changes of the malarial organism in the tissues of a mosquito (Anopheles) which had been fed on the blood of a malarial patient. His work is the basis of modern methods for the prevention of malaria. Sir Ronald is a Nobel laureate, and a Royal medallist of the Royal Society.

Sir HORACE DARWIN may be, not inaptly, termed the apostle of methods of instrumental precision. Receiving his early training at Messrs. Eastons and Anderson, Erith, Kent, he graduated at Trinity College, Cambridge. He is chairman of the Cambridge Scientific Instrument Company, Ltd. Sir Horace gave the first Wilbur Wright Memorial Lecture before the Aeronautical Society in 1913 on "Scientific Instruments: their Design and Use in Aeronautics." It was prefaced by some interesting considerations respecting birds, the flight of insects, and 'winged plants.' Sir Horace was a member (1915 onwards) of the Munitions Inventions Panel.

Societies and Academies.

LONDON.

Royal Society, April 29.—C. H. **Best**, H. H **Dale**, J. P. **Hoet**, and H. P. **Marks**: Oxidation and storage of glucose under the action of insulin. Under the same conditions as those of the following investigation, the total quantity of glucose disappearing from the system under insulin is always equal to the sum of the equivalents of the glycogen deposited and of the oxygen absorbed. The conclusion is drawn that all the glucose disappearing under the action of insulin is either oxidised or deposited as glycogen. The fact that, in the normal animal treated with a fatal dose, the end result is often a disappearance of pre-existent glycogen, with concurrent fall of respiratory metabolism, is attributed to the other action of insulin, in depressing the new formation of carbohydrate in the liver. It is accordingly suggested that insulin in excessive doses produces the same effects as in physiological doses, but with abnormal intensity.—C. H. **Best**, J. P. **Hoet**, and H. P **Marks**: The fate of the sugar disappearing under the action of insulin. When the blood sugar of the eviscerated spinal preparation is kept at a high level for from two to five hours, by the intravenous administration of dextrose, there is no demonstrable change in the glycogen content of the skeletal muscles When a hyperglycæmia is maintained and insulin is administered, no significant part of the sugar which disappears is stored as a phosphate ester in the skeletal muscles. Under these latter conditions, however, there is an increase of glycogen in the muscles sufficient to account for from 40 to 50 per cent. of all the sugar which disappears. When the rate of sugar infusion is so slow that the blood sugar reaches a very low level under the action of insulin, the muscle glycogen is not depleted to form some unknown substance. When sufficient sugar has been available there is a recognisable increase in glycogen. Similar results are obtained when the spinal preparation has not been eviscerated. Hypoglycæmic convulsions, which are eliminated in the spinal preparation, produce a great depletion of the glycogen content of the skeletal muscles.—J. P. **Hoet** and H P. **Marks**: Observations on the onset of rigor mortis. The precipitate rigor mortis observed in rabbits dying after hypoglycæmic convulsions, or after prolonged thyroid feeding, is not due to the accumulation of the lactic acid, nor to increased acidity of the muscle The absence of glycogen and the decrease in lactacidogen of the muscle are the determining factors of this rigor. These facts must be taken into account in discussing rigor mortis and also muscular contraction —J C. **Mottram**, G M. **Scott**, and S. **Russ**: On the effects of β-rays from radium upon division and growth of cancer cells. Tumours growing in rats were exposed to measured doses of β-rays from radium. After various intervals, small pieces of the tumours were removed and counts made of the number of cells in a state of division. Immediately after a dose of radiation large enough to prevent growth of the cells *in vivo*, many cells were found in a state of division, but very soon the cells in mitosis disappeared. When irradiated tumours were left in the rats for some days after the irradiation, there was some return of cells in division, even after very large doses. The variation in the results with the interval between irradiation and examination is intimately bound up with the varying susceptibility of the cells at different stages in their growth.

DUBLIN.

Royal Irish Academy, April 12.—J. J **Nolan**: The breaking of water-drops by electric fields. Falling drops were exposed to a transverse electric field It was found that explosive bursting of the drops occurred at critical values of the field, the relation between the field and the radius of the drop being $F\sqrt{r} = \text{const.}$ This is in agreement with the observations of C T. R. Wilson and G. I. Taylor on soap-bubbles. Drops greater than 0·2 cm. radius showed a type of disintegration for lower values of the electric field than those required to produce explosive bursting. Attempts to determine the ballo-electric charge developed by the bursting of the drops were unsuccessful.

PARIS.

Academy of Sciences, April 7.—Georges **Claude**: The present state of ammonia synthesis utilising coke-oven gas. Reasons are given for the use of the hydrogen from coke-oven gas in the synthetical preparation of ammonia. Photographs are given of the works at Waziers and at Ougree. The preliminary difficulties have been to a great extent overcome, and works using the Claude process in the last quarter of 1925 produced 10,000 tons of sulphate of ammonia or its equivalent.—C. **Camichel**, L. **Escande**, and M. **Ricaud**: Viscosity and turbulence.—Max **Morand**: The luminous phenomena observed in a lithium positive-ray tube.—J **Cabannes** and J. **Granier**: The depolarisation of light diffused by some organic substances —G **Bruhat**: An apparatus for the precise determination of the orientation of a rectilinear vibration in the ultra-violet.—A. **Cotton**: Remarks on the preceding communication.—S. **Schlivitch**: Photovoltaic batteries with unalterable electrodes.—Ch. **Courtot** and C. **Pomonis**: Study in the diphenylene sulphide series. Details are given of a method of nitrating diphenylene sulphide and of the reduction of the nitro product to aminodiphenylene sulphide.—J. Roger **d'Ansan**: Remarks relating to the application of ocular gymnastics to the treatment of myopia and amblyopia.

CALCUTTA.

Asiatic Society of Bengal, April 5.—C. de Beauvoir **Stocks**: Folk-lore and customs of the Lap-chas of Sikhim. A translated collection of Lap-cha myths and fairy-tales, supplying an analysis of the ancient religion The customs and superstitions of the different aspects of Lap-cha life and industries show they are connected with the traditions of a pre-Buddhist faith —S. L. **Hora**: A short note on the distribution and habits of *Balwantia Soleniformis* (Benson). This bivalve lives in burrows excavated either in hard blue clay or in friable sandstone. The species is common in the Daleswary and the Barak rivers in Cachar. It lives in a burrow firmly anchored by its foot at the anterior end, and is enabled to enlarge it by a movement caused by the expansion and contraction of the foot. The Uriya coolies consider the animals of this species as a great delicacy and have devised an instrument for dislodging them from their burrows —J. H **Hutton**: Diaries of two tours in the unadministered area east of the Naga Hills. Notes of a tour made by Mr J. P. Mills and the author in 1923 to a part of the Naga Hills which, so far as known, has never been visited by any European except by Lt. (afterwards General) Woodthorpe in 1876 —D. N. **Majumdar**: Marriage and betrothal amongst the Hos of Kolhan.—W **Ivanow**: Rustic poetry in the dialect of Khorasan. The grammatical peculiarities of the Persian dialect spoken in the province of Khorasan are discussed, together with a large collection of rustic songs from the district of Sabzawar.—Hem Chandra **Das-Gupta**. A few types of sedentary games prevalent in the Punjab. Description of six games played with pieces on diagrams inscribed on rock-slabs or improvised on other material: (1) Dō-guti (two gutis or pieces); (2) Tre-guti (three pieces); Naō-guti (nine pieces), (4) Sher-bakar (tiger and goats); (5) Ratti-chitti-bakri (red-white goats); (6) Khutkā boiā (dug circles). The first two have, as far as known, nothing similar in other parts of India; the third has parallels in Bengal; the fourth in Bengal and Orissa; the fifth in Sumatra; the sixth in Assam, Orissa and Madras.

ROME.

Pontificia Accademia delle Scienze (Nuovi Lincei), March 21.—**Teofilato**: Some questions of ballistics.—**Martinelli**: The annual (for 1926) of the prediction office of the Ministry of Aeronautics, containing numerous notices referring to tides, terrestrial magnetism, atmospheric pressure, etc.—**Scatizzi**: The polar and essential singularities of a summable derivative with variable index.—**Neviani**: The fossil hippopotamus of the Roman Campagna: notes on new discoveries, and bibliography.—**Gianfranceschi**. Certain considerations on the numerical results obtainable with the author's formula for the distribution of energy in the black body spectrum.—Ludovici **Marini**: Climatic notes on Corfu.

Royal Academy of the Lincei, March 7.—G. A. **Crocco**: Possibility of super-aviation. The possibility of extra-atmospheric navigation is considered, and it is shown that if the weight supported is constant the power necessary for horizontal flight is proportional to the velocity, but independent of the altitude, of the flight. Further, for a given initial weight and a constant specific consumption, the amount of fuel necessary to cover a definite distance in horizontal flight is independent of both the altitude and the velocity.—R. **Nasini**: The volatility of orthoboric acid in steam. The recent denial by Anschutz and Riepenkröger that orthoboric acid is volatile in water vapour disagrees with the results of other investigators. This acid may be distilled in steam at reduced pressure if the temperature does not fall below 60°; at higher temperatures it volatilises even at the ordinary pressure. O. M. **Corbino**: The electronic theory of thermo-magnetic phenomena. The Lorentz and Gans theory, when applied to the case of a disc traversed by a centrifugal radial current of heat or electricity, predicts the formation of a circular thermo-magnetic or galvano-magnetic current of the same sense as the current producing the magnetic field. This result is, however, contrary to the truth for both currents with all metals (including bismuth) with the exception of gold, silver and copper. The theory of Livens would permit of the elimination of the contradiction in some instances, but the law of distribution of velocity on which it is founded is not in accord with the laws of electromagnetism.—S. **Franchi**: Gradual change to crystalline calc-schist and marble forms of the fossiliferous Nummulitic and Cretaceous in the Val del Gesso and the Val della Stura di Cuneo.—A. **Russo**: Mixed individuals and gametogens, neutral individuals, and pre-conjugants in the biological cycle of the ciliates, in relation to those of the metazoa.—Vasco **Ronchi**: Recent theories of flying shadows. This phenomenon is explained in the most natural and exhaustive manner by the illumination of the non-homogenous atmospheric stratum by the highly brilliant solar crescent.—A. **Rosenblatt**: Regularisation of the problem of three bodies.—A. **Ferrari**: Comparison between the diameters of the ions of one and the same element, but with different charges. The diameters of quadrivalent manganese and lead ions are respectively 2·50 and 3·10 Å.U., whereas those of the corresponding bivalent ions are 2·95 Å.U. and 3·80 Å.U.—B. **Monterosso**: Structure of *Peroderma cylindricum*, Heller.—Alberto **Chiarugi**. Phenomena of apospory and apogamy in *Artemisia nitida*, Bertol.—Umberto **D'Ancona**: Contribution to the histophysiology of striated muscle fibre.

VIENNA.

Academy of Sciences, March 18.—W. **Dorn**: Fourier's integrals considered as limiting cases of Fourier's series.—O. **Abel**: Morphological investigations on the styloid bones of horses.—M. **Belar**: Communication from the Radium Institute, No. 186. On the coloration of rock-salt by Becquerel rays.—K. **Przibram**: On the theory of the coloration of rock-salt by Becquerel rays.—E. **Flatt**: Regeneration of the long bones after partial removal in the interior of the extremities of the newt (*Triton cristatus*).—M. **Kohn** and G. **Dömötör**: The behaviour of the penta-halogen-phenols to aluminium chloride in the presence of benzole (Communication No. 20 on bromo-phenoles).

Diary of Societies.

SATURDAY, May 8.

Royal Society of Medicine (Otology Section) (Annual General Meeting), at 10.30 A.M.—L. Colledge: Mosher's Method of Skin Grafting.
Royal Institution of Great Britain, at 3.—Dr. P. C. Buck: The Song Form in England as represented by Parry.
Royal Society of Medicine (Balneology and Climatology Section) (at Llandrindod Wells).

SUNDAY, May 9.

Royal Society of Medicine (Balneology and Climatology Section) (at Llandrindod Wells).

MONDAY, May 10.

Royal Irish Academy (Dublin), at 4.15.
Biochemical Society (in Physiological Laboratory, St. Bartholomew's Medical College), at 4.30.—Dr. C. Dorée and E. C. Barton-Wright: A Note on the Stone-cells of the Pear.—Margaret H. O'Dwyer: On the Nature of the Hemicelluloses.—H. D. Carey: The Oxides and Oxyacids of Phosphorus by a New Method of Graphic Formulæ.—Prof. C. Lovatt Evans: Conditions affecting the Formation of Lactic Acid in Plain Muscle.—L. F. Hewitt: The Optical Rotatory Power and Dispersion of Proteins.—G. W. Ellis: A Theory on the Nature of the Absorption of Oxygen by Unsaturated Compounds.—H. P. Marks: The Determination of Small Amounts of Lactic Acid.—R. L. Mackenzie Wallis: The Corpus Luteum and Cholesterol Metabolism.—D. T. Davies, F. Dickens, and E. C. Dodds: Observations on the Properties and Preparation of the Para-thyroid Hormone (Collip).—J. G. Davis, W. K. Slater, and V. Smith: A Thermal Study of a Suggested Anaerobic Mechanism.—H. A. Abramson, P. Eggleton, and M. G. Palmer: The Fate of Sodium Lactate injected intravenously.
Royal Society of Edinburgh, at 4.30.—Principal A. P. Laurie: Modern Research on the Methods of Painting Oil Pictures as illustrated by the Technique of the Fifteenth Century.
Victoria Institute (at Central Buildings, Westminster), at 4.30.—Dr. A. T. Schofield: Religion and Science.
British Psychological Society (at London Day Training College), at 6.—F. C. Bartlett: Sublimation.
Surveyors' Institution, at 8.—Discussion on paper by Sir John Oakley on The Trustee Act, the University Act, the Land Charges Act, the Administration of Estates Act, and the Land Registration Act (concluded).—Discussion on paper by C. H. Bedells on The Settled Land Act, 1925.
Medical Society of London, at 8.—General Meeting.—At 9.—Sir Berkeley Moynihan: Annual Oration.
Royal Geographical Society (at Æolian Hall), at 8.30.—Earl Cawdor: The People of the Tsangpo Gorge.

TUESDAY, May 11.

Manchester Geological and Mining Society, at 4.
Royal Institution of Great Britain, at 5.15.—Dr. G. W. C. Kaye: The Acoustics of Public Buildings (Tyndall Lectures) (1).
Zoological Society of London, at 5.30.—C. A. Merritt Hawkes: On the Massing of the Ladybird, *Hippodamia convergens* (Coleoptera), in the Yosemite Valley.—Dr. H. H. Scott: A Mycotic Disease of Batrachians.—A. S. Le Souef: On the Habits of the Order Marsupialia.—Prof. R. T. Leiper: (a) Some Parasites of Rats in the Zoological Society's Gardens, (b) The Starling as a Factor in the Spread of Gapeworm Disease in Chickens.
Institute of Physics (at Royal College of Science), at 5.30.—H. E. Wimperis: The Relationship of Physics to Aeronautical Research (Lecture).
Institute of Marine Engineers, at 6.30.
Quekett Microscopical Club, at 7.30.—E. Heron-Allen and A. Earland: Selective Building in the Shells of the Foraminifera.

WEDNESDAY, May 12.

Royal Society of Medicine (Surgery: Sub-section of Proctology) (Annual General Meeting), at 4.30.—Prof. J. Fraser, S. Seton Pringle, G. Turner, E. Miles, and Mr. Lockhart-Mummery: Discussion on The Value of the Closed Methods in Resection of the Colon.
Radio Society of Great Britain (at Institution of Electrical Engineers), at 6.—Informal Meeting.
Royal Society of Arts, at 8.—W. S. Bradley: Industrial Welfare in Practice.
Eugenics Education Society (at Royal Society), at 8.30.—W. T. J. Gun: Some Aspects of Hereditary Ability.

THURSDAY, May 13.

Faraday Society (at Institution of Mechanical Engineers) (Discussion on Explosive Reactions in Gaseous Media), at 2.30 and 5.—Part I. Explosive Reactions Considered Generally.—Dr. W. E. Garner: Introductory Survey.—Prof. H. B. Dixon, J. Harwood, and W. F. Higgins: On the Ignition Point of Gases.—Prof. W. T. David: Radiation in Gaseous Explosions.—Dr. S. W. Saunders and Dr. W. E. Garner: Ionisation in Gas Explosions.—Dr. S. C. Lind: Ionisation and Gas Explosions.—Prof. R. V. Wheeler and Dr. W. Payman: The Uniform Movement of Flame.—Prof. W. A. Bone: Explosions at High Pressure.—Dr. Colin Campbell and Prof. H. B. Dixon: Explosion Wave in Cyanogen Mixtures.—At 7.45.—Part II. Explosive Reactions Considered in Reference to Internal Combustion Engines:—Sir Dugald Clerk: Introductory Survey.—Prof. W. T. David: Combustion in Gas Engines.—H. T. Tizard: Explosions in Petrol Engines.
Royal Society, at 4.30.—Sir Arthur Schuster: A Review of Mr. George W. Walker's Magnetic Survey (1915).—Dr. A. E. H. Tutton: The Alkali Perchlorates and a New Principle concerning the Measurement of Space-Lattice Cells.—Prof. G. I. Taylor and W. S. Farren: The Distortion of Crystals of Aluminium under Compression. Part I.—Dr. E. V. Appleton, R. A. Watson Watt, and J. F. Herd: On the Nature of Atmospherics.—T. T. H. Verschoyle: Isotherms of Hydrogen, of Nitrogen, and of Hydrogen-Nitrogen Mixtures, at 0° and 20° C. up to a Pressure of 200 Atmospheres.—*To be read in title only*:—Prof. C. H. Lees: On the Determination of the Specific Heats of Gases at Constant Pressure and at Constant Volume and their Ratio by Adiabatic Expansion.—T. G. Room: A General Configuration in Space of any Number of Dimensions analogous to the Double-Six of Lines in Ordinary Space.—C. N. Hinshelwood and W. K. Hutchison: A Comparison between Unimolecular and Bimolecular Gaseous Reactions. The Thermal Decomposition of Gaseous Acetaldehyde.—P. A. M. Dirac: (a) The Elimination of the Nodes in Quantum Mechanics; (b) Relativity Quantum Mechanics with an Application to Compton Scattering.
London Mathematical Society (at Royal Astronomical Society), at 5.
Royal Society of Medicine (Neurology Section), at 5.—Annual General Meeting.
Institute of Pathology and Research (St. Mary's Hospital, W.2), at 5.—Dr. L. Colebrook: The Chemo-Therapy of Bacterial Infections (Lecture).
Royal Institution of Great Britain, at 5.15.—Sir William Bragg: The Imperfect Crystallisation of Common Things (3).
Optical Society (at Imperial College of Science), at 7.30.—B. Graves: Microscopy of the Living Eye.—Dr. L. C. Martin: The Distribution of Light in Elementary Optical Images.
Oil and Colour Chemists' Association.

FRIDAY, May 14.

Institution of Municipal and County Engineers (North-Western District) (at Blackburn), at 10.45 A.M.
Royal Astronomical Society, at 5.
Physical Society of London (at Imperial College of Science), at 5.—L. Hartshorn: The Properties of Mutual Inductance Standards at Telephonic Frequencies.—Prof. A. L. Narayan and K. R. Rao: A Note on $\lambda 4722$ of Bismuth and the Nature of '*raies ultimes*.'—M. C. Johnson: The Distribution of Intensity in a Positive Ray Spectral Line.—Dr. E. E. Fournier d'Albe: Demonstration.
Malacological Society of London (at Linnean Society), at 6.
Junior Institution of Engineers, at 7.30.—Leslie Smith: Notes on Static Transformer Testing and Test Plant Requirements.
Railway Club (at 65 Belgrave Road, S.W.), at 7.30.—B. M. Bazley: Some Observations on Modern Locomotive Practice.
Royal Institution of Great Britain, at 9.—Seton Gordon: The Golden Eagle and its Neighbours.

SATURDAY, May 15.

Royal Institution of Great Britain, at 3.—Dr. G. C. Simpson: Atmospheric Electricity (1).

PUBLIC LECTURES.

MONDAY, May 10.

Gresham College (Basinghall Street, E.C.), at 6.—W. H. Wagstaff: Geometry. (Succeeding Lectures on May 11, 12, and 14.)

THURSDAY, May 13.

University College, at 2.30.—Sir Flinders Petrie: Recent Discoveries in Egypt.

CONGRESSES.

May 13 to 15.

Institute of Transport (at Birmingham).

May 22 to June 2.

Italian National Congress of Pure and Applied Chemistry (at Palermo).

May 24, etc.

International Geological Congress (at Madrid).

May 24 to 29.

International Ornithological Congress (at Copenhagen).

May 25.

International Society for the Protection of Childhood (at Rome).

SATURDAY, MAY 15, 1926.

Science in Industry.

THE British Science Guild, the annual meeting of which was held on April 29, occupies a peculiar position among kindred societies. We have societies concerned with the promotion of science in general—notably the Royal Society—and of particular sciences such as chemistry, physics, geology, botany and zoology, and their numerous progeny—physical chemistry, biochemistry, and the rest. There are other societies—the Society of Chemical Industry is a good example—which devote themselves to the application of particular sciences to industry. The British Science Guild, founded by Sir Norman Lockyer in 1905 "to promote the application of scientific methods and results to social problems and public affairs," is not a scientific society, nor an institute of industry, nor an educational association. It is a national organisation, the chief purpose of which is to reconcile the interests of science industry, and education, and to co-ordinate their activities. Sir William Bragg, in a recent broadcast talk explaining the work of the Guild, said: "In originality of scientific work, mechanical ingenuity and operative skill, our race is in the forefront." This claim will be confirmed by the most cursory inspection of our national roll of men of science and invention. But there is something lacking, he suggests, and that is "a spirit of unity among all classes through the alliance of science, invention and labour working as a single force for national development and common welfare." To this "spirit of unity" the nation, beset by its war-heritage of financial and industrial problems, will have to pay increasing homage if it is to maintain its leading position, achieved in large measure through its "scientific work, mechanical ingenuity, and operative skill."

The traditional rôle of the British man of science is to discover fundamental scientific principles and to regard their application as a matter of subsidiary interest. Huxley, in his essay on the "Progress of Science," says that the history of physical science teaches that the practical advantages it offers never have been and never will be sufficiently attractive to men inspired by the inborn genius of the interpreter of Nature to give them courage to undergo the toils and make the sacrifices which that calling requires from its votaries. Their real stimulus comes from the joy of discovering the causes of things—from "the supreme delight of extending the realm of law and order ever farther towards the unattainable goals of the infinitely great and the infinitely small between which our little race is run." He refers to the practical applications of science as the "flotsam and jetsam of the tide of investigation" destined to be turned into the wages of workmen and the wealth of capitalists while the wave of scientific investigation advances proudly over the ocean of the unknown.

If Huxley adopted an exalted view of the value of pure scientific investigation, he recognised that the interests of science and industry are identical. There is happily an increasing recognition of the need for "the alliance of science, invention and labour" for which Sir William Bragg pleads, a need often illustrated by our scientific and industrial history. The classical example of the traditional rôle of the British man of science is provided by the history of the aniline dye industry, based on Sir William Perkins's discoveries. It is of interest to recall that when Perkins discovered, in 1856, the first aniline dye, 'mauvine,' he was working on the constitution of quinine. Diverse explanations have been offered of our failure to establish a great industry at an early stage on the basis of these discoveries. It has been said, for example, that after the death of the Prince Consort, Hofmann abandoned his professorship at the Royal College of Chemistry and returned to Berlin, taking with him a band of workers who possessed the expert knowledge of the aniline dyes. The late King Edward VII.'s great interest in the technological developments at South Kensington was due—so he assured Lord Haldane—to the fact that this work would have been accomplished by his father, the Prince Consort, but for his premature death. Others have suggested that the fate of the aniline dye industry in Great Britain was sealed by the control which English chemists exercised through their patents, by which so much money was made that they ceased to care whether the industry developed further.

Whatever may have been the cause, the dyestuffs industry in Great Britain was neglected, and the Germans took it up and by skill and patience developed the industry on a scale of which we are, alas, too often reminded. How much effort and money—both private and public—have been expended to recover the lost ground and what serious risks we have run in the meantime, even as regards our national security? Dr. E. F. Armstrong, in the course of his address at the annual meeting of the British Science Guild, while admitting that the fight is not yet won, was able to express optimism as to the future. He stressed the need for the application of scientific method to technical success, adding, however, that "it is more than ever true that without commercial prudence and ability, complete success is unlikely." The harvest of research ripens slowly, but the industry is finding its faith in research justified. At the present time the dyestuff industry in Great Britain is protected not by a tariff, but by absolute prohibition of the import of dyes and intermediates, except under licence, and it is satisfactory to learn that few licences are granted on the grounds of quality or price.

The original dyestuff industry in Germany, as Dr. Armstrong reminded his audience, grew into a synthetic organic chemical industry manufacturing drugs and many other synthetic products of everyday use. In addition, the industry became "a potential arsenal for chemical warfare." The improvisations made by Britain during the War involved mistakes which were paid for in human life and treasure, "but right well was the work done by our chemists; and the country can never repay, nor should she ever be allowed to forget, the debt she owes to them." Their work is being continued, and the dyestuff industry in Britain has made progress which, all things considered, is regarded as a real achievement by those in a position to judge.

The artificial silk industry occupies a brighter page in the scientific and industrial history of Great Britain. The silk thread is and has always been a manufactured article, not a natural product, whether the agent be a silkworm or a chemical worker. So long ago as the early years of the eighteenth century, Réaumur realised that what a worm could do, civilised man might also hope to accomplish. M. Bon at about this time produced gloves and stockings from a yarn formed from the web of the familiar domestic spider. The inventor and pioneer of the artificial silk industry, Hilaire de Chardonnet, deliberately applied his chemical knowledge to this problem. He succeeded in transforming cellulose into a soluble colloidal form, which he converted into a thread, and on the basis of this discovery he founded a factory in his native town, Besançon, and established a successful industry. Other processes followed, such as the Lehner process, established in Switzerland.

Of special interest to British chemists is the viscose reaction and process, by which cellulose in the form of wood-pulp is synthetically converted in two stages into the water-soluble sulphocarbonic hydrate ester. This process, discovered in 1892, was an incident in a sustained study of alkali-cellulose and the mercerising process conducted by Cross and Bevan from the year 1880. At the appropriate moment, the inventor gave invaluable assistance in the industrial application of the discovery. The industry is greatly indebted to the invention by C. Topham of the centrifugal spinning box known as the 'Topham box.' Finally, the necessary capital and enterprise were forthcoming for commercial exploitation. Messrs. Cortaulds took over the viscose experimental plant at the Kew works of the Zürich Lamp Company in 1904, and established new works at Coventry in the following year. But it was not until

1907 that the process was sufficiently advanced for industrial application on a large scale.

Another process for artificial silk production—the product is now known as 'celanese'—is based on cellulose acetate, the familiar aeroplane dope of the War, manufactured by the process of H. Dreyfus. In this case a great War industry was turned to a peaceful application. Many other processes for the production of artificial silk have been devised both in Great Britain and on the Continent. The exploitation of cellulose in its various forms has indeed attracted intensive and sustained study throughout the world. It is gratifying, especially to those who remember the chequered history of the aniline dye industry in Britain, that the viscose process, a triumph of British science and industry, has now acquired such an assured position.

Both men of science and men of affairs should read, mark and digest those contrasted histories. Their moral is fairly obvious. We have outgrown and outlived the Victorian age with its smug complacency, its narrow political creeds, its devouring animosities. To create a new world from these smouldering embers, we must recapture the Elizabethan spirit of adventure and combine with it "a spirit of unity among all classes through the alliance of science, invention and labour working as a single force for national development and human welfare."

T. LL. H.

Carbon and Silicon: the two Foundation Stones of the World.

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. By Dr. J. W. Mellor. Vol. 6. C. (Part II). Si. Silicates. Pp. x+1024. (London: Longmans, Green and Co., 1925.) 63*s.* net.

DR. MELLOR tells us that the proverb 'diamond cut diamond' is of Hindu origin and that, "consonant with their mystic temperament and glowing imagination, the Hindus consecrated the diamond to their chief gods and attributed to it sovereign virtues."

Our temperament is such, that though mystics may prosper among us, we seem to have no imagination. If we had the least, we should worship diamond as the basis of life and every chemist would proudly display the gem as his sign of office. Every chemist, too, would marvel greatly at the properties of silicon and would seek to contrast them with those of carbon—one the symbol and substance of mobility and life, the other almost that of fixity and death. As it is, the physical chemist learns nothing of the chemistry of carbon and of life and less of that of silicon and silicates, the organic chemist nothing of silicates, though these pave the earth. Silica we can show but sadly, shut up in secrecy—yet we make gems of it and so honour it in silence.

This is the sixth volume of Dr. Mellor's stupendous treatise. Carbon and silicon, chiefly the latter, are the subject matter. It is impossible to do justice to the greatness of his work—to rate it at its proper value, to appreciate the truly scientific spirit in which, throughout the years, he has wrought for us, the excessive modesty of his presentation, his wondrous talent as a compiler, his almost uncanny faculty of unearthing information, his power of curt expression and concise statement, his logical, unbiassed attitude. That one man should accomplish so much is more than remarkable. Knowing him and having had the privilege of admission within his sanctuary, I have some understanding of his method and temperamental peculiarities, including his match-devouring capacity and his phlegm: but all may read his character in his work, if they will. What is not known is the wonderful manner in which the ways of his life are made smooth by the care of a devoted wife. Little as he is seen in the world, all who know him are his admirers and friends. He is not only the bibliophile and dictionary maker but himself a scientific worker and has long been scientific leader of the pottery industry. How entirely our Royal Society system fails in recognising scientific worth, how partial it is in its judgments, is shown by the fact that the Society, to our great loss, does not yet number him among its fellows.

Dr. Mellor's books are not for babes but every one who aspires to be rated a full-grown chemist should possess them and ponder their every page, scarce one of which does not offer many problems. They are costly but worth whatever sacrifice their purchase may entail. We may hope that when teaching is made rational and the farce is no longer perpetrated of calling upon students merely to memorise and reproduce, the existence of books such as Mellor's will be recognised and they will be treated as living instruments. Then, proof of power to read, interpret and *use* them, whenever occasion arise, will be asked for, instead of the parrot-like memorised acquaintance with the text-book now forced upon students.

The real value of the treatise lies in the demand its statements make upon the intelligence—the aid they afford as a key to the literature. Any one who has learnt to use it will have learnt to read: to ask himself what can be the meaning of the numerous, often diverse and irreconcilable statements that are on record. Indeed, the book is only to be read with full profit if it be read always in a critical comparative spirit. The author's attitude is nearly always non-committal: "Here are the statements for which you have paid me three guineas a volume, now take your choice." He never adopts the clerical (? neo-chemical), dogmatic attitude: perhaps he too rarely sums up or makes statements of odds. It is this quality, however, that gives all his writings their peculiar value and charm.

It is impossible to turn over the pages of such a book without being constantly reminded how incomplete and unreasoned is our knowledge. Take the question of the forms of carbon—"are graphite and the various 'chars' distinct forms of carbon, different from diamond?" It is clear, from X-ray analysis, that the carbon in graphite and in 'chars' is, at least in part, different from the carbon in diamond. The structure of the diamond, as determined by Sir William Bragg, is that we should expect on general chemical grounds. It may be regarded as a close-packed assemblage of regular tetrahedra. If we dissect out of a layer, a 'string' of the atoms and fully clothe these with hydrogen, we obtain a paraffin hydrocarbon—a linear assemblage in which lines drawn between the centres of contiguous carbon atoms meet at the tetrahedral angle. If, instead, we dissect out a hexagonal block of six carbon atoms and surround the system with only six hydrogen atoms, we get benzene. Graphite is clearly benzenoid and so are the chars, even the ground substance of coal: still, proof has yet to be given that pure graphite is carbon and carbon only. Sir Charles Parsons has been led to the conclusion, that no valid proof has yet been given that diamond can be produced from 'black carbon' nor indeed from any carbon compound. The heat of combustion of graphite is stated to be so near to that of diamond that a close equilibrium between the two forms is to be expected—if, indeed, they be allotropes. However complex, a purely benzenoid structure would scarcely involve blackness—this is rather to be regarded as proof of the presence of ethenoid carbon in addition to benzenoid. The writer has long inclined to the view that there is but one carbon—the diamond form—and that graphite and the black chars are hydrocarbons in which, may be, only a minute proportion of hydrogen atoms is present, yet sufficient to prevent the system lapsing into diamond.

Examination of the statements brought together by Dr. Mellor with reference to a second form of silicon but lends support to this view—in this case also there is no clear 'proof' of the existence of more than one form of the element.

It is surprising how little attention has been paid to silicon. Carborundum, which is next the diamond in hardness, also has received far too little notice. A colourless, crystalline compound, half carbon, half silicon, a product of the electric furnace, it has revolutionised the practice of machining steel work and almost made the file unnecessary but the chemist has paid it scant attention. What exactly is its structure? X-ray analysis has at least given the interesting result, that the distance apart of the atomic centres is considerably greater than that of the carbon atoms in diamond. A strict comparison is needed of the diamond with silicon and the intermediate carborundum. These fundamental problems, strangely enough, receive but indifferent attention, yet they are of surpassing interest.

Again, though it fashions the world and we are made from it, we pay no heed to carbonic acid—it's such a little one in acidity. Mellor gravely puts K_1 as 23,000 times K_2, according to some great authority's calculation, then quietly writes the formula $\begin{matrix}HO\\HO\end{matrix}\!\!>\!C:O$. Reading between the lines, it is easy to see that we simply do not know what the acid is. It is not bibasic, if the evidence have any force that Worley and I have adduced, indicating that sulphuric acid is unibasic. Still, in all our student's bibles *it is written* that it is—who shall say that our science is not a religion, based upon faith, not fact; who, that we do not need a sense of humour to grasp its contradictions and more imagination to guess its riddles.

Nothing is more striking, in turning over Dr. Mellor's volumes, than the evidence they afford of our casual and unregulated methods of attack: creatures o impulse and opportunity, particularly of fashion, as we are, 'science' thus far has done little to put its big house in order. Thus, a vast amount of work has been done upon the heat of combustion of carbon compounds; yet the fundamental constant, the heat of combustion of carbon proper, in its several forms, has never been subjected to experimental criticism. The values on record are clearly open to question and the discrepancies are not slight. Such an inquiry would obviously be laborious and difficult: the vaunted 'research habit' that is now coming upon us is one which tends rathe to the cultivation of the armchair problem and high-frequency advertisement.

The importance of the volume before us is to b found in the display it makes of the silicate maz Never before has so vast a body of information upo the subject of silica and its combinations been lai bare for inspection but how disconcerting is th picture. Take statements such as the following:

> "The molecular theory of organic chemistry finds n application in the chemistry of the silicates. . . Although the existence of definite radicles is bein recognised, yet the condition of this branch of chemistr is very like that of organic chemistry before Avogadro' hypothesis had been adopted as a guide. Suc molecular formulæ as we have are, at present, o doubtful validity. After all has been said, the con stitution of the silicates is not much in advance o A. Laurent's time, when he could say in his 'Memoi sur les silicates':
>
> "'We have a silicate that contains $Si_{13}O_{31}Mg_{21}Al_4H_2$ and we discuss seriously whether the atoms hav

the arrangement $(11SiO_2 . 21MgO)$ $2(SiO_2 . Al_2O_3)$ 15Aq; or $7(SiO_2 . 3MgO)$ $2(3SiO_2 . Al_2O_3)$ 15Aq; or $7(SiO_2 . 3MgO . 2H_2O)$ $2(3SiO_2 . Al_2O_3)$ Aq; or a hundred other similar formulæ. What is there to prove that the silica is distributed into three principal groups; that the magnesia forms two distinct combinations; that the water occupies two different places? Does this salt by its reactions split into magnesian silicate on the one hand and an alumino-magnesian silicate on the other? I have often read the discussions that have taken place on this subject and I avow that I have never found anything but what was arbitrary or according to routine; what I saw most clearly was that, in general, the greatest regard was paid to authority. . . . We should arrive at results quite as satisfactorily by putting the atomic letters of a formula into an urn and then taking them out, haphazard, to form dualistic groups.' "

Is it right, however, to say that the molecular theory of organic chemistry finds no application in the chemistry of the silicates? The peculiarity of the silicon atom seems to be its great love for oxygen combined with an astounding platonic readiness to share its love with a neighbouring atom of its own kind. I am tempted to think of quartz as built like paraffin-wax, oxygen taking the place of hydrogen, each pair of atoms being shared by two silicon atoms. Just as CH_2 is the ultimate unit in the one, so $Si{}^{O}_{O}$ may be the ultimate unit in the other. We may picture the oxygen atoms climbing, as it were, like monkeys, spirally, up a pole of silicon atoms joined in zig-zags, just as are carbon atoms in stearic acid.

The high-temperature, optically inert form of silica, crystobalite, may conceivably be an ethenoid form of silica more akin to carbon dioxide. The X-ray workers would have us regard the silicon atoms as unpaired and linked by oxygen, each as in touch with four oxygen atoms. If so, we must think of silica in terms of oxygen rather than of silicon. The amazing hardness of quartz is astonishing from this point of view: oxygen seems to provide no soft cushion for silicon to rest upon. We ask for "more" and perhaps more chemical feeling from the rays before deciding. The key to the interpretation of silicates may well be found in petrology—a discipline thus far despised and neglected of chemists—in the study of their evolution as minerals. The chemist who is both chemist and petrologist, with geometric sense and power to interpret X-ray indications, will have open to him a vast and fertile field of exploration. The volume under notice may serve to inspire such a man. Our present neglect of geology is criminal.

Chemist and physicist need put their heads together, if we are ever to solve the problems. The development of pyro- and piezo-electric effects in quartz may be taken as an example. These are regarded by physicists as an intrinsic property of its substance. Quartz seems, however, to be an electrolyte, because of the presence of included silicate. It seems likely that all such effects in crystals are of secondary origin—perhaps mere frictional electricity manifestations.

Dr. Mellor, perhaps unfortunately, makes no attempt to paint broadly the character either of carbon or of silicon and deals with only a few of the simple compounds of carbon. It were time that we developed such themes in setting ourselves cross-word puzzles. We assume that we understand carbon. Supposing that the would-be silicon chemist were to ask: 'What precisely are the ways in which carbon can associate with carbon? I wish to be clear, in order that I may apply your experience of carbon to silicon. Mellor nowhere tells me.' Can we answer?

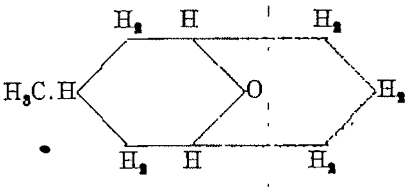
Making this and that statement, we should soon be pulled up. If our friend had the sense of logic he would soon say: 'Yes, you make that assertion but upon what evidence?' Upon revision, organic chemistry seems to the writer to be in a very loose state. It is far too much upon paper. We have made no proper use of the gift the gods would give us. Van 't Hoff began to think in terms of the solid but he only began; he made no full, logical use of the model he adopted. Probably he was carried away by the wonderful consequences of his hypothesis, by finding a satisfactory method of explaining optical activity and so, without inquiry—he was but imperfectly fledged as a chemist—fell in with the current practice of thinking in terms of single, double and triple bonds. So it came that he pictured tetrahedra as united apex to apex in paraffinic, edge to edge in ethenoid, face to face only in acetenoid compounds. He made no attempt to arrange his models in close-packed systems: in fact he took no notice of crystallographic problems.

A solid model of the carbon atom is best made by truncating a regular tetrahedron, so that each face is reduced to a hexagon, by substituting for each of the solid angles a three faced pyramid. When such "tetrahedra" are close-packed, face to face, they form a rigid mass—which is precisely the structure of the diamond, as disclosed by X-ray analysis. We have to picture the four affinities each as directed towards the centre of a face, not to the apex of the tetrahedron. It may be added that only one other form of packing, presumably the ethenoid, is possible.

The consequences of such treatment of the problem are of moment. Limitations are introduced not hitherto foreseen. The models are more suitably made by fitting four rhombic dodecahedra symmetrically together. These may be joined in line, with zig-zag centres, without restriction of length, as in paraffins.

They may also be grouped in closed systems of six, fitting closely, without stress or strain—as in hexamethylene and benzene. The arrangement in these cases is that of the diamond. A compact, symmetrically closed system cannot, however, be formed with less than six carbon atoms. Three tetrahedra can be arranged in paraffinic order but one and three then only touch at a single dodecahedral face. If the three be placed symmetrically, the third, in the median position, is in contact with one and with two at only three dodecahedral faces, that is to say, the contact is only three-eighths that of the paraffinic type; moreover, the three atomic centres are not equidistant. Four may be arranged symmetrically, in which case one and three are united as are the two in the 'symmetrical' arrangement of three, three-eighths as firmly as in a paraffin. The difficulty is with five—one and five touch at only a single dodecahedral face: yet we are told that hexamethylene rapidly passes over into methylpentamethylene. The polymethylenes, therefore, should be a fascinating field for X-ray study. Prof. W. H. Perkin has synthesised a great number of tri-, tetra- and pentamethylene derivatives: it is assumed that these are all closed systems. Convincing evidence of such constitution is needed. Prof. Perkin is known as a great user of the word 'research': by his unrivalled preparative skill he has enriched our lists with a great variety of new products. Let us hope that he will now turn to analytic studies and do a little *re*-search in his own field, so that we may learn to know his numerous progeny better and feel satisfied that they are rightly baptised. Gomberg's work has prepared us to receive surprises. We have too long talked in terms of rings. Our minds are hypnotised by looking always at loosely-strung formula.

One case is clear, that of camphor; this cannot be what it is supposed to be, a dipentamethylene derivative, which is nothing short of a geometrical impossibility. A possible, if not probable, alternative formula is the following:



In this, three carbon atoms are common to two hexamethylene groups. The dotted portion is to be thought of as upright upon the undotted. Almost every change wrought upon camphor probably involves molecular rearrangement —like the juvenile game of chairs, in which almost every child gets up and only some recover their original seats.

The suggestion the writer would make to chemists generally is that we be 'off' with the old before seeking new loves among elusive electrons and polar affinities: that we set our own rather untidy house in order before inviting our colleagues to visit and inspect us with their variously penetrating rays.

HENRY E. ARMSTRONG.

Guides to the French Fauna.

(1) *Faune de France.* Par J.-J. Kieffer. 11: Diptères (Nématocères piqueurs); *Chironomidæ Ceratopogoninæ.* (Fédération française des Sociétés de Sciences naturelles: Office central de faunistique.) Pp. iii+139. (Paris: Paul Lechevalier, 1925.) 18 francs.

(2) *Faune de France.* Par E. Séguy. 12: Diptères (Nématocères piqueurs); Ptychopteridæ, Orphnephilidæ, Simuliidæ, Culicidæ, Psychodidæ, Phlebotominæ. (Fédération française des Sociétés de Sciences naturelles: Office central de faunistique.) Pp. iii+109. (Paris: Paul Lechevalier, 1925.) 15 francs.

(1) THE two most recent fascicules of the "Faun de France" treat of those Diptera Nematocera that have piercing mouth-parts and blood-suckin propensities. The late Abbé J.-J. Kieffer's monograp of the subfamily Ceratopogoninæ provides a concis and up-to-date guide to the study of these small an obscure midges. Prior to about 1900, only about seve European genera were recognised, but during the las twenty-five years quite three times as many hav been disclosed as inhabiting France alone. In tha period we have learned something of the metamorphose of several, and also that some of these flies have th curious habit of sucking the blood of other insects The Abbé's diligence as a systematist has raised hin to the front rank as an authority on the group, and i is satisfactory that he has brought together so muc recent information in a convenient compass.

(2) The remaining blood-sucking groups are treate by M. Séguy, and the most important of these are th Culicidæ, which are held to include also the Dixid of many writers. This family is dealt with in th amazingly small number of 39 pages, which is onl attainable by the use of synoptic keys in place o detailed descriptions—a feature adopted throughou the "Faune de France" series. It is almost amusin to note that after all the nomenclatorial shiftings th yellow-fever mosquito has been subjected to, tha M. Séguy has thought fit to go back to its old nam *Stegomyia fasciata.* The minute papatasi flies (Phle botomus) include four species, and there are twenty four species of Simuliidæ enumerated.

In addition to the above blood-sucking forms, th two small families Ptychopteridæ and Orphnephilidæ are included, the last-mentioned being represented by a single species: its larva and pupa are figured after the recent work of Saunders in Cambridge. Uniformity of treatment and arrangement, in spite of its being the product of a number of specialists, are by no means minor features maintained in this useful guide to the French fauna. Its cheapness and handy proportions raise the wish that something corresponding to it existed with regard to animal life in Britain.

A. D. I.

Colliery Management.

Colliery Working and Management: comprising the Duties of a Colliery Manager, the Superintendence and Arrangement of Labour and Wages, and the different Systems of working Coal Seams. By H. F. Bulman and Sir R. A. S. Redmayne. Fourth edition, thoroughly revised and much enlarged. Pp. xv+393+32 plates. (London: Crosby Lockwood and Son, 1925.) 42*s.* net.

In the opening sentence of Chap. iv. of this work the authors ask: "What manner of man ought a colliery manager to be?" Their answer to this question should be read by all those self-elected critics who at the present time single out the coal-mining industry, from all the industries of Great Britain, in order to level wholesale charges of inefficiency. A perusal of this book reveals the wide knowledge of pure and applied science, and of sociological, commercial, and other problems, required by the colliery manager of the present day.

The book takes a broad view of the British coal-mining industry from the outlook of the colliery manager, and may be read with profit by any one concerned with the control of collieries, or by the general reader inclined to examine for himself the present condition of the science and art of mining. In Chap. i., and indeed throughout the book, interesting historical references are given to show the gradual development in technique and administration through the long history of the industry, and modern methods and practices are also described.

Of special interest is the description of past and present conditions of labour in Chap. iii., and the very full account of the events leading up to the present system of regulating wages under the National Agreement of 1921. Chap. vi. describes the organisation of labour above and below ground, and Chap. vii. gives in detail the elaborate and complicated method of making up wages bills and cost sheets. The remainder of the book is devoted to a discussion of technical methods. Chap. xviii. deals with accidents and their prevention.

The long experience of the authors in the north of England is shown by the slightly greater length devoted to descriptions of practices in this coalfield, although other coalfields are by no means neglected. In any case the authors may be forgiven this slight bias, as the leading part played until recently by the Great Northern Coalfield has undoubtedly influenced practice in other coalfields not only in Great Britain but also all over the world.

Douglas Hay.

Our Bookshelf.

Introduction to Theoretical Physics. By Prof. Arthur Haas. Vol. 2. Translated from the third and fourth editions by T. Verschoyle. Pp. x+414. (London: Constable and Co., Ltd., 1925.) 21*s.* net.

In the second volume of his treatise on theoretical physics, Prof. Arthur Haas maintains the same high standard as in the first volume already noticed in these columns (Nature, vol. 116, p. 267, 1925). The author has wonderful skill in summarising the results of recent investigations, and a sound instinct for the really important parts of his subject. The book is remarkable not only for the power of condensation exhibited, but also for the wide range of the subject matter. It is difficult to judge how the work would appeal to a reader without much previous knowledge of the subject, but it may be questioned whether the unprepared student would not find the treatment in places too condensed and the pace too fast. Thus in the very first chapter he is introduced to three types of elementary quanta—the quantum of electricity, the quanta of positive corpuscular radiation, and the quantum of action.

The quantum theory of the hydrogen atom forms the subject of the second chapter. The subject of Rontgen rays is then taken up, and an account of exceptional interest is given of the behaviour of crystals with respect to these rays. The theory of the elements, taking Moseley's law as a starting-point, forms the subject of the next chapter, and the Part of the volume dealing with atomic theory concludes with an excellent account of the general theory of spectra. Part IV. of the whole treatise deals with the theory of heat, and includes chapters on statistics and thermodynamics. The volume concludes with an exceptionally lucid discussion of the theory of relativity. Prof. Haas has supplied a brief summary of the more important work carried out between the publication of the German edition and of the present English edition of Vol. 2. The translation into English has been admirably done by Mr. Verschoyle, who acknowledges his indebtedness to Dr. R. W. Lawson.

It was no doubt impossible in the space at the author's disposal to give due credit to all the investigators who have made important contributions to the subjects described, but we are surprised to find no reference to Perrin's work on the Brownian movement, or to Richardson's work on thermionics. These are but minor criticisms, and we would conclude by giving a warm welcome to a truly noteworthy book.

H. S. Allen.

The Alkali Industry. By Prof. J. R. Partington. (Industrial Chemistry Series.) Second edition. Pp. xii+344. (London: Baillière, Tindall and Cox, 1925.) 12*s.* 6*d.* net.

Prof. Partington's "concise and connected sketch" of the alkali industry—to use his own words—was first published in May 1918, reprinted in December of the same year, and attained the dignity of a second edition towards the end of 1925. Its merits are many and its defects but few. Written by an academic chemist mainly for students, it is superior to most of the text-books covering the same or similar ground on account of its conciseness, its clarity and accuracy, and the judicious application of the law of mass action and of modern thermodynamics. It is also far more up-to-date than the average text-book. The few defects we have noticed are mainly due to virtues practised in excess. Thus the very concise writing, necessitated by the extent of the subject matter, introduces a 'staccato' touch that makes continuous reading a little irksome; and emphasis on the scientific aspects has subordinated such mundane considerations as costs and yields, matters of vital importance to the budding technologist. Exception has rightly been taken to the title of the book, because almost as much space has been given to acids, etc., as to alkalis: a better title would have been "The Heavy Chemical Industry," which is sufficiently vague and comprehensive for the author's purpose.

In a few respects the information given is not so precise or up-to-date as it might have been. For example, the production of synthetic ammonia in England is referred to in several places; on pp. 1 and 262 we are told that the process is operated by Brunner, Mond and Co., at Billingham-on-Tees, but on p. 199 it is stated that the factory there "is said to be operating." Many erroneous statements have been made by technical writers concerning this manufacture, yet the chairman of the Company, in his address to the annual general meeting in May last year, said that the plant for making 30 tons of ammonia per diem (equivalent to 114 tons of ammonium sulphate) had been operated for a long time, although below its output-capacity, and that it was being enlarged to produce 50 tons. In May 1925, the 30-ton plant was running smoothly at full capacity and showing profits; and measures were being taken to increase the production to 200 tons of ammonia a day.

Drawing: its History and Uses. By W. A. S. Benson. With a Memoir by the Hon. W. N. Bruce. Pp. xxxiii+109. (London: Oxford University Press, 1925.) 6*s.* 6*d.* net.

The author of this little book, who died in 1924 in his seventieth year, was a lifelong exponent of artistic expression in various forms rather than an artist in any conventional sense. His association with William Morris gave a bias in his attitude towards art which finds expression in the opening sentences of his book, in which he lays it down that the variety of purposes for which drawing serves in education and in life is not too well understood; it is not merely a gymnastic exercise or an introduction to the fine art of painting, but a mode of expression, an alternative to speech from which all forms of written language have arisen. In support of his view he traces the growth of graphic art from its earliest beginnings in the palæolithic cave, through the conventional decorative art of the neolithic period, and analogous stages of culture, in which *motif* is dependent directly or indirectly on the technique demanded by material, and through the artistic formula which gave rise to the art of writing, to the modern picture in its frame, and its relation to interior decoration. The treatment of the subject is stimulating, and it may be hoped will bring home to a wider public the significance of early forms of art less well known than that of palæolithic man.

Natur und Mensch: die Naturwissenschaften und ihre Anwendungen. Herausgegeben von Dr. C. W. Schmidt. Erster Band: Weltraum und Erde. Von Dr. H. H. Kritzinger und Dr. C. W. Schmidt. Pp. xii+494+30 Tafeln. (Berlin und Leipzig: Walter de Gruyter und Co., 1926.) 36 gold marks.

This is the first of four volumes which are planned to cover all aspects of natural history in its widest sense, including geology, botany, zoology, ethnology, and the application of scientific knowledge. The first volume deals with astronomical and geological problems, the latter including physical and historical geology and mineralogy. The chapters are popular without being childish, and cover the ground with remarkable thoroughness. They are admirably illustrated with diagrams, beautifully reproduced photographs, and a few coloured plates. In fact, the book is lavishly produced, and as a popular work should make a wide appeal, even though the price is somewhat high.

Economic Geology. By Prof. H. Ries. Fifth edition, revised. Pp. v+843. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1925.) 25*s.* net.

This fifth edition of "Economic Geology," like its predecessor the fourth, deals almost wholly with the economic geology of North America. Its excellent illustrations, numerous references, and good index, together with its balance of treatment as regards scope and descriptive detail, make it a useful and popular text-book so far as the deposits of economic minerals in North America are concerned. As regards deposits other than those of North America, however, it is much less satisfactory. Indeed, in this respect it needs both amplification and correction, and the author would do well in future editions either to make these amplifications or adopt a more appropriate title, as was done in the first three editions.

Two Ornithologists on the Lower Danube: being a Record of a Journey to the Dobrogea and the Danube Delta, with a Systematic List of the Birds Observed. By H. Kirke Swann. Pp. vi+67. (London: Wheldon and Wesley, Ltd., 1925.) 5*s.* net.

This is a slim volume by the late Mr. Kirke Swann describing an ornithological visit to the Rumanian reaches of the Danube. The region is but little known to British ornithologists, and at the present time official restrictions make it an inconvenient one to visit. It is, however, rich in interesting birds, notably in birds of prey and in members of the heron family. Mr. McNeile adds some photographs of nests, and of the people and local scenes.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Eclogite and the Surface History of the Earth.

The interest which has lately been evinced in the surface history of the earth has necessarily extended to the nature of the substratum underlying continents and oceans.

There appears to be general consensus of opinion that this, in its higher levels, is basaltic in character. The evidence for this is strong, and no opposing evidence of importance appears forthcoming. The physical properties of basalt are in every respect in agreement with the requirements.

But there appears to be a certain amount of evidence that at greater depths a change of character may occur. The evidence is mainly seismic, and seems to indicate material of higher density existing at levels which have been indicated as at 60 km. beneath the continental surface (Mohorovičić) and again at 40 km. beneath the oceans (Angenheister). It is generally held that such a discontinuity may be due to deep-lying peridotite, an ultra-basic rock having a density of about 3·4 and the existence of which beneath a basaltic covering has, on petrological grounds, a certain genetic probability. In my writings upon this subject I have referred to this view and to the consequences which must arise as affecting the periodicity and magnitude of the 'revolutions.'

The possibility that eclogite may be the deep-lying substance has been suggested by several writers It is with reference to the physical consequences which may be expected to arise, should this suggestion be correct, that I would revert to the subject. I am not aware that these consequences have been pointed out previously.

Eclogite is generally classed by petrologists among the ultra-basic rocks. The classification is somewhat misleading, however. There is little or no chemical difference between eclogite and basalt, although these two rocks are very unlike in appearance and mineral composition. In Rosenbuche's "Elemente der Gesteins Lehre" (1898) six analyses of eclogite are cited. The means agree with those for gabbro and basalt as averaged by Daly or as determined by Washington for the plateau basalts or the basalts of the volcanic islands. A molten eclogite must differ in no respect from a true basaltic glass.

The physical properties of the two types differ, however, in a very important respect; the density of solid basalt is about 3·0; that of eclogite 3·4 This difference would, of course, cause it to affect the propagation of seismic waves just as would peridotite. The mineral composition of eclogite is radically different from that of a gabbro or basalt. It consists mainly of a pyroxene and a garnet, the latter having a density of about 3·7. It is the abundance of this mineral (which may be regarded as replacing the normal plagioclase and olivine of the gabbros) which confers its high density upon the rock. It is significant that this mineral shows unmistakable signs of instability. "Its presence," write Hatch and Wells in their recent valuable "Petrology of the Igneous Rocks," "indicates consolidation under very great pressure, otherwise its components would have appeared as olivine and plagioclase. Eclogite is, therefore, heteromorphous with gabbro."

It is very probable that at the great pressures prevailing deep in the substratum this rock would come into existence. No process of magmatic differentiation is required. When the basaltic magma had parted with its heat of liquefication, and in the course of sufficient time, we may expect that this substance will take the place of the magma. Of course, this view does not negative the possibility that peridotic layers, resulting from magmatic differentiation, may also exist

The presence of a deep-lying stratum of eclogite carries with it consequences the significance of which may be considerable and which, indeed, may have played an important part in the events of the surface history of the earth. This appears when we consider the great volume-change which must attend its liquefication, and again its subsequent resumption of the solid and crystalline state. For in the fluid state it possesses the density of a basaltic glass; when it is finally consolidated and crystallised it possesses the density of a true ultra-basic rock.

It is probable that under the conditions of viscosity prevailing in the depths a considerable time-element must enter into its resumption of the crystalline state. But there is abundance of time. The effects at the surface of the earth would, in this case, be long-continued and attended with gradually expiring orogenic movements—all the more effective as occurring when the ocean floor had recovered much of its original strength and rigidity.

Eclogite is a rare substance at the surface of the earth. Its origin has been ascribed to extreme dynamo-metamorphism of gabbroid rocks. Its radioactivity has not as yet been specially investigated, but there is no reason to believe that it differs from that of gabbros, dolerites and basalts. J. Joly.

Trinity College, Dublin,

The Source of Stellar Energy.

Many besides astronomers will have received pleasure from reading Prof. Eddington's lecture which appears in Nature of May 1, but I doubt whether mathematicians, physicists or chemists will be prepared to accept his proposed means of escape from the difficulties which beset his theories. He considers (in spite of mathematical proof to the contrary) that a star built on the uranium model—built, that is, of matter in which the generation of energy proceeds spontaneously without regard to changes of temperature and density—would be unstable. He then proposes to secure stability by supposing the star to be built on what may well be described as the gunpowder model: "To save the star we must suppose that the increase of temperature and density . . . causes an increase in E," E being the rate at which the star generates energy.

This seems to be a step from an imaginary frying-pan into a real fire, if the uranium star were unstable, surely the gunpowder star would be doubly so. Any increase of temperature resulting from a small disturbance would cause more energy to be generated, thus heating the star still further, producing still more energy, and so on indefinitely. This is what is meant by instability. To Prof. Eddington's dramatic question, "Can we suppose that energy issues freely from matter at 40,000,000° as steam issues from water at 100°?" the only possible answer seems to be a prosaic "No." When steam issues from water at 100° there is a positive 'latent heat' of transformation of about 536 cal. per gm. This regulates the issue of steam; 1 gm. issues from the water for each 536 calories of heat supplied to the water. If the latent heat had the negative value of − 536 cal.

per gm, no steady supply of heat would be needed, and we could evaporate a whole ocean by dropping in a lighted cigarette Now the transformation of matter into radiation has a huge negative latent heat equal to $-C^2/J$ or $-2{\cdot}15 \times 10^{13}$, and if the heat set free by generation of energy itself causes more generation of energy, we at once have a highly unstable state. In the case imagined by Prof. Eddington, as soon as the centre of a star reached 40,000,000° the heat generated would raise the neighbouring parts to 40,000,000°; these would generate more heat, and so on, the high temperature spreading explosively through the star. The true analogy would not be the issue of steam from water but the explosion of a magazine of gunpowder. The whole question is of course one for exact mathematical treatment. In an investigation which Prof. Eddington does not mention (*Mon. Not R A S.*, October 1925) I have shown that the uranium star would be stable and the gunpowder star unstable. The investigation goes further than this, and shows that considerations of stability practically limit us to the uranium model.

Although the central temperature of most stars is near to 40,000,000°, that of some of the brightest stars in the sky is as low as one or two million degrees (*e.g.* Antares, Betelgeux). This seems to negative the idea that a temperature of 40,000,000° is associated with any special generation of energy. Apart from all theories, the astronomical fact which requires explanation is that 40,000,000° appears to be a sort of upper limit, never exceeded by stellar matter, and that the central temperatures of most of the stars are fairly near to this limit. I suppose 95 per cent. of visible stars have central temperatures between 24 and 36 million degrees, although nothing can be said as to dark stars. My own view is that for some reason not yet fully explained, the transformation of matter into energy is inhibited somewhat abruptly at about this temperature, so that most stars balance their generation and expenditure of energy by taking up a temperature within the range mentioned. It is just within this range that ordinary atomic nuclei become stripped bare of electrons, and this may explain the stoppage in the generation of energy; perhaps only bound electrons are liable to annihilation.

Prof. Eddington states very frankly the difficulties that he sees in his own theories (although I think there are many more than he sees). But by omitting all mention of the successes claimed by rival theories he conveys the impression that the whole problem is in a state of confusion and inconsistency. I consider the situation ought to be painted in far brighter colours. A lot of the confusion arises, I think, from Prof. Eddington repeatedly saying 'unstable' when he ought to say 'stable,' and vice versa. Incidentally he also says 'overstability' when he means plain everyday instability with a time-factor $e^{(\alpha \pm i\beta)t}$; this explains the difficulty he finds in steering his star "between the Scylla of instability and the Charybdis of overstability." Conditions of stability, rightly handled, lead inevitably to stars built on the uranium model, and this in turn leads, practically inevitably, to the view of stellar evolution I have recently put forward (*Mon. Not. R.A.S.*, October 1925, and NATURE, January 2, p. 18). This escapes the difficulties which trouble Prof. Eddington, and seems so far to agree well with observation.

As Prof. Eddington raises the question of the origin of the idea of annihilation of matter as a source of sub-atomic energy, may I be permitted to add that the first mention I can find of it occurs in a letter by myself in NATURE (vol 70, p. 101, June 2, 1904) in pre-relativity days, in which I considered the possibility of there being "conservation neither of mass nor of material energy" but "an increase of material energy at the expense of the destruction of a certain amount of matter." The earliest reference I can find to it in Prof Eddington's writings also occurs in a letter to NATURE (vol. 99, p. 445, August 2, 1917), thirteen years later, in which he says the idea was suggested by me.

J. H. JEANS.

May 1.

The Drop-weight Method for the Determination of Surface Tension and the Weight of the Ideal Drop.

FOR nearly fifty years certain errors, which concern the weight of the maximum drop of liquid which will remain hanging from the lower circular face of a vertical cylinder and that of the drop which falls, have been present in the literature without adequate correction. It is true that during this period, and even earlier, correct treatments of the subject have appeared, but without the effect of diminishing the popularity of the errors. Unfortunately, the most prominent of these, that the weight of the drop which falls is equal to a constant multiplied by the circumference of the tip, is still given support by the statement of prominent text-books that it is sufficiently accurate for practical purposes, even although—but this they do not state—errors of so much as 60 per cent. may be involved.

It is not the purpose of this letter to discuss such an apparent blunder, but to consider certain fallacies which are even more objectionable because they are much more insidious. One of these in particular has been given such a marked recrudescence that Harkins and Brown have been severely criticised in NATURE, the *Philosophical Magazine*, and the *Journal of the Chemical Society*, for their failure to subscribe to the error, even although their paper on this subject (*J. Am. Chem. Soc.*, 41, 499, 1919) was written several years before its recent vigorous revival, and they were therefore entirely unaware that it would so soon become the vogue of the period.

Harkins and Brown introduced the conception of the weight of the *ideal drop* as equal to $2\pi r\gamma$ or the circumference of the tip multiplied by the surface tension ($c\gamma$). It happens that this is just the weight of liquid upheld by the surface tension in a capillary tube, but the choice of this value was due to two reasons. First, this is the weight given by the most complete theory concerning the form of drops, that of Lohnstein, for either the maximum drop which will hang or the drop which falls from an infinitesimal tip. Secondly, it is the value approached, as the tips become smaller, by the *actual weight* of the falling as well as of the hanging drop, as shown by the data of Harkins and Brown, together with a single point of Ollivier, and the work of others.

Notwithstanding the above facts, Iredale (*Phil. Mag.*, 45, 1088, 1923) asserts that the weight of the ideal drop is not $2\pi r\gamma$, but is only half this, or $\pi r\gamma$. Upon the basis of this assertion he intimates that the simple and exact method for the calculation of the surface tension from the weight of the falling drop as given by Harkins and Brown should be supplanted by his method, one which is in fact not entirely correct, and is in addition indirect, cumbersome, and involved, since it requires eight arithmetical operations to give a partly erroneous result in place of the four essential to our exact method. Also the most fundamental operation involved is taken directly from our work, and the data used are wholly those of Harkins and Brown.

Iredale gives as his reason for the choice of $\pi r\gamma$ the statement that in 1881 Worthington obtained this as the value of the weight of a drop which has a vertical contact with the tip. While it is true that Worthington did obtain this value, he did so only by neglecting a term which is fundamentally important in the theory of the form of hanging drops. Only two pages earlier Worthington includes this term, but in an endeavour to correct a fancied error attributed to Quincke, he neglects it. Thus he obtains the equation for the weight (W) of the drop as $W=2\pi r\gamma - \pi r^2\gamma/r = \pi r\gamma$ in which r is the radius of the tip, and also the radius of curvature of the drop in the plane of contact, only by neglecting $1/s$, the curvature in the meridian. That Worthington used the conception of curvature in a dual sense was pointed out to the writer by Dr. A. C. Lunn, professor of applied mathematics in the University of Chicago. The correct equation is, obviously, $W=2\pi r\gamma - \pi r^2\gamma\left(\frac{1}{r}+\frac{1}{s}\right)$, which does *not* give $\pi r\gamma$. To obtain vertical contact the tip must be very small (the more exact condition is that r/a shall be very small) *in which case* s has a sign opposite that of r, and furthermore is nearly equal to r in absolute magnitude, so the term $1/r+1/s$ is either very small or else equal to zero. For this reason the weight of the maximum hanging drop approaches $2\pi r\gamma$, and not $\pi r\gamma$, as the radius of the tip becomes extremely small.

It may be mentioned also that the equation $K^2=\gamma_1\rho_2/\gamma_2\rho_1$ used by Iredale to calculate surface tension (ρ = density) is incorrect from the theoretical point of view, and, in general, does not give such exact results as the theoretically correct form, equivalent to $K^2=\gamma_1\rho_2 g_2/\gamma_2\rho_2 g_1$, used by Harkins and Brown, even although he uses our data to obtain the values of K^2.

Thus Iredale's criticisms of the methods of calculation used by Harkins and Brown are wholly the result of his own errors. Since, however, his experimental work seems to be good, and he makes no application of the relation of $W=\pi r\gamma$, and since the error actually involved in the equation which he uses to apply the data of Harkins and Brown obtained in Chicago in his calculations, where g is different, happens to be small in its effect upon his own results, the present letter need not and would not have been written if Rideal and his associates had not espoused the fallacies and used them as the basis of reiterated criticisms in various journals. Thus, in reviewing Taylor's "Treatise of Physical Chemistry" in NATURE of February 28, 1925, Rideal states: "It is a pity that the erroneous conceptions concerning the determination of the surface tension of solutions by the drop-weight method are finding a place in standard text-books. Harkins' extension of Lohnstein's work on this subject might well be replaced by that of Iredale in a future edition." The peculiar nature of this criticism may best be realised when it is learned that the treatise to which the review relates does not contain any statement which presents the writer's "extension of Lohnstein's work." It does give, without previous reference to Lohnstein or myself, the opinion of the contributor to the 'Treatise" that "the surface tension is therefore equal to a constant times the weight of the drop where this constant has to be evaluated. This has been done by Harkins." The reference appended is to a preliminary paper printed three years before that of Harkins and Brown.

In an article in another journal, Dr. T. F. Young and I expect to give a more extensive treatment of the relations mentioned in the present letter, since sufficient space is not available here for a discussion of all of the factors involved

WILLIAM D. HARKINS.

The Disappearance of the Crystalline Style.

JUDGING by his letter in NATURE for April 10, p. 518, I do not think that Mr. Berkeley quite understands my theory as to the cause of the dissolution of the crystalline style, or the reasons why I am unable to agree with his opinion that the disappearance of the style in molluscs kept under anaerobic conditions may be, in part, "a direct response to the lack of oxygen."

Mr Berkeley is to be congratulated on his discovery (*Journ. Exp. Zool.*, vol. 37, p. 477) of the presence of an oxidase, possibly accompanied by an oxidising agent, in the substance of the style. I have been able to confirm his findings, as I have found an oxidase in the styles of all the lamellibranchs which I have examined, and I am at present carrying out further experiments on the subject with the style of *Ostrea edulis*. At the same time, Mr. Berkeley appears to me to make unwarranted assumptions when he endeavours on the basis of this discovery to account for the dissolution of the style.

I have shown (*Journ. Mar. Biol. Ass.*, vol. 13, p. 938), and have since confirmed in further experiments, an account of which will shortly be published in the same journal, that the style dissolves rapidly in water which is alkaline or slightly acid, but that at a certain critical pH (which varies according to the species but is usually in the region of 4·0, and probably represents the isoelectric point of the globulin of which the mass of the style is composed) it ceases to be dissolved or is dissolved extremely slowly. Since the fluid in the stomach always has a pH above this critical point (in spite of the fact that, as a result of the dissolution in it of the acid style substance, the pH of the stomach is invariably lower than that of any other region of the gut), it follows that the head of the style which projects into the stomach will be dissolved away—quite irrespective of the oxygen demands—while at the same time fresh material is being secreted in the style-sac behind. Under normal conditions, therefore, the style is only maintained as a result of a balance between the rate of its secretion and the rate of its dissolution. Mr. Berkeley does not seem to grasp the essentially physical nature of the dissolution, since he refers to the "consumption of the style substance for digestive purposes."

When a mollusc possessing a style is placed under adverse conditions, details of which are given in my paper, the style disappears—*but only in those animals in which the style lies in a groove in free communication with the gut.* In animals such as *Mya arenaria*, on the other hand, in which the style lies in a separate cæcum, only the *head* of the style is dissolved away even though the animals are kept out of water for *fourteen days*. Surely it is not unreasonable to suppose that the balance between rate of secretion and the rate of dissolution has been disturbed: the vital activities of the animals have been reduced and so secretion lowered. But dissolution still proceeds at the usual rate, and as a result the style will be dissolved except when it lies in a separate cæcum, when only the head can be dissolved, the remainder being sheltered from the action of the dissolving fluid. Mr. Berkeley criticises my experiments on the ground that they all resulted in the animals being kept under anaerobic conditions, but, as Dr. Orton (*Fishery Investigations*, Ser. 2, vol. 6, No. 3, p. 54) has stated to be the case in *Ostrea edulis* and as I have found in *Mytilus edulis*—both lamellibranchs with the style in free communication with the gut—the style is often absent in animals which are in poor condition even though the water is well aerated.

The style is re-formed when animals are replaced under normal conditions, and the presence of food is *not* essential for this process as the work of recent investigators has shown. Mr. Berkeley considers this evidence in favour of his theory, since the style is regenerated by aeration alone. But I fail to see that it invalidates my theory, since in these circumstances the vital activities of the animals will be restored—even though they are starved, for lamellibranchs can undergo months of starvation and be still perfectly healthy at the end—and secretion of the style substance will be increased until it resumes its normal dimensions, and so the usual balance between the rate of production of the style and the rate of dissolution will be regained.

Again, and this is a point to which Mr. Berkeley does not refer, if his theory is correct there should be some correlation between the size of the style and the habitat of the animal. If an animal possessing a style is normally exposed to anaerobic conditions, one would expect that it would have a larger style than one which never suffered from lack of oxygen. There is, however, no such correlation, a fact to which I directed attention in my paper, while exactly the same point was raised by Prof. T. C. Nelson (*Biol. Bull.*, vol. 49, p. 86) in a review of recent work on the crystalline style published about the same time as my own paper, both of us being in complete ignorance of the work of the other. He compares the habitat of *Pisidium idahoense*, which lives in the mud at the bottom of Lake Mendota, Wisconsin, " where for two-thirds of the year the water may be completely devoid of oxygen," with that of Mactra, which lives " in or close to the breaker line along sandy coasts, where the water at all seasons of the year is saturated with oxygen." Yet the style of Pisidium is no larger than that of related species living in well-aerated water, while the styles of all species of Mactra are exceptionally firm and large.

Like Prof. Nelson, I find myself unable to accept Mr. Berkeley's views as to the cause of the disappearance of the style, nor do I agree with him that the matter should be considered *sub judice*; since I consider that my experiments demonstrate clearly that the dissolution of the style is a purely physical process and not in any way, in the words of Mr. Berkeley, " an expression of an effort on the part of the animal to offset the strain on its vital activity induced by anaerobiosis." C. M. YONGE.

Ultramicroscopic Organisms of Filterable Viruses.

IT appears to me that the fundamental significance (apart from its medical importance) of Mr. J. E. Barnard's[1] observations on the ultramicroscopic organisms known as filterable viruses has not been sufficiently recognised by biologists. These observations show the existence of a group of organisms as different from bacteria as bacteria are from yeasts or molds. The term cell cannot properly, in my opinion, be applied to them. Mr. Barnard's observations and photographs with ultra-violet light, particularly of the organism causing bovine pleuropneumonia, show minute hollow vesicles devoid of nucleus or of a cell wall in any proper sense. The ' wall ' of the vesicle is evidently the living material of the organism, and it appears justifiable to apply to its substance the term protoplasm. But its methods of reproduction show that there can be little differentiation of the presumably protein materials composing this ' wall.'

These organisms appear to multiply in two ways: (1) by the appearance of minute papillæ on the surface of the vesicles. These are later attached to the vesicle only by threads, and they finally grow into new vesicles. This process bears some resemblance to the budding of yeast cells, but there are fundamental differences. (2) A vesicle may elongate into a flattened hollow structure which then breaks up into a row or group of particles like the papillæ, having the same property of growing into vesicles. This process might perhaps be compared with gonidia formation in such bacteria as Crenothrix. It was also found that the vesicle stage could be separated from the particle stage by filtration through a collodion membrane.

This group of ultramicroscopic organisms in its extreme simplicity and methods of reproduction brings us a distinct step nearer the inorganic. They are not strictly cells in the sense in which that term has hitherto been used by biologists. We appear to have here organisms reduced to their lowest terms, undifferentiated particles of protoplasmic material which can grow into hollow vesicles reproducing by budding and fragmentation. It becomes a question whether any organisms could be yet smaller and still show the essential phenomena of life. I suggest for these organisms the name *Protonta*, to contrast them with the plant and animal unicells which Haeckel grouped together as the Protista. It is quite possible that a world of organisms of this class exists, which are neither plants nor animals nor cells, and are as extensive and ubiquitous as the Protists. We have no present means of recognising their existence except in the case of those which are, like the virus diseases, parasitic in animals and plants.

That these organisms stand distinctly nearer the inorganic than bacteria is obvious. Investigations of the so-called d'Herelle phenomenon and of enzymes by similar methods, by showing the condition of aggregation of these bodies, will help to indicate just how wide is the gap which still separates such bodies from the strictly inorganic.

My apology for intruding into this field must be that it is one in which I have long been interested.

Half-integral Vibrational Quantum Numbers in the Magnesium Hydride Bands.

THE new quantum mechanics predicts[1] that both the rotational and vibrational quantum numbers in band spectra should have half-integral values. Numerous examples of half-integral rotational quantum numbers have been reported in recent work, but as yet only one case where the evidence is in favour of half-integral vibrational quantum numbers has been recorded. Mulliken has shown[2] that the magnitude of the isotope effect in the BO bands is such as to argue for the adoption of half-vibrational quantum numbers. Indeed, accurate observations of isotope effects apparently constitute the only available method for getting evidence on this point.

P. Rudnick and the writer[3] have recently noted the presence of the approximately correct rotational isotope effect in the fundamental (λ5211) band of magnesium hydride. I have made some new calculations of our data with the object of deciding as to the applicability of half-vibrational quantum numbers to these bands, with the following result: Assuming half-integral values for n' and n'', the initial and final vibrational quantum numbers, with a minimum value $+\frac{1}{2}$, the band-origins of this system can be represented approximately by the equation

---

[1] W. Heisenberg, *Zeit. f. Physik*, 33, 879, 1925.
[2] R. S. Mulliken, *Phys. Review*, 25, 279, 1925.
[3] *Astro. Journal*, 63, 20, 1926.

$$\nu = \left.\begin{matrix}19217\\19224\end{matrix}\right\} + (1603{\cdot}5n' - 34{\cdot}75n'^2) - (1493{\cdot}5n'' - 31{\cdot}25n''^2).$$

Placing the values of these coefficients in the equation for the vibrational isotopic displacement as given by Mulliken,[4] and taking the isotopes of magnesium to be 24, 25, and 26, one readily computes that for the $\frac{1}{2} \longrightarrow \frac{1}{2}$ band,

$$\nu^n_{25} - \nu^n_{24} = -0{\cdot}042 \text{ cm.}^{-1},$$

$$\nu^n_{26} - \nu^n_{24} = -0{\cdot}082 \text{ cm.}^{-1}.$$

That is, the faint pairs of lines due to the less abundant isotopes 25 and 26 found on the low-frequency side of each strong doublet in the Q and R branches should be displaced by these amounts in addition to the (much larger) rotational isotopic displacement (also to the red). As a matter of fact, of 27 recorded pairs of Mg (26) lines, every one is displaced farther from the Mg (24) pair than is allowable as a pure rotational isotopic effect. The average increased displacement is $-0{\cdot}073$ cm.$^{-1}$, which is in good agreement with the theoretical value $-0{\cdot}082$ cm.$^{-1}$, considering the smallness of the shift. For the Mg (25) pairs the agreement is not quite so satisfactory (the measurements of the lines being less accurate), the observed average increased displacement, however, being fair, $-0{\cdot}029$ cm.$^{-1}$, as opposed to $-0{\cdot}042$ cm.$^{-1}$, as given by the theory. It is to be concluded, then, from these results that the vibrational quantum numbers in this band system must be given half-integral values.

Origin of Yolk in the Eggs of Spiders.

IN a remarkable paper on the oocyte of *Pholcus phalangiodes* published in the last century (*Arch. de Biol.*, tome 15, 1898), Van Bambeke described a uxta-nuclear ring, the pallial layer or the pallial substance (see Wilson's "The Cell," third edition, p. 340), which with the growth of the oocyte separates rom the nucleus, and, after fragmenting finely hroughout the cytoplasm directly, gives rise to fatty leutoplasm. He also described ordinary yolk spheres which are albuminous in nature and arise independntly in the cytoplasm.

During the last winter I have been working on the ggs of the common spider in Patiala, and I have seen very much impressed by the remarkable acuracy of Van Bambeke's account in spite of the erious shortcomings of the technique (so far as the xation of lipoids is concerned) in vogue in his time. have shown that the pallial layer of Van Bambeke eally consists of granular mitochondria, embedded n which are the Golgi elements in the form of rings r crescents. Indeed, Van Bambeke figures granules nd rings in his pallial substance, but naturally he as not able to identify them. Mitochondria, of ourse, had been discovered earlier, but the Golgi pparatus was not yet known.

I strongly confirm Van Bambeke's statement that here are two kinds of yolk in the egg of spiders—tty and albuminous. Further, his statement that e albuminous yolk arises *de novo*, and the fatty olk is derived from the pallial substance, is correct. Now the pallial substance consists of mitochondria and the Golgi elements. Is the fatty yolk derived from the mitochondria or from the Golgi elements? I have proved that the Golgi elements are directly metamorphosed into the fatty yolk, as in Lithobius (Nath, *Proc. Camb. Phil. Soc. Biol. Sci.*, 1924), *Helix aspersa* (Brambell, *Brit. Jour. Expt. Biol.*, vol. 1), Saccocirrus (Gatenby, *Quart. Jour. Micr. Sci.*, 1922), Patella (Ludford, *J.R.M.S.*, 1918), and possibly in Palamnaeus (Nath, *Proc. Roy. Soc.*, London, 1925). The mitochondria remain unchanged. A full account will be published later.

On the Occurrence of 2n+1 and other Chromosomal Mutants.

CHROMOSOMAL mutants with one extra chromosome (or the corresponding $n+1$ gametes) have been found in Oenothera, Datura, Matthiola, Nicotiana, Uvularia, and perhaps Mirabilis. It seems probable that they could be found in many other plants, if investigation *ad hoc* were made, either as somatic or gametic mutations. Such $2n+1$ offspring have also been found fairly often in Drosophila, and doubtless occur in other animals.

We have now a tolerably rapid method for counting the chromosomes of mammals, by the use of pieces of the amnion, stained with hæmatoxylin, and mounted in balsam. It is possible that portions of this membrane may be examined directly in iron-acetocarmine. In this case the chromosomal number of individual mammals could often be rapidly determined at birth. It would be of especial interest to know whether $2n+1$ forms occur in man. There should be, of course, 24 possible $2n+1$ forms in Homo (disregarding the Y chromosome), which is the same number as in tobacco. The possible occurrence of haploids, triploids, or tetraploids in mammals (as in several plants and in Drosophila) is also of interest, since $2n$ gametes have been seen (Painter) in Homo It is hoped that investigations may be made on this point in mice, rats, or guinea-pigs.

The Growth of Crystals.[1]

By Prof. C. H. Desch, F.R.S.

GEOMETRICAL crystallography, which has reached a state of such remarkable perfection since its beginnings a century and a half ago, is concerned with the conditions of symmetry in crystals and with their possible faces, but it attaches little importance to the relative development of those faces, so that variations of habit, of such interest to the mineralogist, are mostly ignored. Since crystals of strikingly different habit, such as the many varieties of calcite, may all be derived from the same primitive crystal, their peculiarities must be due to variations in the conditions during growth, and this fact gives to the study of the growth of crystals a special importance.

A simple crystal immersed in a solution of the right degree of supersaturation may continue to grow whilst retaining its original shape unimpaired, as in the perfect octahedra of the alums which have been prepared by some manufacturing firms. Such crystals may grow to a large size without change of shape; and when an octahedron of chrome alum, for example, is allowed to grow in a solution of the isomorphous common alum, the regularity of growth is obvious from the uniformity of the colourless sheath enveloping the coloured nucleus. The increase in size has been brought about by the deposition of a uniform layer of new material on each face. On the other hand, faces may disappear or new faces may make their appearance in the course of growth, and an explanation has to be sought in the external conditions and in the internal structure of the crystal, both factors being concerned in producing the result.

It has long been known, certainly since the eighteenth century, that the presence of small quantities of foreign matter will sometimes produce a change of crystalline form. Common salt, which usually crystallises in cubes, forms octahedra if grown in a solution containing urea. When the quantity of urea is small, crystals with the faces of both the cube and the octahedron are produced. The crystals of organic compounds often vary very greatly according to the solvent which has been used. Such facts as these give the first clue to the problem of growth.

THE SPACE LATTICE IN CRYSTALLOGRAPHY.

The use of X-rays in the study of crystal structure has placed crystallography on an entirely new footing. All modern studies of crystals start from the idea of the space lattice. The atoms, whether occurring singly or grouped to form molecules, are so arranged in space that a single unit is exactly repeated at regular intervals in three dimensions. Through such an assemblage planes may be drawn in any direction. Certain planes so drawn will contain a greater number of atoms in a given area than any planes drawn in a different direction, and it is these closely packed planes which play the principal part in crystal structure. Moreover, in crystals in which the atoms are of more than one kind, different planes may contain the atoms in different relative proportions, so that they may be assumed not to be chemically identical. Any plane may be imagined as a possible face of the crystal, although only a few of them are realisable in practice.

The several planes must have different chemical properties. This follows from our conception of the space lattice. The forces which hold the atoms in position are electrical in character, and depend on the number and arrangement of the electrons in each atom. The chemical behaviour is dependent on the same conditions, and the chemical properties of a crystalline surface must vary with the grouping of the atoms within it. What chemists often call residual affinity must vary with the denseness of packing of the atoms in a plane, so that each set of similar faces must have its own chemical characteristics. This supposition is confirmed by the action of chemical agents on crystals. In the etching of metals by acids it is easily seen that the reagent penetrates more readily along certain planes than in any other direction, as clear facets, of cubes or octahedra in most instances, make their appearance and give the characteristic lustre to the etched surface.

THE PROCESS OF CRYSTAL GROWTH.

It has been shown by Johnsen, Gross, and others that the faces which survive during growth are those which have the lowest velocity of growth in a normal direction, and that these are in general the most closely packed planes. More openly packed planes have a higher velocity of growth, but their relative area diminishes as the crystal increases in size, and they ultimately disappear. The experiments of Nacken on salol and benzophenone are instructive. By attaching a small crystal of salol to a copper hemisphere immersed in the molten substance maintained at a constant temperature, and withdrawing heat by cooling a copper rod attached to the hemisphere, the rate of cooling could be varied; and it was found that when this was very slow the liberation of latent heat by the solidification of the salol and its removal by conduction kep pace with one another, and the surface of the growing crystal was spherical or nearly so, being determined only by the thermal conductivity, which varies only slightly in the direction of the different crystallographic axes. As the rate of cooling is increased, the growth perpendicular to certain directions fails to keep pac with the rest, and faces having a low velocity of perpendicular growth begin to make their appearance at first with oval outlines. As the crystal increases in size, the area of such faces increase until their boundaries meet, and the crystal at las assumes its typical form, with plane faces and straight edges.

The experiments of Volmer and others on the formation of crystals of zinc and mercury in an evacuated vessel, by the impact of a stream of molecules o the metal on a plane surface, have thrown much ligh on the process. Nuclei are at first formed, and thos grow which have the basal plane (the crystals being hexagonal) perpendicular to the direction of the strean This plane has the lowest velocity of growth in direction normal to itself. With mercury at −60° (

---

[1] Substance of two lectures delivered at the Royal Institution on March 16 and 23.

thin leaflets result, the thickness of which is only one ten-thousandth of the diameter. A quantitative interpretation of these experiments, together with those of Marcelin, which proved growth to be a discontinuous process, occurring by the formation of successive thin sheets, leads to the conclusion that atoms or molecules are first adsorbed as a layer of unit thickness, the atoms or molecules in which have a certain freedom of movement. In the course of such movement, groupings which may be regarded as two-dimensional crystal nuclei may arise, and the whole layer then assumes an orderly arrangement, in conformity with the underlying space lattice.

Since adsorption plays so large a part in growth it is not surprising that an alteration of habit may be produced by the presence of impurities. The observations of Gaubert on lead nitrate are particularly instructive. This salt separates from water in octahedra, but when methylene blue is added cubic faces appear, these faces being stained blue while the octahedral faces remain colourless. As the quantity of the dye is increased, the crystals become completely cubic, with blue faces. Evidently adsorption of the colouring matter by the cube face has lessened its rate of growth, so that it survives at the expense of the more rapidly growing octahedral face. It is probable that differences of habit in naturally occurring minerals are largely due to the influence of small quantities of foreign matter, but a very small quantity may suffice, so that the impurity responsible for the result may not have been detected in the course of an analysis.

Well-developed crystals are usually formed by comparatively slow growth, so that as material is withdrawn from the solution, or as heat is given out by the solidification of a melt, there is ample time for readjustment. Miers has shown that the solution in immediate contact with the growing face of a crystal of a salt is actually denser than the bulk of the solution, suggesting that the dissolved molecules undergo a preliminary rearrangement in the liquid before separation as a solid. For this view there is some evidence, notably from the fact, observed by Nasini and others, that solutions which are undercooled through the freezing-point show small discontinuities in properties, although no solid separates. It will be of considerable interest to examine this point by means of the X-ray method.

On the other hand, when growth is very rapid, the supply of material by diffusion may not keep pace with it, and the conditions are disturbed. Simple geometrical considerations show that the sharp angles of the crystal are more favourably placed for the reception of material by diffusion than the middle parts of faces; so that growth occurs at the angles by preference. The effect is cumulative, so that the crystal assumes a star shape, which in course of time undergoes branching, the process being repeated at each branch. This is the origin of dendritic crystals, which are so common in Nature. They are most easily obtained by allowing crystallisation to take place rapidly, as when a solution of a salt is evaporated quickly on a glass slide. The internal symmetry of the crystal is not destroyed, and most such crystals may be regarded as parallel growths, one axis being usually favoured. Thus native copper branches in the direction of the octahedral axes, whilst common salt forms growths parallel with the trigonal axes.

The process of diffusion may be hindered, and dendritic growth encouraged, by making the solution more viscous, as by adding gum. In highly viscous materials, such as glasses, slags, and pitchstones, very beautiful dendritic growths are frequently present. The 'trees' formed by the electrolysis of solutions of metallic salts have a similar structure.

PERIODIC CRYSTALLISATION.

Periodic crystallisation is an interesting phenomenon, which again has a bearing on the origin of naturally occurring mineral structures. It was observed more than seventy years ago by Brewster in ancient glass which had undergone a process of decay. It may arise from several different causes in different substances.

The effect is very simply observed in molten salol. When a thin layer is melted on a slide and allowed to cool, slender needles are seen to radiate from each centre. The advancing point of each needle withdraws material from the liquid, and a gap is left, the molten salol standing up as a wall in front of the crystal edge. Owing to its viscosity, an appreciable time is required for the liquid to flow until it is again in contact with the crystal, when growth is resumed. This process is repeated, so that the advance of the needle is intermittent, and the crystal when complete is marked by transverse lines indicating the stages of growth. The process may be followed under the microscope with ease.

Some salts crystallise from water with a very definite periodicity, the best example being potassium dichromate, a thin layer of a solution of which, if rapidly evaporated, will yield concentric rings of minute crystals with very regular intervals. The effect is here no doubt one of supersaturation, the solution being impoverished by the separation of one ring of crystals, so that the process is interrupted until the right concentration is again reached by diffusion, and so on. Similar structures are seen in glazes on porcelain and, although more rarely, in slags. They are closely connected with the phenomenon of periodic precipitation in jellies, the formation of Liesegang's rings.

The study of periodic crystallisation throws light on some natural structures, especially of agates, which are in all probability formed by the periodic crystallisation of silica from the gelatinous contents of a cavity in a rock. Ruskin maintained that the banding in agates was due, not to periodic infiltration of a liquid, but to segregation, and his view is confirmed by modern work. In particular, the so-called canals, which have been supposed to represent the passages by which liquid entered and left the cavity, are seen, by laboratory experiments on periodic crystallisation, to be merely geometrical effects produced by the meeting of different systems of advancing bands.

Dendritic and periodic crystallisation depend on more complex causes than change of habit, and are correspondingly more difficult to study in a quantitative manner; but there can be little doubt that the examination of the chemical properties of the several planes in crystals will throw much light on these as on other problems of crystallisation.

New Arctic Expeditions.

THREE expeditions, each aiming to cross by air the unknown regions in the heart of the Arctic Ocean, have been or are at work in the north. Capt. R. Amundsen, profiting from his experience of last year, when he found his range of flight seriously limited by lack of petrol, substituted a semi-rigid Italian airship for an aeroplane. The *Norge*, under the command of its designer, Col. U. Nobile, and piloted by Major G. F. Scott, reached Pulham from Rome on April 11, Oslo on April 14, Leningrad on April 15, and King's Bay, Spitsbergen, early in May. The polar flight took place on May 11-13, the *Norge* passing over the Pole at 2 A.M. on May 12. On her flight from Rome to Pulham the *Norge* covered 1400 miles at an average speed of 47 miles an hour. Only two of the three 250 horse-power engines were used, each being rested in turn. From Spitsbergen to Point Barrow in Alaska via the Pole is 1800 miles, and in favourable weather Capt. Amundsen appears to have crossed in 45 hours.

The *Norge* descended safely at Teller, 650 miles from Point Barrow, having accomplished a total distance of 3393 miles from Spitsbergen in 72 hours. Damage was caused to the balloon fabric by fragments of ice, due to condensing moisture, being thrown violently from the propellers. Capt. Amundsen reports that lack of sleep and freezing of food supplies were the only discomforts on the journey. Thin ice and some open water were seen at the Pole, where the *Norge* descended to within 600 ft. of the sea.

The *Norge's* fuel capacity is seven tons, which, at a speed of 50 miles an hour, gives her a range of 3000 miles, in calm air, or about 60 hours. Her gas capacity of 660,000 cubic feet is about a third that of R. 33. Her length is 348 ft., and her maximum speed is 60 miles per hour. Wireless communication was maintained throughout the flight. The crew numbered 15, including Capt. Amundsen, Col. U. Nobile, and Mr. L. Ellsworth. Lieut. Larsen was the pilot.

An American expedition under Lieut.-Commander R. E. Byrd, U.S. Navy, with Mr. F. Bennett as pilot, is also at King's Bay with a three-engined Fokker monoplane. The original plans included six flights. According to the *Times*, the first was to be one of 400 miles from Spitsbergen to Peary Land, North Greenland, to land oil and provisions. On returning to the base the aeroplane was to make a second journey to Peary Land with more supplies, and then leave on an 850 miles' flight to the Pole and back. On May 9, Lieut.-Comdr. Byrd left on a flight to the north and returned in 15½ hours, announcing that he had reached the Pole. Confirmation is still lacking.

The third flying expedition is the Detroit Arctic expedition under Mr. G. H. Wilkins, who has arrived at Point Barrow with two Fokker aeroplanes. With Mr. C. B. Eielson as pilot, Mr. Wilkins proposes to fly northward over the heart of the unexplored Beaufort Sea. If no land is discovered he hopes to continue across the Pole to Spitsbergen. On the other hand, if land is found, the aeroplane will return to Point Barrow and both machines will go north and attempt to make a base on the new land, whence one aeroplane will continue to Spitsbergen. Mr. Wilkins, who gained his polar experience with Mr. Stefansson, proposes to adopt his former leader's precept; he will carry as much petrol as possible, and depend on seals for food if he is forced to descend. Near land this may prove possible, but Mr. Stefansson in 1914 crossed areas of the Beaufort Sea in which he saw no seals, and Capt. Amundsen last year reported only one seal at the place of his forced descent.

It is unlikely that any of these expeditions will report new land. Evidence of its existence in the unexplored parts of the Arctic Ocean is lacking, and the results of the recent expedition of the *Maud* supports this point of view. In any event, it is improbable that rapid flights across polar regions can achieve results of great scientific interest.

Less sensational, but more promising in results, are several expeditions to Greenland. Prof. W. H. Hobbs, of Michigan, is leading an expedition to study the glacial anticyclone. He proposes to sail in July for his main base at Holstenberg, a little north of the Arctic Circle on the west coast of Greenland, where the ice-free margin of the land is about 100 miles wide. Here in a sheltered valley the main base, with a hangar for two aeroplanes, will be established. A second station will be near the coast at a height of about 1000 metres, a third at about 2500 metres on the ice cap, and a fourth, well in the interior, in the area of calms and light winds which Prof. Hobbs believes to exist in the heart of the anticyclone. This last station will be visited frequently, but the other three will be inhabited, it is hoped, for fifteen months and will be in charge of Mr. P. Freuchen, the Danish explorer of Greenland. A snow motor and two aeroplanes will be used to establish the stations and main base connexions. There will also be wireless communication with Godthaab and with Dr. L. Koch's expedition on Scoresby Sound. Prof. Hobbs, who will return with many of his staff in October, has received the collaboration of Mr. V. Douglas, Dr. W. Koeltz, and Prof. H. T. Barnes. The expedition has the support of the U.S. Coast and Geodetic Survey and the U.S. Weather Bureau.

An expedition of seven members under Mr. J. M. Wordie is leaving Aberdeen in June for the east coast of Greenland. Mr. Wordie, who was foiled in his attempt to reach the coast in 1924, intends to make for Shannon Island, and, having got through the pack-ice, to make southward to Franz Josef fjord for geological work. The expedition will return at the end of the summer, but is carrying the necessary equipment and stores in case of a forced wintering, which, however, is improbable since in September the coast south of Scoresby Sound is relatively free from ice. Further south, Dr. L. Koch intends to continue his exploration of Greenland from a base on Scoresby Sound, where an Eskimo colony was founded last summer. Other colonies are to be founded in the same district on the site of former Eskimo settlements at Cape Stewart, Cape Hope, and Cape Tobin. The Field Museum of Chicago announces a collecting expedition under Dr. D. B. Macmillan to sail in July to Baffin Land and Ellesmere Land. Several other Arctic expeditions have been prepared for this summer, including a French attempt under Lieut. Sales northward from Spitsbergen in motor sledges, but their start is uncertain. R. N. Rudmose Brown.

News and Views.

The scheme proposed by Sir Frank Heath for the re-organisation of the Commonwealth Institute of Science and Industry has been tabled in the Australian House of Representatives. The outstanding aim in the scheme is to obtain the utmost co-operation of all the States with the Commonwealth in the formulation of advice through carefully selected men of responsible position and wide outlook, it being recognised that the vast distances of Australia and the wide range of its climates demand a degree of decentralisation much greater than is necessary or desirable in a smaller and more populous country. It is recommended that the purposes of the Institute be defined under three heads: (1) To provide for the training of young men and women in scientific research and for the encouragement of research workers who have already shown capacity for original work; (2) To take responsibility for conducting scientific investigations into problems of importance either (*a*) to the whole industrial activities of the Commonwealth, whether primary or secondary, or (*b*) to the interests of Australian consumers as a whole; (3) To encourage and assist under suitable conditions the solution of scientific problems of importance to particular States or groups of States, which, though urgent in themselves, do not affect the whole Dominion.

Three derivative functions for the Commonwealth Institute of Science and Industry are added to the main purposes set out in Sir Frank Heath's scheme for re-organisation: (*a*) To act as a clearing-house for information on scientific matters affecting the industries of the country; (*b*) To act as the principal and official means of *liaison* in scientific matters between the Governments of the Commonwealth and those of Great Britain and other parts of the British Empire; (*c*) To become, as it wins the confidence of the world of industry and science, the adviser of the Government on the scientific aspects of policy. It is proposed that the Institute be constituted a body corporate consisting of the Prime Minister for the time being and an advisory council of a chairman and eight members, under the title of the Department of Research in Science and Industry. The chairman and two members are to be appointed by the Governor-General and are to form an executive committee with very extensive powers. The other six members are to be the chairmen of State advisory committees. Each of the latter is to include two members nominated by the State Government from its scientific staff, two members of the State University nominated by the Australian National Research Council, and two representatives of the principal industries of the State.

It is suggested that the advisory council which is to constitute the body corporate of the Commonwealth Institute of Science and Industry should meet twice annually at equal six-monthly intervals. It may initiate proposals for research and must consider proposals sent to it by State committees. Between these meetings the executive committee may exercise all the powers of the council. The chief executive and accounting officer to the Institute will be appointed by the Governor-General and act as secretary to the advisory council. As member of his staff he will have in each State an officer who will be secretary of the State advisory committee. The responsibilities placed upon the executive committee of three will be continuous and important, though it is not proposed that its members should be full-time officers. Sir Frank Heath urges that in their selection the first test to be applied should be the certainty that their presence on the advisory council will bring prestige and public confidence to the work of the Institute. Taken as a whole, the proposals for general organisation and future operations follow, as closely as circumstances permit, the lines which have proved successful in the Department of Scientific and Industrial Research in Great Britain, and provision is made for developing the maximum possible co-operation between the British and Australian organisations.

The annual Halley Lecture of the University of Oxford was delivered on May 5 by Dr. G. M. B. Dobson, Lincoln College, University lecturer in meteorology, who took as his subject "The Uppermost Regions of the Earth's Atmosphere." The higher regions of the atmosphere were defined as having a lower limit of say 20 kilometres. Exploration of these tracts is difficult: something can be done by means of dirigibles and balloons: Goddard in America has suggested rockets, by which he hopes to obtain instrumental readings up to a height of two or three hundred kilometres. The amount of each gas present in the atmosphere seems to be fairly constant at moderate altitudes; above these, the large bulk of hydrogen emitted by volcanoes introduces a difference, which would make a difference in the pressure. Some information as to the higher regions can be gathered from the aurora borealis. The occurrence of this phenomenon shows some correspondence with the period (27 or 28 days) of the sun's rotation. Sunspots are often, but not always, present at the time of an auroral display. At the fine display of a few weeks ago there was no visible sunspot. The spectrum of the aurora shows the presence of nitrogen; there is also a characteristic bright line in the green, probably due to oxygen and helium bombarded by electromagnetic particles. A second source of information is the appearance of meteors, chiefly consisting of iron. These become visible at a height of from 30 to 160 kilometres. The temperature of the air, which falls at first, appears to rise again at heights above 120 kilometres. Observations of the trails of meteors enable us to estimate the direction of the wind at different heights. Yet another means of learning something of the constitution of the upper atmosphere is the phenomenon of 'luminous clouds.' These often resemble the 'northern lights,' but their spectrum is that of sunlight, and is without the bright green line characteristic of the aurora. They probably consist of dust from volcanoes, and not of water-vapour. The distribution of dust-clouds shows foci of intensity within areas of vacancy; this is analogous with the distribution of the sound of an explosion.

Air Vice-Marshal Sir W. Sefton Brancker gave some interesting information concerning air transport on the occasion of the fifth Gustave Canet Memorial Lecture which he delivered before the Junior Institution of Engineers on April 30. He said that in no case within Europe has air transport paid its way, it exists only by the grace of subsidies. The British company Imperial Airways has complete freedom in its policy, and, with its predecessors, has already carried more than 70,000 passengers across the Channel, with only four fatal accidents. The first British Empire air-link outside Europe is about to be established. Imperial Airways have accepted a contract to operate a fortnightly service between Cairo and Karachi via Baghdad, to commence on January 1, 1927. Four days are permitted for the voyage of 2500 miles, but it is proposed ultimately to perform the journey in thirty hours. The British Government has decided to go on with airship development, two big ships being at present on order. The present plan is to operate an experimental service to India, with a base at Karachi and a temporary calling-station at Ismailia. The most difficult problem which confronts air transport is the reduction of costs to render a Government subsidy unnecessary; the total cost of carriage by air is now about 5*s.* a ton-mile at 90 miles an hour. The predominant factors are overhead charges, operating costs, and revenue. Obsolescence and depreciation are usually estimated at 20 per cent. per annum, but that is not sufficient. Most of the existing machines ought to be replaced by all-metal craft fitted with air-cooled engines and provided with stability and economy devices. As regards engine maintenance, it was stated that about 60 per cent. of engine defects are due to the water system, valve breakage or distortion, or oil circulation. The development of the heavy oil engine for use in the air is going on steadily. The engine is appreciably heavier than the normal petrol engine, but shows considerable saving in weight of fuel burnt per horse-power.

In the course of a Chadwick Public Lecture delivered at Bangor on May 4, on "The Collection and Utilisation of Small Water Supplies for Rural Communities and Single Houses," Mr. Henry C. Adams said that the recovery and utilisation of underground waters is of comparatively recent origin. In the earliest ages streams and springs formed the only supply of water; to-day they still form the only supply for many thousands of the population in Great Britain, but they can no longer be regarded as essentially a pure or even a safe source of supply for potable purposes. The amount of water which may reasonably be required varies within wide limits. For cottage property 10 gal. per head per day is an ample allowance; indeed, when water has to be carried for use the consumption frequently does not exceed 8 gallons. When, however, a piped supply is afterwards laid on, consumption generally increases at once to about 15 gal. Natural filtration through a considerable depth of permeable strata will arrest the organic and bacterial impurities in the water, but in default of this, artificial filtration is the most practical and effective method to adopt. If space is limited it may be preferable to put down mechanical or rapid filters in place of sand filters. In 1914 the Ministry of Health reported that 285 million gallons of water a day was supplied in Great Britain for domestic purposes from underground sources, excluding springs. The nature of the source from which water is obtained changes as one traverses England. On the east, with its porous surface strata, surface supplies are generally unknown, saving for occasional springs here and there. In the Midlands, examples are found of water from all types of sources; while on the west coast, with its impermeable rocky surfaces, deep underground supplies are practically unknown and surface waters are used almost entirely.

Mr. P. Dunsheath gave an interesting lecture on "Science in the Cable Industry" to the Royal Society of Arts on March 3, which has recently been published in the Society's journal. The application of science to cable making is not entirely a modern innovation. More than sixty years ago Kelvin gave a theory of electrical transmission in the submarine cable. Generally speaking, the cable industry has flourished under the direction of practical men guided by masses of collected data rather than by scientific principles. Cable making has been an art rather than a science. During the last fifteen years, however, the introduction of high electric pressures has made it necessary for the designer and manufacturer to have both the highest technical skill available, and also the help of scientific men with a thorough knowledge of the latest theories. In the lecturer's opinion, cable manufacture offers to-day the widest and most promising field for scientific research. The problems are mainly in connexion with conductors and insulators, and their solution demands the highest mathematical and experimental skill. The British Electrical and Allied Industries Research Association and the National Physical Laboratory have done work which has been of the greatest commercial value to the industry, and the work of the individual researcher has been of equal importance. Cable of British manufacture has always been in the front rank in the markets of the world, and scientific research is being utilised to the full to enable it to keep that position.

The increasingly important part played by light in the modern treatment of disease is illustrated by the receipt recently of numbers of two journals devoted entirely to this subject. *Raggi Ultravioletti*, published at Milan, is a monthly review of ultra-violet therapy, which has now reached its second year of publication. It contains original articles on the treatment of diseases such as rickets and tuberculosis by means of light, short clinical notes on cases of interest and abstracts of current literature. Improvements in technique and medical news are also included. It should be of interest especially in bringing forward the Italian viewpoint on various diseases of world-wide distribution. The other publication received is *Modern Sunlight*, which has recently been published in London. This journal, while including a number of short scientific articles, is primarily devoted to supplying information on the subject of sunlight, natural or artificial, to the lay public. The important part which can be played by ultra-violet light in the treatment and cure of certain diseases may tend to an over-enthusiastic use of it in all kinds of conditions, with a certain amount of resulting disappointment. The fact, however, that these rays seem to play a part in the improvement of the general health of the body, suggests that they may usefully be combined with a specific treatment in a large number of diseases in which the general health has deteriorated. An appreciation of their uses and abuses on the part of the general public will avoid the dangers of over-enthusiasm and lead to their more ready use in conditions in which they are definitely indicated.

WE welcome the appearance of the first number (January 1926) of the *Indian Journal of Psychology*, a quarterly publication and the official organ of the Indian Psychological Association. The article of most general interest is by Dr. N. N. Sengupta on "Psychology, its Present Development and Outlook." The author reviews the chief trends of present-day psychological studies, relating them to their historical background, and outlines the more dominant schools of thought. He points out the enormous wealth of untouched material available in India, with its many races, religions, and cultures, enabling problems to be studied on a large scale, which in England are inevitably vitiated through insufficiency of data. He states that psychology in India is not so advanced as its importance demands, and gives as reasons its close dependence on philosophy, the tendency to be content with mystical explanations, the unnatural divorce between general and experimental work, and the vagueness as to its relation to physiology. It may be some consolation to the author to be assured that India is not the only country where such conditions prevail. The same difficulties appear in many English controversies. However, certain branches of psychology have emancipated themselves from the thraldom of preconceived notions and are making efforts to build securely on observation. India will doubtless not lag far behind. Dr. Sengupta makes a special plea for the co-ordination of many workers. If his schemes can be realised even in a small degree, India will have much to teach England, and we wish the new movement every success

WE much regret to announce the deaths of Dr. H. B. Guppy, F.R.S., distinguished for his work on plant dispersion and coral-reef formation in the Pacific, which occurred on April 23, at the age of seventy-one years; and of Mr. Stephen Paget, founder of the Research Defence Society and author of the biography of Sir Victor Horsley, on May 8, aged seventy years.

WE learn from *Science* that Dr. Edgar F. Smith, professor of chemistry at the University of Pennsylvania, has been awarded the second Priestley medal, bestowed every three years by the American Chemical Society upon a chemist for outstanding achievement in the science. The first Priestley medallist of chemistry was Ira Remsen, former president and professor of chemistry of the Johns Hopkins University.

MR. C. CUTHBERTSON, F.R.S., who is working at the Davy-Faraday Research Laboratory, 20 Albemarle Street, London, W.1, informs us that he requires 20 c.c. or more of krypton and xenon for research purposes. Inquiry at likely sources has been unsuccessful, and we understand that there is considerable difficulty in obtaining any of these gases in Great Britain. Mr. Cuthbertson would welcome information relating to available supplies.

THE Air Ministry announces that applications to enter machines for the Air Ministry Helicopter Competition, 1925–26, which closed last April, were received from thirty-four competitors, but only one competitor actually sent a machine to Farnborough, where the tests were to be carried out. This machine did not, however, carry out any of the tests, and none of the prizes offered has been won. It has been decided not to renew the competition.

THE following awards for the period 1923–25 have been made by the Royal Society of Edinburgh: Keith Prize to Prof. H. W. Turnbull, professor of mathematics in the University of St. Andrews, for his papers on hyper-algebra, invariant theory, and algebraic geometry, published in the *Proceedings of the Royal Society of Edinburgh*; Neill Prize to Prof. F. O. Bower, for his recent contributions to botanical knowledge, and in recognition of his published work extending over a period of forty-five years.

AT the end of the present session Prof. A. G. Perkin will retire from the chair of colour chemistry and dyeing in the University of Leeds, severing thereby a connexion with the University which has extended over thirty-four years. In view of Prof. Perkin's long period of service and the valuable work which he has done in building up a school of research into colour chemistry and the chemistry of natural colouring matters, work which is of great value to the textile and dye industries, a committee has been formed for the purpose of raising a fund which will enable the esteem in which Prof. Perkin is held to be signalised, either by the presentation to the University of his portrait, or in some other suitable manner. Subscriptions are invited for this purpose, and should be sent to Prof. A. F. Barker, The University, Leeds.

THE Royal Society will receive from Messrs. Brunner, Mond and Co., Ltd., a donation of 500*l.* in respect of the current year towards the cost of scientific papers on the physical side The Society will also receive a Publication Grant of 2500*l.* from H.M. Government during the current year. Both grants are available for helping the publications of other scientific societies as well as for assisting the separate publication of books, memoirs, etc., of a scientific nature. Applications for grants for the current year will be adjudged by the Council of the Royal Society at its meeting early in July, but should be received before the Council meeting of June 10. Applications from societies will be received by the secretaries of the Royal Society; those from individuals must be brought forward by members of Council.

The Rockefeller Medical Fellowships for the academic year 1926–1927 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 10. These Fellowships are provided from a fund with which the Medical Research Council has been entrusted by the Rockefeller Foundation. Fellowships are awarded by the Council to graduates who have had some training in research work in the primary sciences of medicine or in clinical medicine or surgery and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. A Fellowship will have the value of not less than 350*l.* a year for a single Fellow, with extra allowance for a married Fellow; travelling expenses and allowances will be made in addition Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 15 York Buildings, Adelphi, London, W.C.2.

We much regret that in the paragraph in our issue of May 1, p. 630, referring to the bicentenary of the birth of Major-General William Roy, who initiated the primary triangulation of Great Britain, the name "Roy" was printed as "Ray."

The editors of "Organic Syntheses," an annual publication of satisfactory methods for the preparation of organic chemicals, now have at hand a large number of preparations in addition to those to be included in Volume 6, which is now in press, and in Volume 7, which will soon go to the printer Chemists interested in any of these preparations can procure copies from Prof. Frank C. Whitmore, Northwestern University, Evanston, Illinois.

Applications are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in geography in the University of Manchester—The Internal Registrar (June 21). A professor of anatomy at the Royal Veterinary College—The Secretary, Royal Veterinary College, Camden Town, N.W. (July 1). A radio engineer, a physicist or radio engineer, a radio engineer, and a radio experimentalist—The Secretary, Royal Engineer Board, 14 Grosvenor Gardens, S.W.1. A senior physics master at Oundle School—The Headmaster, The School, Oundle, Northants.

Our Astronomical Column.

Naked-eye Sunspot.—Two months have elapsed since the last appearance of a naked-eye spot, No. 5, reported in Nature for March 6. The present group of spots was seen as a naked-eye object for a few days only. It was of the typical 'stream' formation; that is, a well-defined regular spot followed at a distance of 8° or 10° of solar longitude by an irregular spot breaking up into a cluster. These two chief components are found to be almost invariably of opposite polarity. The longitude of this group is not far from that of the great northern spot of December and January, the position of which still remains marked by faculæ. Details of the new spot are as follows:

No.	Date on Disc.	Central Meridian Passage.	Latitude	Area.
6	May 8-20	May 13 7	20° S	1/1100

(Area expresses the proportion covered of the sun's hemisphere)

Nova in a Spiral Nebula.—A telegram from the I.A.U. Bureau, Copenhagen, announces the discovery of another faint nova in a spiral nebula, Messier 61, in the constellation Virgo. The position for 1926·0 is R.A. $12^h\ 18\ 3^m$, N. Decl. 4° 54′. The magnitude is given as 13. The discovery was made at the Königstuhl Observatory, Heidelberg, by Prof. M. Wolf and Herr Reinmuth, evidently by photography. The spiral character of this nebula was detected at Parsonstown by the late Earl of Rosse.

The nova is distant 70″ from the nucleus, in position angle 351°.

It is important to follow these distant novæ for as long a time as possible, in order to compare their light-curves with those of galactic novæ. It will be remembered that Dr. Hubble was able to trace the light-curves of the faint Cepheids in M31 and M33 down to magnitude 19 or 20.

The Sun's Velocity derived from Faint Stars.—*Lick Observatory Bulletin* No 374 describes a research by P. van de Kamp on the solar velocity derived from the radial velocities of stars of average magnitude 9·2. The research was intended to test Seares's result that the sun's velocity is greater with respect to faint stars than to bright ones, amounting to 25 km./sec. for tenth-magnitude stars. The spectra were photographed with a one-prism spectrograph mounted on the 36-inch refractor The scale is small, and the individual results rather untrustworthy, but the errors should nearly go out in the mean. The list comprised 105 stars, equally divided between the apex and antapex regions. Their spectral type is as follows (from Henry Draper Catalogue): A and F 45 stars, G 32 stars, K 28 stars.

The resulting value of the sun's velocity is 18 km./sec., the values from the different spectral types being accordant. This value is slightly smaller than the usually accepted value, derived from brighter stars, and thus fails to support Seares's hypothesis. Some other approximate methods of obtaining the velocity with respect to faint stars are discussed, and found to indicate still lower velocities than the present research. The absolute magnitudes of the K stars were estimated as lying between −1·6 and +3·1, so that none of them are faint dwarfs. The assumed position of the solar apex was R.A 270°, Decl. +30°.

Research Items.

THE HUMAN FACTOR IN ACCIDENTS.—The importance to industry of a study of accidents, major and minor, cannot be exaggerated, but when definite causative relations are sought the difficulties and complexities seem to render scientific treatment almost impossible. The immediate relation is between machinery and an accident, and quite rightly have efforts been made to diminish the risk due to machinery. More detailed study reveals, however, a number of determinants which point to less obvious factors. Report No. 34 of the Industrial Fatigue Research Board (H.M.S.O., price 5*s.*) is a contribution by Miss Newbold to the study of the human factor in the causation of accidents. It is a statistical analysis of minor accidents reported from many firms and covering a considerable period of time. It is found (1) that in nearly all the groups the average number of accidents is much influenced by a comparatively small number of workers, and that the distributions among the workers are far from chance; (2) that there are many indications that some part is due to personal tendency; (3) that the people who have the most accidents are, on the whole, those who pay most visits to the ambulance room for minor sicknesses The study is very important not only for what it brings forward in the way of positive evidence, but as an example of scientific method applied to a very difficult problem where vague speculation and prejudice frequently masquerade as fact. The writer suggests that further detailed investigation should be undertaken along the lines of individual study and experimental psychology.

MAN IN THE GLACIAL PERIOD IN GREAT BRITAIN.—In *Man* for April, Mr. J. Reid Moir discusses the inferences to be drawn from the discovery of a palæolithic implement on the foreshore at Eccles-on-Sea, Norfolk, by Mr. W. W. R. Spelman. The implement is an oval core-implement, unpatinated and unrolled. Its form and flaking assign it to the class of specimens concerning which, in the present state of our knowledge, it can only be stated that they belong either to Late Chelles or Early Acheulean. The unabraded condition of the implement suggests that it must have been uncovered just prior to discovery from a bed underlying the beach, as the sandy beach and low cliff reveal no humanly flaked flints. Such a bed must have been the stratum designated as 'First Till' In all probability the First Till represents one of the deposits laid down during the second Glacial Period of East Anglia, and was separated from the Upper Chalky Boulder Clay (of the third Glacial Period of East Anglia) by the inter-glacial phase represented at Hoxne, Foxhall Road, Ipswich, and elsewhere. As St. Acheul implements occur in this phase, it becomes of importance to ascertain whether the present implement is of Chellean or Acheulean date. The main fact, however, is that a definite flint implement of Lower Palæolithic Age has been found under conditions making it probable that the specimen was derived from a glacial boulder clay and thus affords additional evidence of the existence of man in England during the glacial period

RESEARCH IN THE FAYUM—In *Ancient Egypt* for March, extracts are given from correspondence from Miss Gertrude Caton-Thompson, and Miss Elinor W. Gardiner, who are working in the Fayum on behalf of the British School of Archæology in Egypt with the view of linking the archæology to the close of geological changes. Writing from Dimeh, a little south of the lake, Miss Caton-Thompson says that it is plain that there was more than one simple rise and fall of the lake in Pleistocene times. A shore line 189-190 feet above the present lake (46 ft. over sea) yields much evidence of the prehistoric people. On a slope down to the Birket Qarun, flint was obtained at 176 feet on a ridge on which it was unlikely to have been washed (*i.e.* 32 feet over sea, submerged since 9000 B.C.). Pigmies with pigmy cores came down to 138 feet (6 feet below sea, submerged since 17,000 B.C.). Investigations at Kom have settled the question of the contemporaneity of the polished flints, the pottery, and the bone arrows, but only one culture is represented Miss Gardiner writes that the most important fact in the geology of the area is that the Fayum people were living on an old lake surface and not tertiary rock as supposed. There is distinct evidence of two lakes. The older dried up and the deposits denuded very considerably before the waters of the second lake gained access to the Fayum. A section in a wady shows gravels full of flints, mostly wind worn, at 185 feet above lake level, probably belonging to the older lake beds. The surface of the gravel is 185 feet above lake level (submerged since 8000 B.C.). A considerable number of Fayum implements were found upon it. (The statements in brackets are from explanatory notes by the editor of *Ancient Egypt.*)

A DIET CHART.—We have received a copy of the "Grassendale" Diet Chart prepared by S. G. Willimott and Frank Wokes, Grassendale, Liverpool (price 6*d.*), which appears to have been designed for the benefit of the general practitioner of medicine who wishes to place his patient on a known diet before sending samples of blood, urine, etc., to a biochemical laboratory for chemical examination. At the same time, it should be of use to all who wish to treat their patients by means of strict dieting. The information given on the chart is comprehensive: for a large variety of natural, and a few patent, foods the following data are set forth in a series of columns; the percentage composition (carbohydrate, protein, and fat), the energy value, the digestibility coefficient of the carbohydrate present, and the most important of the inorganic elements contained in the food, and whether it leads to the formation of acid or base in the body, its relative power in this respect being indicated by a numerical figure. At the same time, the relative content of the material in the three vitamins, A, B, and C, and the presence of purines, are also indicated Blank columns are given for entering the amounts of each food eaten in the twenty-four hours and for the results of the calculations of the quantities of protein, fat, or carbohydrate assimilated. Explanatory notes of the chart are given on the back: those on vitamins might perhaps have been a little clearer; dry seeds contain vitamin B, but on germination it is vitamin C which appears in large quantities. The information given in the chart should be of use in dieting cases of diabetes mellitus, gout, and nephritis, being available in a compact and handy form; whilst sent to the laboratory with the specimen it will enable a more correct interpretation to be placed on the results of the chemical examination

THE SWIM BLADDER OF SOME INDIAN FISHES.—In his thesis recently presented to the Faculty of Sciences in Paris, D R. Bhattacharya has given an account of the structure and relations of the swim bladder of Indian fishes belonging to the families Sciænidæ and Ophiocephalidæ In the former the swim bladder is oval and extends the whole length of the abdomen. Issuing from it is a complex system of branches passing to the head and to the tail—those in the head region have an arborescent form, and some of them enter into relation with the auditory capsule, being separated from the perilymph only by thin fibrous tissue. Some of the blind branches also penetrate the operculum and the pectoral fin and their ends come to lie just under the skin. In *Sciænoides pama*, two lateral lobes arise from the swim bladder and extend between the peritoneal epithelium and the body-wall and form a complete sac around the body cavity. A dorsal sac is formed in a similar manner and completely envelops the swim bladder dorsally. The two sacs meet laterally, and thus in a dissection one comes upon this large sac enveloping the swim bladder. In the Ophiocephalidæ the swim bladder is an elongate sac extending from the anterior part of the abdomen to the tail, and does not give off diverticula. Details are given of the glands of the swim bladder in each family.

Effect of Light on the Movement of Earthworms.—E. Nomura has made (*Science Reports Tohoku Imp. Univ.*, Japan, fourth series, vol. 1, pp. 293-409, 1926) careful investigations on the effect of light on the movement of *Allolobophora fœtida* to test the differential effect of light on fresh and on fatigued worms, to ascertain the average limit of the free or random movements, the influence of light—horizontal, and from above, and in flashes—on worms with the cerebral ganglia removed and on worms in the course of regeneration. His general conclusions may be summarised as follows: The orientation of the worm is determined by the antagonistic functioning of the cerebral ganglia and of the ventral nerve cord. The brain causes negative orientation and forward crawling, while the nerve cord causes positive orientation and crawling either backwards or forwards. By the predominant influence of the brain the longer exposure to light of stronger intensity causes the stronger negative phototaxis. With light of a given intensity the strongest negative phototaxis is produced when the light rays fall at an angle of about 25° to the horizontal. The most anterior part of the ventral nerve cord causes the strongest positive orientation, the more posterior parts cause a progressively less pronounced reaction—that is, the worms exhibit axial gradient in these reactions.

Some non-Marine Mollusca of the Western Hemisphere.—A fifth part of Dr. H. A. Pilsbry's notes and descriptions of South American land and fresh-water molluscs, that were begun in 1924, has appeared detailing various new species, including one of that remarkable land snail Megaspira (*Proc. Acad. Nat. Sci. Philad.* 77). The same author on later pages in the same publication, deals with other new non-marine mollusca. The most remarkable of these is a very small Physa from Zion Canyon, Utah. No snail can be found in the swift-running stream at the bottom of the canyon, but where the water trickles out of the rock joints of the almost vertical walls of the canyon, the wet rock faces become coated with green algæ, and it is on these isolated patches of algæ the little *Physa zionis* lives. This account is followed by descriptions of new non-marine shells from Querétaro, Mexico.

Modifications in the Calyx of Primula.—Since recording in Nature of April 10, p. 518, the occurrence in phyllody of the calyx *Primula vulgaris* (Huds.), Mr. F. R. Browning writes that he has seen hybrids of *P. vulgaris* with *P. veris*, sometimes termed *P. variabilis*, Goup., showing a completely petaloid calyx. The three flowers examined were 'pin-eyed,' two of them having five petals and five petaloid sepals, which alternate with them normally. The third flower has six petals and five petaloid sepals; the sixth is diminutive though decidedly petaloid. It also differs from the others in that it has not the well-marked ridge at the midrib, which characterises the other sepals. The size attained by this unusual calyx is in all cases the same as that attained by its enclosed corolla.

Domesticated Plants in Spanish America.—An interesting field of research is opened up in a paper on the plant content of adobe bricks by George W. Hendry and Margaret P. Kelly which has been published by the California Historical Society. Missionaries and travellers who visited California in the Spanish period are known to have introduced a number of cultivated plants into the country, but precise information, especially as to varieties, is lacking. An examination of bricks from a number of buildings, ranging in date from 1771 to 1845, although representing a small sample only, has furnished a considerable amount of exact information on the point. The adobe bricks were made of a variety of soils, ranging from sandy loam to heavy loam, some natural, others the result of artificial mixing, and contained organic matter chopped into two-inch lengths, usually wheat or barley straw, but also weeds and grasses of various kinds. Of the twenty-two weeds, eleven are introduced European species. Six varieties of wheat were identified. This establishes a new date for the introduction of Big Club wheat (*T. Compactum Humboldti*) not previously known as a mission crop. One wheat, California Club wheat (*T. Compactum Crinaceum*), is not grown in California to-day, but disappeared prior to the Mexican period (1822–45), and another, a beardless wheat (*T. Vulgare Albidum*), is unknown. Propo wheat (*T. Vulgare Graecum*), supposed to have been introduced from a Chilean strain about 1875, was also found, and may have persisted from the original Spanish stock. Only one variety of barley (*H. Vulgare Pallidum typica*) was found. One wild oat kernel is of doubtful authenticity. Of two cultivated oats, *Avena sativa*, which belongs to a group not adapted to central California, may represent an unsuccessful experiment.

Chromosomes of Roses.—In a reprint from his *Experiments in Genetics*, Dr. C. C. Hurst discusses the origin of species in Rosa. Starting with a hypothetical decaploid rose (which would have ten times seven chromosomes), he supposes that the various septets of chromosomes became differentiated under subpolar conditions, so that each set was pre-adapted to a different climate. This all happened within a single (hypothetical) decaploid species of rose. The hexaploid, pentaploid and diploid existing species were afterwards formed by the throwing off of different septets of chromosomes successively until the present diploid species were arrived at, each adapted to different conditions. This highly hypothetical speculation is contrary to all that is known concerning polyploidy in other plants. It also implies a sort of evolution *in vacuo* of the chromatin, which is contrary to every experimental evolutionary view of the relation between the organism and its environment. The evidence from other plant genera is that polyploid species are derived from diploid ancestors, and not the reverse.

Mean Sea-level in the Oceans.—The relation between wind or current and mean sea-level in the Indian and Atlantic Oceans and adjacent seas is discussed by P. H. Gallé in a short paper in the Proceedings of the Koninklijke Akademie van Wetenschappen te Amsterdam, vol. 27, No. 10. Mr. Gallé concludes that the range in mean sea-level is mainly due to fluctuations of wind and current, either near at hand or far distant. He believes that while the north-east trades and the equatorial current are causes of fluctuations in mean sea-level on the European coast, the main cause must be looked for in fluctuations of the north Atlantic high- and low- pressure systems. The correlation factor between monthly departures of the velocity of the current and strength of the wind and departures from mean sea-level is given as varying between 0·829 and 0·957. The time relation between changes of velocity in the equatorial current and mean sea-level on Atlantic coasts varies from one month in the Azores to three months in the English Channel and four months on the north coast of Norway.

Atlantic Doldrums.—The Meteorological Office, Air Ministry, in "Geophysical Memoirs," No. 28 (London: H.M. Stationery Office, 1926. Price 1*s.* 6*d.* net), has issued a discussion of "The Doldrums of the Atlantic" by Mr. C. S. Durst. The author rightly gives considerable credit to Captain Toynbee, the first Marine Superintendent of the Meteorological Office, for his study of this district and the publication of the observations for the Nine Ten-Degree Squares comprising the area of the Atlantic Doldrums. A previous discussion was undertaken of Square 3. The copious letterpress accompanying these charts by Captain Toynbee is full of valuable information, especially on the direction of upper clouds with the different surface winds. The author notes that the minimum of pressure in the Doldrum belt follows the position of greatest humidity rather than the position of maximum temperature, and he is of opinion that over the ocean it would seem that convection must be started dynamically rather than thermally. If obtainable, synchronous weather charts over the Doldrum area would add much to our present knowledge of this interesting region.

The Colour of Red Formations.—In the *Journal of Geology*, No. 2, 1926, a valuable discussion of the origin of the colour of red beds is presented by G. E. Dorsey. It is shown that the non-red rocks often contain more iron and even more ferric oxide than do the red beds. The red colour is due not merely to oxidation—which is widespread—but to dehydration. Favourable conditions for the production of the red hydroxide, turgite, and the red oxide, hæmatite, are found in warm moist climates, and not, as has previously been asserted, in deserts or semi-arid regions. Ferric hydrate turns red spontaneously by dehydration, even under water, if given time enough. In the tropical belts heat favours dehydration, and the heavy cover of vegetation keeps the soil from being rapidly removed, so that time is available for the reaction to proceed. Most sediments are carried to the seas and there, exposed to the reducing action of the decay of marine organisms, they lose any red colour they originally possessed. But red detritus is able to retain its colour if it comes to rest upon the continents where no widespread reduction is in progress. Thus for the most part the red formations of the geological column represent continental deposits; though it is recognised that occasional wedges may be found in marine series, like that now forming off the mouth of the Amazon, where fresh water and red detritus are sufficiently abundant to force the true marine conditions farther off-shore.

Investigations on the Earth's Crust.—The *Year Book*, No. 24, for 1925 of the Carnegie Institution of Washington includes, *inter alia*, reports on the work of (i.) the Geophysical Laboratory directed by Arthur L. Day, (ii.) the Advisory Committee on Seismology, and (iii.) of certain physicists associated with the Institution. The latter include S. J. Barnett, formerly attached to the Department of Terrestrial Magnetism, who is continuing his valuable researches on rotation by magnetisation, and vice versa, at the California Institute of Technology, Pasadena. Much of the work done under R. A. Millikan in the Norman Bridge Laboratory at Pasadena is also subsidised by the Institution. In the Geophysical Laboratory at Washington a large part of the work has consisted of experiments involving very high pressures; the attainment of a pressure of 15,000 atmospheres (225,000 lb. per sq. in.) on a small sample of material has now become "a matter of simple routine"; this corresponds to the pressure at a depth of 30 miles below the surface of the earth. Still higher pressures are readily obtained, but beyond the limit stated the work is liable to be interrupted by expensive and annoying explosions. The compressibilities of the more important rocks and minerals have been investigated under these high pressures: the results are of special interest in determining the speed of earthquake waves through the earth. Less directly, the work bears on the temperature within the earth, and has led to an estimate of 850° C. at 30 miles depth, and 1700° at 100 miles, values which are much lower than has generally been supposed. Laboratory studies and 'field' observations (at Vesuvius and elsewhere) on volcanic problems have also been considerably advanced. The Committee on Seismology plans to establish a central seismological laboratory at Pasadena, and has completed the development of new instrumental installations for the accurate measurement of the horizontal and vertical components of local as distinct from widespread earth movements (such as ordinary seismographs record). It is hoped to furnish a considerable number of seismological stations with such installations. In co-operation with the Coast and Geodetic Survey, triangulations are in progress for the determination of relative surface displacements in a large region around California. The measurements already made indicate that the stations on the west side of the fault between Monterey and the Santa Barbara Channel have all been moving northward, the maximum movement recorded, whatever its source, being about 24 feet, at a station situated a few miles west of the city of Santa Barbara.

A Microluminometer Light Source.—At the meeting of the Physical Society on May 14, Dr. Fournier d'Albe demonstrated an apparatus for producing very minute measurable fluxes of light and illumination. The original source of light was a small glow lamp of ⅛ c.p. candle power, which illuminated a ground-glass disc with an aperture of ¼ in. This disc acted as a secondary source of $\frac{1}{16}$ c.p. in the direction of propagation. A number of lengths of tubing, 2 in. long, were telescoped together, each length ending in a $\frac{1}{16}$ in. diaphragm covered with ground glass. The amount of light emerging from each successive diaphragm was $\frac{1}{250}$th part of the light emerging from its predecessor. The candle power thus obtained was $1·6 \times 10^{-4}$ c.p. at the first stop, $6·4 \times 10^{-7}$ c.p. at the second stop, $25·6 \times 10^{-10}$ c.p. at the third stop, and 10^{-11} at the fourth stop. The light emerging from the fourth stop is quite invisible, even after prolonged accommodation, and represents, indeed, a star of about the seventh magnitude. The microluminometer source is intended for a comparison of the efficiencies of photoelectric cells and selenium respectively in detecting faint light. It is claimed that the faintest source is measurable within 2 per cent.

The Indian Science Congress at Bombay.

UNDER the presidency of Mr. A. Howard, Director of the Institute of Plant Industry, Indore, and Agricultural Adviser to States in Central India, the thirteenth annual meeting of the Indian Science Congress was held at Bombay on January 4-9. In addition to sectional meetings, joint discussions were held on recent scientific work directed to the improvement of cotton-growing (Sections of Agriculture, Mathematics and Physics, Zoology and Botany) and on the structure of the atom and quantum theory (Sections of Mathematics and Physics and Chemistry). Public lectures on droughts and famines, by Dr. H. H. Mann, on life at higher altitudes in Western Tibet, by Prof. Shiv Ram Kashyap, and on modern applications of X-rays, by Prof. H. Parameshwaran, were arranged, as well as visits to places of scientific interest in the neighbourhood of Bombay.

Brief accounts indicating the activities of some of the sections of the Congress are printed below.

In his presidential address, Mr. A. Howard, after dwelling on the predominance in modern scientific agriculture of the biological sciences, went on to stress the diversity of the sciences with which modern research in agriculture is concerned. The study of the growth of the economic plant, according to Mr. Howard, opens up the great problem of the agriculture of the near future, and that is the *intensive* cultivation of improved varieties; it is not sufficient to breed new varieties: the methods by which maximum production can be obtained must be studied. From his general argument, Mr. Howard developed the thesis that the need of the future is team work. The real subjects of research in agriculture have far outgrown the old tradition inspired by the work of Liebig: the attack through a single science is no longer possible. It is rightly pointed out, however, that successful team work presupposes the presence of a competent leader and, it may be added, a spirit of subordination to which men with the real pioneering aptitudes do not readily submit.

An unusual and suggestive feature of Mr. Howard's address was the special reference to the connexion between canal irrigation and public health. He thinks that no satisfactory explanation has yet been given of the correlation between canal irrigation and the prevalence of malaria. He pointed out that the connexion cannot be wholly due to the formation by canals of breeding grounds for mosquitoes, and suggested that a contributory cause may be nutritional—the deficiency in the food crops grown with canal water of essential mineral and other ingredients. He urged the need for immediate investigation and deplored the cessation, for financial reasons, of the work of McCarrison (*Jour. Roy. Soc. of Arts*, 83, 1925, p 152) in this direction. This investigator showed that certain nutritional diseases were prevalent in Madras as the result of differences in the manurial treatment of the millet crop.

In relation to the diseases of plants, also, Mr Howard broke fresh ground with a suggestion that cultural conditions rather than specific infection play the most important part in the causation of outbreaks. In some of his work at Quetta in connexion with fruit growing, he was able to show that attacks of aphis could be induced experimentally by altering the time of irrigation. He found, again, that Eincorn (*Tr. monococcum*), which is generally believed to be immune to *Puccinia graminis*, becomes highly susceptible when grown in the hot climate of Pusa in Bengal Mr. Howard's reputation in applied botany is so well established that his views, particularly on possible administrative developments, merit serious consideration.

The programme of the Section of Anthropology indicates an active and serious interest in the varied problems of Indian ethnology and culture. If, however, those who took part in the proceedings had flung their nets wide, it is to be regretted that the burden of ethnological investigation still appears to rest on the shoulders of a few, and that the number of individual workers taking part was small. Further, while religious and sociological investigations were well represented, the study of material culture received little attention.

Among so many communications presenting features of interest it may appear invidious to select any for mention; but attention may be directed to Mr. L. A. Cammiade's account of the Kurnool bone caves in relation to the problem of prehistoric man in India, Sarat Chandra Roy's description of the Asurs, a tribe of iron-smelters of Ranchi; Sarat Chandra Mitra's record of two recent cases of exorcism, one from Southern Bengal, for driving out the spirit of disease sent by Kali, a second from eastern Bengal, where treatment of a person possessed of a ghost by repeated immersion in water resulted fatally. The same author recorded two cases of propitiation by self-mutilation: a man cut off the tip of his tongue as an offering to Tapeswari at Cawnpur, while another individual in Kathiawara cut off his own head as an offering to Siva. An interesting rite to prevent hydrophobia, also recorded by Sarat Chandra Mitra, involves the turning by incantations, but otherwise unaided, of a saucer on which the patient stands. D. N. Majumdar presented further communications dealing with the customs of the Hos of Kolhan in continuation of those already published in several Indian periodicals.

In the Section of Zoology, under the presidency of Prof. H. R. Mehra of Benares, twenty-nine of the thirty-one papers presented are by Indian workers. They afford evidence of considerable scientific activity in the observation more especially of protozoa, parasitic worms, and Arthropoda.

Under the presidency of the Rev. W. E. Blatter, no less than 52 papers were communicated to the Section of Botany. These range over a wide field, many of them recording results of very general interest The president is himself responsible for several ecological papers, mainly on the Indus delta; C. McCann also presented several papers on the grasses of the Bombay presidency; whilst several Indian workers supplied records of studies of special vegetation formations. The life-history of various Indian plants also received attention; a number of interesting communications in plant physiology are reported, and papers on parasitic fungi, on marine and fresh-water algæ, on cytology, teratology, heterophylly, and other biological features of interest in Indian plants, are included In fact, the proceedings of the section suggest that the prosecution of research upon the interesting vegetation of India is actively pursued, and that Indian investigators are themselves taking a prominent share in the work.

The proceedings of the Section of Geology were noteworthy for the many papers devoted to Burma and its problems. A. S. Subbaiyer dealt with the production and reserves of petroleum and its stratigraphical distribution He concludes that there may still be vast unexplored resources in the little-known Eocene oil-fields. In a third paper he discussed the genetic relationship between coal and oil, and suggests mapping the fixed carbon ratios in conjunction with structures as likely to lead to successful results, particularly along the Pakokku foot-hills. H. L. Chhibber contributed a valuable account of the extinct volcano Mt. Popa, one of the most conspicuous landmarks of Upper Burma. He also described the ferruginous concretions of the Irrawaddian Series, and the ancient slag-heaps and deserted furnaces found in the neighbourhood of Mt. Popa. Another paper by the same author described ferruginous bands of a rhythmic character occurring in the silicified tuffs of Kyankpadaung. H. L. Chhibber and L. D. Stamp collaborated in a paper dealing with the origin and constitution of the fossil wood which is such a conspicuous feature of the late Tertiary beds of Burma. The petrography of Green Island, near the mouth of the Salween, is described by L. D. Stamp, who directs attention to the extensive assimilation, lit-par-lit injection, and development of banded gneisses that have taken place. K. K. Mathur *et aliter* discussed the mechanism of intrusion and the differentiation of the laccolith of Mt. Girner, the rocks of which were described many years ago by Dr. J. W. Evans. The Ranikot beds at Thal were shown by L. M. Davies to present a more complete series of the earliest Eocene horizons than has been discovered elsewhere. B. Sahni is engaged on a revision of the fossil plants in the collection of the Geological Survey, and presented a summary of his work on the conifers, ranging from the Lower Gondwana to the Cretaceous. Other papers dealt with cordierite, staurolite and mica, and various local faunas and strata; and J. Ribeiro describes the natural caves recently discovered in Bombay. The large number of contributors and the wide variety of subjects discussed testify to the healthy activity of geological research in India and Burma.

Nearly a hundred papers were presented to the Section of Mathematics and Physics. Seven of these deal with pure mathematics, five with hydrodynamical problems, and two with relativity and non-Euclidean space. The physical papers cover a wide range. Surface tension, efflux of gases, motion of projectiles, vibrating strings, flame temperatures, entropy, radiation, scattering of light, spectra, X-ray investigation of crystals, magnetism, electrolysis, photo-electricity and wireless signalling, were all discussed, while the weather, rainfall and floods of Bengal were not forgotten. Prof. M. N. Saha, as president of the section, read a valuable paper on the application of subatomic thermodynamics to astro-physics, portions of which were printed in NATURE of May 8. The programme showed that India is keeping well abreast of recent developments in the mathematical and physical sciences.

Co-operation in Oceanography.

UNDER the title "L'Oceanographie dans la Vie International," Prof, Odon de Buen writes an interesting account of the various organisations which are materially assisting the co-operation of adjacent countries in oceanographical investigations (*Scientia*, February 1, 1926). The international movement is particularly active both in physical and biological oceanography, where the problems encountered by each country extend far beyond its own coasts, and the natural difficulties and expense of collecting data at frequent intervals over a wide area of the ocean necessitate such collaboration.

This necessity is increasing. Our present knowledge of the average conditions of the seas is built up from numerous painstaking observations made by a limited number of expeditions carried out from time to time. The fluctuations in the fisheries, of national importance to the countries concerned, centre interest more and more upon the fluctuations rather than upon the average condition in the physical and chemical conditions of the seas.

The Conseil Permanent International pour l'Exploration de la Mer now includes those countries bordering on the continental shelf from Norway to Portugal and Spain. Its influence in furthering our knowledge of the oceans in general has been potent since its foundation in 1899. Similar organisations deal with the publication of data and the co-ordination of investigations, both in the Mediterranean and also in the fertile area famed for its cod fishery north-east of North America.

These three co-ordinating organisations are represented in the Oceanographical Section of the Union International Geodesique et Geophysique by their respective presidents It is of interest to hear that this section has commenced the difficult enterprise of publishing an annual *Bibliographical Bulletin*.

As any feral industry grows, whether it be hunting animals or fish, an accurate knowledge of the factors which control fluctuations in the population of the hunted animal becomes increasingly useful to the hunting nations. It is to gather this knowledge that the network of organisations has sprung up, fathered originally by the Scandinavian countries, to whom their fishing industry is an asset of relatively great importance. An interest in the sea is inherent in all seafaring nations, and concerted action has already been of great help to the progress of scientific oceanography.

The Swiss National Park.

PROF. CARL SCHROETER of Zürich delivered the fourth Hooker lecture at the Linnean Society on April 15 on the Swiss National Park. The movement for Nature protection is very strong in Switzerland, and civil law permits even expropriation in the interest of natural and historical monuments. The formation of the League for the Protection of Nature (Naturschutzbund) has made the matter a national one; it has about 30,000 members, who pay an annual subscription of 2 francs, or 50 francs for life membership. The League has been instrumental in many ways, but the most effective measure is the creation of the Swiss National Park, which occupies about 54 square miles in the Lower Engadine. Here shooting, fishing, manuring, grazing, mowing and wood-cutting are entirely prohibited. No flower or twig may be gathered, no animal killed, no stone removed, and even fallen trees must remain undisturbed. There are no hotels, only simple Alpine shelter huts, and camping and the lighting of fires is not allowed. The aim is to exclude the effect of human interference so far as possible: scenery, plants and animals are absolutely protected.

The Park is controlled by five trustees nominated by the Government, which pays the rent (up to 30,000 francs per annum). The League pays the incidental expenses (*e.g.* there are four resident keepers) and for scientific research which is organised by the Swiss Society for the Advancement of Science.

The size of the Park and its physiography allow of Nature equilibrium. The mean elevation is high; the snow-line consequently reaches so much as 3000 metres; the tree-limit 2300 metres. It is well wooded with extensive forests of the erect mountain pine (*Pinus* *montana* var. *arborea*) and *Pinus Cembra*, mixed woods of spruce and larch, an endemic variety of Scotch pine (*Pinus sylvestris* var. *engadinensis*), and extensive areas of creeping mountain pine (*P. montana* var. *prostrata*). The herbaceous flora is rich and varied, the different geological strata allowing of both calcicole and calcifuge plants; the division between the floras of the western and the eastern Alps passes through the Park, many of the Swiss eastern species occurring only here. Animal life is abundant—chamois, marmots, deer, roes, foxes, mountain- and heath-cocks, golden eagle, etc.

After ten years of reservation the favourable effect is clearly visible: the flora of the now abandoned pastures has developed abundantly. The number of animals has much increased. From 1918 to 1925 deer had increased from 12 to 90; roe from 60 to 190; chamois from 1000 to 1250; mountain cock from 10 to 60, heath-cock from 40 to 190; ptarmigan from 120 to 310, and golden eagle from 15 to 40. The preservation of certain beasts of prey is requisite as a hygienic measure, as they kill sick animals first.

The last bear was killed in the Park in 1904. The ibex disappeared from Switzerland in 1809, but an effort is being made to reintroduce it from colonies at St. Gallen and Interlaken, which have arisen from young animals smuggled from the valley of Aosta.

All the influences of man due to shooting, fishing, wood-cutting, haymaking and so on will take time to efface, and the successional changes are being studied by a special commission of fourteen members elected in 1915 and divided into four sections, geologico-geographical, climatological, botanical, and zoological. So far forty investigators have worked in the Park. Several monographic studies have been published, and an attempt is being made to get a "complete notion of the inorganic and organic nature of our National Park."

The lecture was illustrated by a magnificent series of coloured lantern slides.

University and Educational Intelligence.

BRISTOL.—The Society of Merchant Venturers offers for competition fifteen scholarships tenable in the Faculty of Engineering of the University of Bristol, provided and maintained in the Merchant Venturers' Technical College. Candidates must be not less than 17 years of age and must have matriculated. The scholarships provide free tuition: one of the scholarships is open to pupils in any secondary school receiving grants from the Board of Education; three are restricted to pupils of secondary schools in the counties of Gloucestershire, Somerset, and Wiltshire (one to each county); ten are restricted to the sons of officers in His Majesty's Service who were killed in the War, and whose mothers or guardians are in needy circumstances; one is restricted to a son of a citizen of Bethune who has passed either the B. ès L. or the B. ès Sc. examination. A War Memorial scholarship is also offered, with a preference to a candidate who needs pecuniary help, who is the son of a former student who lost his life while serving with H.M. Forces during the War.

CAMBRIDGE.—The late Sir John B. Harrison bequeathed to the Sedgwick Museum his collection of more than 2000 rock slices; these were made from the rocks of British Guiana and the West Indies.

Dr. F. J. Gaskell, of Gonville and Caius College, has been appointed demonstrator in medicine, and Mr. E. G. Holmes, of Christ's College, has been appointed as assistant to the Downing professor of medicine.

A lectureship in advanced and economic entomology has been advertised as vacant; the stipend will be 350*l.* with a "fellowship allowance" of 150*l.* if the holder is not a fellow of a college. From this it would seem that the principle of granting an extra emolument to persons on the staff of the University who are not fellows of colleges has been conceded. Similar provisions are made in the conditions of appointment to lectureships in moral science and Persian which are also announced.

The General Board of Studies has presented a report on the readership in ethnology. The present office was created for the duration of Dr. Haddon's tenure, and he has announced his intention of retiring at the end of the present academic year. The Board considers that the subject is now well established in Cambridge and its educational importance generally admitted; it is therefore suggested that the readership should become a permanent university post.

OXFORD.—On May 12, Mr. G. R. de Beer, fellow of Merton College, the lately appointed John Wilfred Jenkinson lecturer in embryology, delivered an inaugural lecture on the organisation of the embryo. He made special mention of the embryological work of the late J. W. Jenkinson, in whose memory the lectureship has been founded; and directed particular attention to the orientation of the embryo, as manifested in the results of transplantation and in the phenomena of the 'grey crescent.'

DR. I. J. KLIGLER, formerly of the Rockefeller Institute and for the past three years Director of the Malaria Research Unit attached to the Department of Health of the Government of Palestine, has been appointed head of the new Department of Hygiene established at the Hebrew University of Jerusalem.

THE University Grants Committee's Returns for 1924–25 give 41,794 as the total number of full-time students of both sexes in the universities and university colleges of Great Britain in receipt of Treasury Grants. This is less by 1098 than in the preceding year, but the decrease is more than accounted for by the decrease (1458) in the number of students assisted under the Government scheme for the higher education of ex-service men. The tables in which the full-time students are classified according to faculties show decreases under medicine (970 men and 367 women) and technology (496 men) and increases under arts, including theology, fine arts, law, music, commerce, economics, and education (557 men and 353 women). A large proportion of the decrease in the medical group is accounted for by the dental students. In the Scottish Medical Schools there were 537 fewer men and 178 fewer women last year than in the year before. Under engineering, metallurgy, and applied chemistry there were decreases: from 3413 to 3036, from 187 to 140 and from 338 to 280 respectively, whilst the number of mining students increased from 263 to 275. The table exhibiting the home and university residence of full-time students shows that 49 per cent. came from homes within a 30-miles radius, 42 per cent. from other parts of the British Isles, 6 per cent. from other parts of the British Empire, and 3 per cent. from foreign countries. Of the men, 19 per cent., and of the women, 33 per cent. were accommodated in colleges or hostels. Next to Oxford and Cambridge and the Durham Colleges, University College (now the University of) Reading ranks highest in regard to the number of full-time students thus accommodated. The number of students in lodgings was 14,070, or 34 per cent. of the total number.

Contemporary Birthdays.

May 15, 1847. Sir E. Ray Lankester, K.C.B., F.R.S.

May 18, 1867. Prof. Edward Fawcett, F.R.S.

May 19, 1876. Prof. William King Gregory, Corr. Mem. Zool. Soc. Lond.

May 22, 1860. Major B. F. S. Baden-Powell, F.R.A.S.

May 23, 1864. Sir Arthur Smith Woodward, F.R.S.

Sir E. RAY LANKESTER, emeritus professor of zoology in University College, London, and a foreign member of the Paris Academy of Sciences, is a Londoner. He was educated at St. Paul's School, Downing College, Cambridge, and Christ Church, Oxford. From 1891 until 1898 Lankester was professor of comparative anatomy in the University of Oxford; afterwards he was for some years Fullerian professor of physiology in the Royal Institution. In 1898 he was appointed director of the Natural History Departments of the British Museum, retaining office until 1906. Just over forty years ago he received one of the Royal medals of the Royal Society, at the hands of Prof. Huxley, its president, for labours even then extending over two decades, in the field of animal morphology and palæontology. We believe that no other man of science lives to-day who can lay claim to any kindred personal act on Huxley's part. "Prof. Lankester," said the president, "has been active in many directions, and has everywhere left his mark, not only as an energetic teacher and accurate worker and a philosophical thinker; but as one who, in times when the example is more than ever valuable, has always been careful to remember that speculation should be the servant and not the master of the biologist."

Prof. FAWCETT, who holds the chair of anatomy and is Dean of the Faculty of Medicine in the University of Bristol, was educated at Blencow Grammar School and the University of Edinburgh.

Prof. WILLIAM K. GREGORY, palæontologist and morphologist, was born at New York City, and educated at Columbia University. Research assistant to Prof. H. F. Osborn (the newly-elected foreign member of the Royal Society) from 1879 until 1913, he afterwards became assistant curator of the Department of Vertebrate Palæontology in the American Museum of Natural History, where he is now curator of the Department of Comparative Anatomy. On his special subjects Prof. Gregory has long been an illuminating lecturer in Columbia University. He is the author of "The Orders of Mammals" (1910), "On the Structure and Relations of Notharctus, an American Eocene Primate" (1919), "The Origin and Evolution of the Human Dentition" (1922).

Major B. F. S. BADEN-POWELL was educated at he Charterhouse. Early interested in aeronautics, he devised man-lifting kites. He is a past honorary ecretary and past president of the Aeronautical Society, n institution which owes much to his energies in days gone by.

Sir A. SMITH WOODWARD, the well-known geologist, was born at Macclesfield, and educated at Manchester Grammar School and Owens College. Entering the Natural History Department of the British Museum n 1882, he attained finally the Keepership of the geological section. Sir Arthur is a past president of the Geological Society, and of the Linnean Society. n 1917 he was a Royal medallist of the Royal ociety.

Societies and Academies.

LONDON.

Geological Society, April 21.—**L. R. Cox**: *Anthracopupa britannica* sp. nov., a land gastropod from the Keele beds of Northern Worcestershire. The occurrence is recorded, for the first time, of a pulmonate gastropod in British Carboniferous rocks. The specimens were collected by Mr. W. Wickham King in 1924 from a grey calcareous claystone, interstratified with the vermilion marls of the lower part of the Keele beds, on the northern slope of Clent Hill. One species is a land shell, referable to the family Pupillidæ; it is very close to *Anthracopupa vermilionensis* (Bradley), from the Coal Measures of Illinois, but is slightly stouter, and differs in detail.—**H. P. Lewis**: On a rock-building bryozoan with phosphatised skeleton from the basal Arenig rocks of Ffestiniog (North Wales). The black, usually ovoid masses in the basal Arenig rocks (Garth Grit) on both sides of the Harlech Dome, have been designated 'lumps,' 'pebbles,' and 'nodules.' On the evidence of etched surfaces and microscope-sections, the structure of these masses is found to be originally organic, but modified later by inorganic processes. A new genus of the Ceramoporidæ of Ulrich is described. It is represented by one species—the earliest bryozoan known in British rocks. It was responsible for the building-up of the nodular masses, which contain a large amount of calcium phosphate.—**C. A. Matley**: The geology of the Cayman Islands (British West Indies), and their relation to the Bartlett Trough. With an appendix on the species of Lepidocyclina and Carpenteria from Cayman Brac and their geological significance, by **T. W. Vaughan**. The Cayman Islands are an isolated group of three islands, with an area of 100 square miles, all very similar in their geological structure and history, although each is a separate faulted block. The islands are built entirely of calcareous rocks free from terrigenous materials other than fine dust. There are two formations present, an older Bluff Limestone, and a newer, Ironshore Formation, lying unconformably upon the former, which makes a coastal terrace with a maximum height of 12 to 15 feet above the sea. The Bluff Limestone, a white, massive, semicrystalline limestone, containing casts of mollusca, badly preserved corals, nullipores, and foraminifera, resembles lithologically many parts of the White Limestone of Jamaica. Cayman Brac is Middle Oligocene, while Little Cayman and Grand Cayman seem to be of Miocene age, not newer than Lower Miocene. On the coastal shelf formed round each island by marine erosion the calcareous Ironshore Formation, with its mollusca and corals of living species, was deposited. Its emergence, in Pleistocene or recent times, as a low platform backed by the ancient cliffs, is probably the result of a fall of sea-level. The almost completely submerged Cayman Ridge on which the islands stand, and the Bartlett Trough which flanks it on the south, are examined in the light of the Wegener hypothesis. The Ridge may once have lain near the Jamaica-Honduras Ridge, with Jamaica itself confronting the Sierra Maestra of Cuba; further, the separation has taken place by the development of a great crustal fissure (initiated probably in Pliocene, or at the earliest in Middle Miocene, times) which has become the Bartlett Trough.

PARIS.

Academy of Sciences, April 12.—**Paul Appell**: The arithmetical nature of Euler's constant.—**André Blondel**: Contribution to the theory of the musical singing arc.—**Léon Guillet**: The addition of nitrogen to ordinary and special steels. Superficial hardening of certain steels is produced by heating to about 500° C. in a current of ammonia. A study of this reaction, with special reference to the nature of the steel, shows that ordinary steels become fragile. Nickel steels give no increase in superficial hardness, but slight increases are shown by chrome steels, manganese steels, silicon steels. Remarkable increases are given by aluminium steels.—**Winogradsky**: The fixing power of soils (for nitrogen).—**Paul Vuillemin**: The family of the Sarcosporidia.—**Bertrand Gambier**: The deformation of tetrahedral surfaces, with conservation of a conjugated network and rigidity of an asymptotic.—**Miécislas Biernacki**: A theorem of M. Denjoy.—**Julius Wolff**: A generalisation of a theorem of Schwarz.—**Ernest Esclangon**: The mechanical and optical asymmetry of space in respect to the absolute movement of the earth.—**R. Baticle**: A solution of the problem of a wall sustaining a powdered mass.—**Turpain** and **Bony de Lavergne**: Experiments on the Magnus effect.—**A. Dauvillier**: The nature of soft X-rays. A discussion of the causes of the differences between the experimental results of the author and Holweck.—**Francis Perrin**: The fluorescence of long duration of salts of uranium, solid and in solution. Experiments confirming the view that the luminescence of uranium salts is a fluorescence of long duration, analogous with the short fluorescence of certain colouring matters, such as fluorescine.—**Ch. Courtot** and **C. Pomonis**: Researches on diphenylene sulphide. A development of the most probable formula for the diaminodiphenylene sulphide described in a previous communication.—**A. Demay**: The cristallophyllian stratigraphy of the Pilatus massif near Saint-Étienne.—**Paul Corbin** and **Nicolas Oulianoff**: The elements of the two tectonics, hercynian and alpine, observable in the protogine of Mont Blanc.—**Michel-Durand**: The solvents for tannins. The tannins soluble in alcohol or in acetone are also soluble in water, and the use of these liquids in succession for extraction, even including ether, gives no higher yield than hot water.—**Th. Kraschenninnikoff**: The gaseous exchanges of the brown algæ of the Arctic region exposed at low tide. In the Arctic region (island of Kildine) in algæ exposed to the air at low tide, there is very energetic assimilation, which, under good lighting conditions, is much more intense than the respiration, resulting in the formation of large quantities of organic material.—**Émile F. Terroine** and **R. Bonnet**: The causes of the specific dynamic action of the proteids.—**E. Fleurent**: The composition of the seed of fenugreek and its admixture with wheat intended for milling. The presence of fenugreek seeds in wheat, owing to the objectionable smell of its essential oil and bitter taste of its resin, renders flour made from such wheat unsuitable for bread-making. Even such a small proportion as ¼th per cent. of fenugreek seeds can be tasted in the bread.—**Constantino Gorini**: The action of streptococci on milk.

Hours, Wages, and Welfare in Industry.

OF all the problems which have been left to Great Britain as a legacy of the War, that of unemployment has proved to be the most tragic, most persistent, and most intractable. Ever since the short-lived boom of 1919 the nation has had to contemplate week by week the spectre of anything from 1 to 2 million workers unemployed. Although the anxiety arising from this fact has been alleviated in some degree by the knowledge of the relief arising from the operation of the Unemployment Insurance Act, it is to our credit as a nation that we have never ceased to concentrate attention on remedies for this evil as well as on palliatives of its worst defects. Private investigators have inquired carefully and scrupulously into the effects of unemployment, and official analyses of the unemployed have been made in order to get so far as possible to the tenacious, deep-seated roots of the trouble.

It was not, therefore, surprising that when the first Labour Government came into power it should follow the excellent British tradition of appointing a committee to inquire into the conditions and prospects of British industry and commerce, with special reference to the export trade. Accordingly, the Committee on Industry and Trade was set up by Mr. MacDonald on July 28, 1924, with a distinguished and impartial personnel ranging from members responsible for the conduct of large industrial undertakings, with economic experts and the chief economic adviser to the Government, to representatives of the wage-earners As is the British custom also, the political colour of the Commission was blended in a judicious pattern. In a memorandum accompanying the terms of reference, the Committee was asked to direct its attention first to the position of British Overseas Trade and the prospect of British participation in the markets of the world. In pursuance of this request, the Committee issued in July 1925 a first volume entitled "Survey of Overseas Markets," in which it surveyed Overseas trade and brought together in a convenient and accessible form a mass of valuable data upon that subject.

Another of the three questions put up to the Committee in the memorandum referred to was that of the relations between those engaged in production. In the words of the memorandum, "This will involve inquiry into methods of industrial remuneration, the main causes of unrest and disputes, and the methods of avoidance or settlement of disputes, as, for example, co-partnership, co-operation, wages boards and voluntary arbitration, State regulation of wages, and compulsory arbitration and compulsory enforcement and extension of agreements."

Faithful to this term of reference, the Committee has now produced a second volume,[1] which covers the ground indicated by our quotation. The main part of the book consists of six chapters on population, wages, conditions of labour, unemployment, machinery for industrial negotiation, and statistical data respectively. As the terms of reference required the Committee to have special regard to the export trade, the investigations were limited to those industries which account for the major part of exports of British manufactures, namely, coal mining, iron and steel, engineering and shipbuilding, electrical manufacturing, cotton, woollens and worsted, chemicals, and clothing. The information in the six chapters referred to has, of course, been mainly supplied by the Government Departments concerned. Upon the Registrar-General fell the labour of providing statistics as to population; the rest of the burden was mainly carried by the Ministry of Labour, the Mines Department, the Board of Trade, and the Home Office. In what is termed an introduction, of 53 pages in length—practically a review of the mass of the information gathered—the Committee surveys the field of labour and brings out the principal facts and tendencies. The keynote of this survey is to be found in the statement that "the primary objects of this volume are descriptive throughout and no systematic attempt has been made therein to trace and co-ordinate the underlying causes of the phenomena described, still less to formulate conclusions as to remedial measures."

The publication of the volume rests upon the Committee's belief "that the impartial ascertainment and publication of authoritative data on certain essential aspects of industrial relations in Great Britain will not only be of value to a large number of persons who desire a trustworthy book of reference, but will also conduce towards the better understanding of present-day economic problems, both by limiting the field of controversy and by facilitating and clarifying discussion." To the constant student of economics, therefore, this volume brings little added knowledge. It is a praiseworthy book of reference, but little more. Nevertheless, on that account alone its value is not to be denied. We may therefore with advantage pick out some of the principal facts established in order the better to equip ourselves in our consideration of the industrial problems which Great Britain has yet to solve.

Although it is customary to speak of four agents of production, namely, land, capital, labour, and organising ability, in the ultimate analysis, all is seen to depen upon the productivity of human effort. Land i limited in quantity, and has its own degrees of fertility Capital is itself the fruit of productivity, stored up i quasi-permanent form. The free gifts of Nature, th sunshine and the rain, are beyond human choice c control. Labour therefore, excluding for the preser its small but important sub-class of organising ability is of supreme importance to the Committee on Industr and Trade. The growth and distribution of th population thus naturally receives first attention i this report.

During the decade from 1911 to 1921, containin the War years, the increase of population in Grea Britain was less than 2 millions, or scarcely mo than half of that of the preceding decade from 1901 t 1911. This figure, of course, includes children, wive and others who followed no industrial occupation, an omitting this, the War decade showed an increase i the number of occupied persons, whether employe or employees, of just over a million. But the Wa with its heavy loss of adult male lives, left its mar in the altered distribution by ages of the occupie population. Practically the whole of the millio increase referred to took place in the older-age group those above 45 years. This decline in the proportio of workers of the most efficient ages cannot be ove looked in weighing the degree of productivity availab to industry, and the Committee, in noting this fac points out also that future years are likely to sho this factor of disadvantage in an increasing degre Britain has thus two million more mouths to fee with one million more workers, but the producti efficiency of the working population as a whole mu be taken to have been diminished, though but slightl by the heavier proportion of workers in the older-a groups. Here is one definite result of the War, whi is not likely to be remedied by natural events for ma years. To offset it, one must look largely to improv ments in industrial organisation.

Another striking problem which has remained to from the War is the mal-distribution of the worke among the industries. Statistics on a comparab basis for 1911 and 1921 are available for England a Wales only. Speaking in terms of percentages of th number of occupied persons, we notice that for agr culture the figure has fallen between 1911 and 19 from 7·55 to 6·54 per cent., for the manufacture clothing (including boots and shoes) from 6·45 to 4· per cent., and for building, decorating, and contracti from 5·29 to 4·42 per cent. To those who ha followed the history in recent years of agricultu economics, the fall in this industry will come as surprise. But the Committee on Trade and Indust not concerned with this, and the absence of any mment is not surprising. We had, however, expected me comments on the two other decreases we have entioned. Perhaps it is assumed, and rightly, that e public is already sufficiently aware of the difficulties providing the additional labour in the building industry. But what is the reason for the fall in the number f persons occupied in manufacturing clothing? We ave two million more to clothe, yet the percentage of orkers engaged has decreased by more than 25 per cent.

---

[1] "Committee on Industry and Trade. Survey of Industrial Relations Based on Material mainly derived from Official Sources, with regard to Industrial Remuneration, Conditions and Relationships in Great Britain and certain other Countries so far as available, together with Statistical Tables." With an Introduction by the Committee. Pp. v+497. (London: H.M. Stationery Office, 1926.) 5s. net.

It is not, however, so much the decreases as the creases in various industries which invite attention. oal mining in 1921 occupied 6·59 per cent. of the cupied population, compared with 5·96 per cent. in 11. Here, again, the Committee rightly assumes that tle comment is needed. In the chemical and paint dustry the percentage has risen from 0·81 to 1·15, striking increase. In metals, machines, implements d conveyances, the increase is from 9·31 to 12·37 r cent. The Committee is content to record these cts. We should have welcomed some exploration of eir causes, their effects, and the possibility of some elioration of the economic disadvantages to which ey have given rise. How far, for example, are the nt Restriction Acts, with their paralysing effect on bility, to be saddled with the responsibility for the rsistence of these abnormalities? At a later stage the introduction, the Committee discusses the lation between sheltered and unsheltered trades, but is important fact of supply is not brought into the ena. It is considered that the prime difference tween sheltered and unsheltered trades depends on e element of time. From that we must dissent. regards the relation of these facts also to unployment, the Committee is content to state that does not deal with the large problem of the mobility labour, because there are no official data enabling cumulative effect to be estimated.

After treating of population, the Committee turns the kernel of this part of the terms of reference, d deals with wages and earnings. As is pointed t, on this subject there is the view of the emyer and the view of the worker. To the former, e governing consideration is the amount of earnings r unit of output; to the latter, the primary conderation is the total quantity of necessary or desirable mmodities which he can purchase with his weekly rnings. The necessity of distinguishing, so far as acticable, between wages as an item of cost and as means of livelihood is therefore emphasised. Here ain we are faced with the lamentable paucity of icial statistics. There has been no comprehensive vey of wages since the partial inquiry of 1906; re has been no effective census of production since 1907; there has been no adequate inquiry into the household budgets of the workers since 1904. In the present year we may hope to have the results of official inquiries in the first two of these fields; as for the third, we must still possess ourselves in patience. The Committee records, therefore, that it is compelled to resort to imperfect methods of estimate.

From the slender information available, the Committee concludes that the net rise in money wages per week on the whole averages between 70 and 75 per cent., but that, first, the proportionate rise has been greater for the less skilled than for the more highly skilled workers; and secondly, the proportionate rise has been less for industries directly exposed to the blast of foreign competition than for those which are less exposed to that competition. As already mentioned, it is the real cost of labour with which the employer is concerned, and the Committee therefore proceeds to examine this aspect of the question. Since the index number of wholesale prices for 1924 was about 66 per cent. higher than its pre-War level, it follows that, *ceteris paribus*, there has been, on the average, a small increase in real wages, and therefore a small increase in the wages element in the real cost of production. But here again there is the same condition of unequal distribution between the sheltered and unsheltered industries, or unexposed and exposed industries, as the Committee prefers to call them.

The reliability of these conclusions is, however, somewhat weakened by the fact, pointed out by the Committee, that everything depends upon the *ceteris paribus*. If other factors have not remained constant, if the efficiency of labour or of industrial organisation, for example, has varied, then some of this reasoning must be revised. The Committee therefore postpones its final conclusions until the results of the evidence it is taking and of its own special investigations can be reviewed. When this point is reached we may hope the fallacy of averages will be borne in mind, and that the Committee will be content with recognised lines of statistical technique.

From the point of view of the worker, concentrating on the purchasing power of his weekly wages, the cost of living index must be substituted for the index of wholesale prices. As the mean of the monthly numbers for that index was 75 per cent. above the pre-War figure, the Committee notes that, again on the average, there was little if any change in real wages to the worker, but that the same disproportionate distribution appears between skilled and unskilled men, between sheltered and unsheltered trades. The validity of all these conclusions is, however, impaired by the limitations to which the evidence on which they are based is subject. It is stated, for example, that "the information at the disposal of the Ministry of Labour is insufficient to enable the average percentage increase for all industries and occupations to be computed with precision, but it is estimated. . . ." Again, "No information is available, however, as to changes which have occurred in rates of wages in industries, or sections of industries, in which neither standard nor minimum rates, nor the general amount of increase or decrease in rates of wages, have been fixed by collective agreements, arbitration awards, Statutory Orders, etc." And finally, "No corresponding figures [of pre-War and 1925 wages] can be given as regards the earnings of piece-workers, who form a large proportion of the skilled work-people in many of the principal export trades."

We do not wish to dwell too strongly on these defects, but that there may be a substantial difference between estimates based on rates of wages and facts as to actual earnings is shown, on the one hand, by the inclusion of skilled engineers in a table under the heading of "Increases substantially below the general average," and on the other hand, by the definite statement, based on statistics furnished by the Engineering Employers' Federation, that for engineering workers, skilled and unskilled, the general average rise of money earnings was about 73 per cent. when working on piece, and 65 per cent. when working on time, or taking both together, and including the shift over from time to piece which has taken place since 1914, an increase of 73 per cent. This compares with the 75 per cent. increase in the cost of living. As we are also told that piece-work is widely prevalent in the textile, mining, iron and steel and clothing groups, but that time work is still much the more usual method in the engineering and kindred trades (despite the tendency to change from time to piece), we begin to have some doubts whether the difference between sheltered and unsheltered industries is so clean-cut and definite as the Committee's report suggests.

We have only space to mention some of the other topics of absorbing interest brought together in this survey. There are interesting tables of the movements of real wages in other countries, but the impossibility of relating different national standards of living, to say nothing of the incomparability of national methods of calculating the movements in the cost of living, robs them of much value. Comprehensive particulars are here brought together of changes in hours of labour, welfare work, unemployment, conciliation and arbitration machinery, all relevant to the problems of industry to-day. We notice, for example, that the time lost through sickness amounted in 1924 to more than 26 million weeks, or more than eighteen times the number of weeks (1·4 million) lost through trade disputes in the same year. Yet there are many wh deem national expenditure on health and welfare worl a waste of money.

Every thoughtful student of national well-being mus be very grateful to the Committee on Trade an Industry for this publication. We may perhaps b permitted also to include in this recognition of worl well done all the labour which fell upon the Governmen Departments concerned. Two-thirds of the Committee' task has been accomplished, but the greater part stil remains. The productive capacity and organisatio of British industry, the supply and efficiency of capita labour and management, the present extent of larg scale production, its possibilities and limitations, th current methods of industrial and commercial financ etc., have yet to be investigated. In this sphere, anywhere, the Committee must come to real grips wit its problem, namely, the root causes of the depressio of the coal, iron and steel, textile and other industrie which have steadily lost ground in the last seven year We look forward eagerly to the remaining volume, which the Committee will deal with these baffli problems, and on which the justification for its appoin ment and labours will be almost entirely judged.

W. H. COATES.

Avian Migration.

Problems of Bird-Migration. By Dr. A. Landsborou Thomson. Pp. xv+350. (London: H. F. a G. Witherby, 1926.) 18*s*. net.

THE study of avian migration has been elevat to a higher scientific plane than heretofore Dr. Landsborough Thomson in the book under revie The phenomenon of migration has at all times been secret of absorbing interest and speculation not on among scientific men but also among those whose hob has been of a scientific nature. As a means where evidence can be collected to assist the biologist and help solve the larger biological problems, a valua source can be found in avian migration, now that importance has been recognised. "To study t migration of birds is to investigate the nature of anin behaviour, and to do this is to probe the inn mysteries and to ask the very meaning of L itself" (p. 327).

The book is unsatisfactory in the sense that it fa to satisfy, but at the same time it completes the pictu in as thorough a manner as our present knowledge w permit. A creditable, over-cautious strain permea the whole book, which is delightfully free from dogma or fanciful theories.

Part I. summarises all known facts bearing on t subject, serving as an excellent basis for further inves gations. Part II. specialises in individual migration with special reference to the results of bird-marking. Part III., which deals with the main complex problems of bird migration, stands out as the most important part of the book, giving much food for thought and many lines for further investigation. In the past, avian migration has been studied as a whole, theories being frequently built up to fit in with existing evidence, which, to say the least of it, has been fragmentary. In the first place, migration is not a phenomenon confined to birds alone, and, if the secret is to be probed, some knowledge must be gained of the migrations of fishes, insects, and mammals. The periodic transfer of residence is identical in many branches of life, though probably the stimuli and initial causes are widely different.

It appears to the writer that the correct study of the larger problems of migration is to examine in closest detail the movements not only of single species but also of individual communities among birds; and indeed, as one can now do with the aid of bird-marking, the movements of the individual bird itself.

Assuming for the moment that both the Darwinian and Mendelian principles express truths on evolution, and that the making of the species in some cases follows one, sometimes the other, and sometimes a combination or modification of both or either, can we not apply such doctrines to a problem such as migration? Avian migration as witnessed to-day, ranging, in the case of some high-level birds, from a simple altitudinal move from alpine meadows to sheltered valley, to the vast periodic movement of other species from the Arctic to the Antarctic, have every degree of intermediate form, and the one could easily, as argued by Dr. Landsborough Thomson, spring from the other. Then we have what Dr. Thomson terms irregular migration phenomena (Chapter vii.). Birds which adopt this habit, dispensing with the slower Darwinian principle, perform in one bound an act which in other birds may have taken countless ages to evolve in its perfect shape.

No simple explanation, however, fits every case; hence the difficulty. The stimulus which sets free the desire to migrate may have a hundred variations. That the desire is deep-seated is beyond question, and it is difficult to believe that such a desire is not as much a part of the germ plasm as is the ability of birds of a species to build nests of remarkable similarity. Dangerous as are analogies to logic, nest building is as regular, as true to type, and as accurate in heritable qualities as is migration, and is probably subject to precisely the same laws of evolution as the formation of a species or of a geographical race.

It may be found, and probably Dr. Thomson would agree, that a particular migration route, or a particular stimulus which sets free the desire to migrate, or the particular means by which birds find their way on migration, will apply to a particular species or even a community within that species, and will not be true of others apparently carrying out a similar migration. This can only be verified by an intensive study of the species or individual. When that is complete it will be time enough to generalise and find out what influences are common or general.

In his last few chapters Dr. Thomson seems wilfully to tantalise his reader by nibbling at many by-products of migration. He bites into the much-vexed question of the inheritance of acquired characters. Perhaps space, perhaps mental digestion (or indigestion), forbade more than a bite. But one would have welcomed his views, as migration seems to offer such valuable evidence.

The home of the bird. The original centre of dispersion. Where is it? In many cases, such as the Petchora pipit (*Anthus gustavi*), *Acrocephalus griseldis* breeding in Iraq and wintering almost entirely in east tropical Africa, and *Irania gutturalis*, we find a winter quarters almost as restricted as the breeding quarters. Why again should certain species (*Apus a. pekinensis*, *Falco naumanni pekinensis*, and *Falco vespertinus amurensis*) travel to restricted winter quarters in South Africa? It is most unlikely that the amenities of South Africa were accidentally discovered, or even that such amenities do not exist at nearer ranges in south Asia or Africa. Why do many species travel from north Europe to south-east Asia every year, and others from north-eastern Asia to South Africa? There must be a meaning, and if we knew more about the original home of the bird a clue would be supplied.

Again, why should birds sometimes select a different return route in spring from their autumn route? In addition to the cases cited by Dr. Thomson, two races of the Willow warbler (*Phylloscopus trochilus trochilus* and *eversmanni*) pass through Egypt in autumn in countless thousands, but in spring their occurrence is a great rarity, though in Palestine they occur in spring almost as commonly as they occur in autumn.

The ability of birds to find their way on dark nights and over great distances without the aid of landmarks is perhaps as complex a problem as exists in the whole story of migration, and no attempt will be made here to fathom such a fascinating subject beyond quoting a curious experiment undertaken by the writer near Karachi in 1913.

A night was spent on a sandy beach where the Loggerhead turtle was known to breed, and at a time of year when the young should be emerging from their sandy nests. Both sea and wind were dead calm. On the south side of the beach was the open Indian Ocean. To the north was a deep, wide lagoon, only connected with the sea at high tide. Young turtles do not all emerge from their sandy nest in a bunch, but do go singly or in small parties, and a few early ones give one warning of the general hatching. Two active nests were located, and in each case the sloping beach was levelled and a sand parapet erected four feet from the nest in order to prevent slope of terrain or sight of sea acting as hints in direction to the babies. The first nest gave its young to the world with the earliest blush of dawn, the second nest after sunrise but before the sunlight bathed the beach, a tall belt of palms screening the rays. In eleven observed cases out of a total of nineteen, the babies scuttled towards the open sea, over our parapet, and into the ocean without a moment's hesitation. In the other eight cases there was slight hesitation, which seemed due more to daze than to uncertainty. The slight traces of those baby flippers on the sand were obliterated by our party as soon as they were formed. In this case the roar of the surf, the smell of the ocean, wind, sight, and slope of ground were eliminated so far as one could, and yet these babies, but a few minutes old, acted without undue hesitation and apparently certain knowledge. It is indeed difficult to deny the existence of inherited knowledge based on ages of experience.

The young cuckoo, and many other birds, set out every autumn at the appointed time on a definite journey with a definite object, without apparent guidance. Instinct is a lazy and meaningless explanation. Science requires something more exact, based on evidence. But it is to instinct we would address the question: Why?

There is one biological aspect of migration to which we had wished Dr. Thomson had addressed himself. He does not touch on the influence of migration on power of flight and evolution. Is there such an influence? Must we accept the old dogma that migratory birds have wings more suited to migration than others which are resident? Are we to believe that a mere incident in a bird's life (all-important though it be) will influence structure?

Dr. Thomson has taken us all up one rung of the ladder in a book where simplicity, logic, and science go hand in hand. As a book of educational value, or as a reference book, the work is unique. It has summarised, modernised, and, so far as existing evidence allows, helped to elucidate problems of immense scientific import. Migration has at last received the attention it has deserved at the hands of a trained scientific brain and has been lifted up from the plane of conjecture and spasmodic research to that of sound logic and scientific analysis.

Surveying.

(1) *Text-Book of Topographical and Geographical Surveying.* Edited by Col. Sir Charles Close and Col. H. St. J. L. Winterbotham. Third edition. Pp. iv+366. (London: H.M. Stationery Office, 1925.) 15*s.* net.

(2) *Surveying Instruments: their Design, Construction, Testing and Adjustment.* By R. M. Abraham. Pp. ix+309. (London: C. F. Casella and Co., Ltd., 1926.) 7*s.* 6*d.* net.

(3) *Surveying for Everyone.* By A. Francon Williams. Pp. 114. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1925.) 3*s.* 6*d.* net.

(1) THE "Text-Book of Topographical and Geographical Surveying" embodies the experience of surveyors who have carried out surveys in most parts of the British Empire, and under very varied conditions. Each method, or process, included in the book has been tested and used with success, and is described by a writer who has employed it. The book has therefore gained the confidence of practical surveyors. The second edition having been out-of-print for some months, the appearance of the third edition has been eagerly awaited, and will be warmly welcomed.

The third edition is the same size as the second, but the type is a little smaller, so that more information is contained in the same space. The price has been doubled, but the book is still good value.

Much new information has been added, but few alterations or corrections have been found necessary in the original matter. There are three new chapters dealing with surveys in war, photographic surveying, and the prismatic astrolabe. The chapters on surveys in war and photographic surveying are necessarily little more than introductions to large subjects. The prismatic astrolabe is an instrument which is likely to be used, in conjunction with radio time signals, for the determination of astronomical longitudes. A clear account is given of the methods of using it, and reducing the observations. A new section dealing with the reception of radio time signals is a valuable addition to the book. Another new section is devoted to Prof. Jeffcolt's direct-reading tachymeter.

The most important change that has been made in the original matter is the substitution of the mid-latitude formula for computing geographical latitudes, longitudes and reverse azimuths for Puissant's method. The computations involved are simpler, and the results not less accurate.

In a book which contains so much information, it is perhaps unfair to search for omissions, but space might perhaps have been found for a description of the Transverse Mercator projection, which is recommended for war maps, and may be adopted for the small scale maps of the Ordnance Survey. The elimination of distortion in field sheets, by pasting them on to a thin sheet of aluminium or zinc, before mounting them on a plane-table, might also have been mentioned, as this is likely to become the standard practice.

The book deals, in a clear and practical way, with every important problem that is likely to confront a surveyor. It is an excellent example of how a textbook should be written.

(2) In the past, surveyors have often been handicapped by a lack of knowledge of the first principles of optics and instrumental design, with the result that they have not been able to make the best use of their instruments, or competent to suggest improvements in the design of them. "Surveying Instruments" gives a clear and concise account of every instrument used by the surveyor, and an analysis of most of the instrumental errors which may be expected. It is a book which should be consulted by every surveyor who wishes to use his instruments to the best advantage, and it is to be hoped that it will establish a closer liaison between the surveyor and the instrument maker. On the other hand, the instrument designer should remember that the way to test his instruments is to observe with them on a cold, dark, windy day. If the instrument stands steady in the wind, if all the necessary adjustments can be made with frozen fingers, and the required observations made in dull light and without any uncertainty, the instrument will earn the surveyor's confidence. But if it fails in any of these respects, he will probably discard it for another, which, though less accurate, is better adapted to field work.

It is probable that in the most accurate modern instruments the errors of observation are largely due to varying and unequal illumination of the field of the micrometer microscopes. This is a point that deserves the attention of the instrument designer. The Wild theodolite, recently designed and manufactured in Switzerland, is arousing much interest amongst surveyors, and it is to be hoped that British instrument makers will study, and test, the new methods and principles incorporated in this instrument.

An account might perhaps have been given of the 'constant bubble' spirit level, and of the latest pattern of geodetic levelling staff as used on the Ordnance Survey.

(3) This is a small handbook designed for the instruction of those who have no knowledge of surveying, and whose mathematical knowledge is limited to simple arithmetic. It describes in simple language how a survey of a small area may be made with a chain, a plane-table, or a prismatic compass. The computation of areas, contouring, and scales are also dealt with.

The Manufacture of Sugar.

Sugar. By Geoffrey Fairrie. Pp. xiv + 233 + 62 plates. (Liverpool: Fairrie and Co., Ltd., 1925.) 12*s.* 6*d.* net.

SUGAR, the sucrose of the chemist, is very widely disseminated in the vegetable kingdom, where in many plants it forms the most important carbohydrate reserve substance. Originally consumed as a condiment, or even taken as a medicine, it has during the last few centuries become one of the most important articles of dietary among the nations of the world. Great Britain, which next to the United States is the largest sugar-consuming country in the world, consumes sugar in different forms at the rate of more than 90 lb. *per capita* per annum. The two chief sources of sugar are the sugar-cane, *Saccharum officinarum*, and the sugar-beet, *Beta vulgaris*, whilst sorghum, maple, and palm occupy subsidiary positions.

In view of the importance of sugar as a food material, a book on the subject of its manufacture, which enables the general public to understand how it is extracted from plants, and how it is refined into a product fit for consumption, should be welcomed. The author of the work before us states that his object has been to present general information on the subject of sugar in such a form that it can be understood by the laity. But far more than this has been done. The author has produced a book not only for the laity, but one which, in many parts, may also be studied with advantage by the intending technician. At the present time the technology of sugar manufacture has increased in importance in Great Britain, in view of the rapidly developing beet-sugar industry.

Pure science is touched on in this work to a slight extent, and most of the information given is of a 'scrappy' character. The object of the book is, however, to deal with the practical side of the subjects, and it contains a complete description of the manufacture of sugar from cane and beet, giving illustrations of the plant employed. The diagrams giving the general arrangement of plant in a cane-sugar and beet-sugar factory are particularly instructive. The separate plant employed, vacuum pans, centrifugal machines, etc., are clearly described both in the text and by illustrations. Some space is devoted to decolorising charcoal and carbons—their method of preparation and use. The physiology of sugar is dealt with, and finally the analysis of sugar by the polarimetric method is described.

We cordially commend this work, not only to the general public, but also to those scientific men, chemists, engineers, etc., who desire to obtain a succinct account of the manufacture and refining of sugar.

ARTHUR R. LING.

communicating to those that seek their aid only such information as is based on accepted fact. The monograph may indeed be recommended as a model for those who seek to gain the sympathetic understanding of the community they serve and thus to secure for their science further opportunity.

Electrical Photometry and Illumination: a Treatise on Light and its Distribution, Photometric Apparatus and Illuminating Engineering. Pp. xvi+427. By Prof. Hermann Bohle. (London: Charles Griffin and Co., Ltd., 1925.) 25*s.* net.

THIS second edition of Prof. Bohle's work is considerably revised and extended and is much more complete than his original treatise, which was based on lectures delivered at the University of Cape Town. The opening chapters follow the now familiar order, and are well adapted for the use of students. Chap. i. deals with photometric quantities, Chap. ii. with radiation and its effects. Subsequent chapters deal with the eye, photometric apparatus, the testing of electric lamps, shades, globes and reflectors, and illuminating engineering in general. The sections on photometric apparatus and the testing of electric lamps and illumination are exceptionally full.

Throughout the book the author shows himself conversant with recent work in Great Britain and the United States, though the illumination-photometers described appear to be mainly German and American, and the most recent British models of the lumeter and luxometer type seem to have been overlooked. The final chapters deal with practical problems, such as the lighting of schools, libraries, churches, theatres, etc., and there is a special section on industrial lighting. We notice that a reference is made to the first report of the Home Office Departmental Committee on lighting in factories and workshops. In a further edition some account might be given of subsequent reports and of the contents of American codes.

The book contains some effective illustrations, including a number originally presented before the Illuminating Engineering Society in England. Whilst the title conveys that the work is devoted to *electric* lighting, it might be advisable to include some reference to natural lighting, as comparisons of conditions by natural and artificial light are helpful to the student. At the end of the book there is a useful bibliography and an adequate index.

Geology of India: for Students. By D. N. Wadia. Second edition. Pp. xx+400+20 plates. (London: Macmillan and Co., Ltd., 1926.) 18*s.* net.

THE second edition of this work follows closely on the lines of the first, and, by the use of small type for details and subsidiary matter, the bulk has not been increased, in spite of the additions needed to bring it up-to-date. In a book which, in less than 400 pages of text, covers the whole ground of the geology, both pure and applied, of a region so extensive as the Indian Empire, the information must at times be pemmicanised, but in any criticism it must be remembered that one purpose of the book is to provide students with answers to examination questions. For the rest, the judgment passed in our review of the first edition might be repeated almost word for word; the general commendation remains as true as the criticism of certain passages which remain almost unaltered.

An outsider may marvel at the confidence with which the unfossiliferous, presumably pre-Cambrian, rocks of widely separated regions are correlated, and it is surprising to find that the great valleys of the Himalayas are still unhesitatingly accepted as examples of antecedent drainage. At the outset stress is laid on the time-honoured distinction between the peninsular and extra-peninsular regions of India; in this the author follows earlier writers, and will doubtless be followed by later, though the advance of knowledge has shown that the distinction, true enough as regards existing geography, is, when applied to geology, merely a partial view of one aspect of a many-sided problem. Yet with all this the book remains a useful one, and the only one of its sort at present available.

A Treatise on Hydromechanics. By Dr. W. H. Besant and A. S. Ramsey. Part 1: Hydrostatics. Ninth edition (revised). Pp. viii+136. (London: G. Bell and Sons, Ltd., 1925.) 7*s.* 6*d.* net.

"BESANT and Ramsey" is a classic, and has been so for several generations of students. It is, therefore, of some considerable interest that this—the ninth—edition should be very appreciably modified on production. It is not stated in the preface that these alterations are the result of any changed outlook by the author on the scope of the work or on the manner of presentation. The abolition of the order of merit in the Tripos makes it no longer profitable for the average student to devote much of his time to hydrostatics or to the solution of elaborate problems. In conformity with this, a substantial amount of the book work in previous editions has been omitted, along with numerous examples. We do not think the book has suffered from this at all; on the contrary, it has probably become much more readable to a larger number of students, for whom the parts that are essential have been retained. It is, however, an interesting illustration of how the examination system practically decides the text-book, and the text-book the teaching.

Wire-Drawing and the Cold Working of Steel. By A. T. Adam. Pp. 212. (London: H. F. and G. Witherby, 1925.) 40*s.* net.

THE author of this work, being on the research staff of a manufacturer's laboratory, is in a position to put into book form much valuable information on the subject of the wire-drawing and cold working of steel. The main object of the book is to explain the nature of wire-drawing and other cold-worked processes, and little attention is given to actual manufacturing methods except in so far as they are relevant to the main purpose of the book. The various scientific aspects of the subject are treated from a practical viewpoint, and not the least interesting chapters are those devoted to theories of plastic flow in cold-worked metals and to what the author calls the "pathological aspect of cold-worked operations." Judging from the large number of references given at the ends of the various chapters, the author, in addition to giving the benefit of his own practical experience, has done a service to metallurgical science in having included so much scattered information in a book of this kind.

Letters to the Editor.

The Distribution of Freshwater Fishes.

As a mere sciolist in geology it sometimes occurs to me to wonder whether enough attention has been given to the distribution of freshwater fauna in estimating the origin of British land contours and the course of rivers. It is generally accepted that until the North Sea was formed by an extensive subsidence of land in an age not geologically remote, all eastward-flowing rivers south of and including the Yorkshire Ouse were tributaries of the Rhine. The natural result of this should be that the fishes of the Rhine should continue to inhabit its ancient tributaries, as in fact they do in all rivers between and including the Ouse of Norfolk, the Ouse of Yorkshire, and the Trent system. But there is a notable absence from the Thames and the Medway of two species common to the aforesaid rivers and the Rhine—namely, the burbot or eel-pout (*Lota vulgaris*) and the grayling (*Thymallus vulgaris*).

It is true that within recent years grayling have been introduced into the upper waters of the Thames in the interest of anglers, just as in 1816 they were brought by the Houghton Fishing Club to the Test from the Itchen, where they had been established at some previous time. Izaak Walton, writing in the seventeenth century, mentions grayling in the Hampshire Avon, but had they been indigenous there, they would surely have been so in the other rivers of Hampshire also, as the brook trout (*Salmo fario*) undoubtedly is. During the nineteenth century grayling were transported to, and became naturalised in, very many English and Scottish streams in the interest of anglers; but there is no record of any attempt so to distribute the burbot, in which fish anglers take no interest, and in fact it exists only in Great Britain in the rivers between and including the Yorkshire Ouse and the Norfolk Ouse. The question seems to have some significance why these two prolific species should inhabit these rivers and be absent from the Thames.

The following passage in Leonard Mascall's "Fishing with Hooke and Line" (1590) has misled some writers into stating that burbot did inhabit the Thames three or four hundred years ago.

"There is a kind of fish in Holand [south-east Lincolnshire] in the fennes beside Peterborrow, which they call a poult; they be like in making and greatness to the whiting, but of the cullour of the loch [loach]; they come forth of the fennes brookes into the rivers nigh there about, as in the Wandsworth river there are many of them."

It is natural that in writing the "Wandsworth river" Mascall should have been understood to mean the Wandle, which flows into the Thames at Wandsworth. I was deceived in that way myself, until it occurred to me as strange that Mascall should leap suddenly from the Fen district, about which he was treating, to the Surrey side of the Thames. This led me to examine the topography of "the fennes beside Peterborrow," when it became clear that he was referring to the Nen at Wansford, near Peterborough. Probably a London printer familiar with the Wandle thought he was doing the author good service in changing the name.

If, as I think, it may be assumed that neither the burbot nor the grayling ever were natives of the Thames, Sir Andrew Ramsay, had his attention been directed to that fact, might have cited it in support of his theory that the Thames originally flowed westward into the lower Severn valley, which in his opinion was "one of the oldest in the lowlands of England" ("Physical Geology and Geography of Britain"). He considered that the Chalk and Oolite strata through which the Thames flows sloped originally towards the west, and that they received a tilt eastward in consequence of the extensive depression that formed the North Sea.

"When this slope of the Chalk and the overlying Eocene strata was established," he says, "the water that fell on the long inclined plain, east of the escarpment of the Chalk, necessarily flowed eastward, and the Thames, in its beginning, flowed from end to end entirely over Chalk and Eocene strata."

Later geologists have failed to reconcile Ramsay's theory with the formation of the Goring Gap and other clefts in the Chalk escarpment, and I certainly am not competent to call their decision in question. Nevertheless the question still remains (more puzzling to a field-naturalist than to geologists) why burbot and grayling, which are common to English tributaries of the Rhine system, are absent from the Thames and the Medway, and are not native to any westward or southward-flowing rivers in Great Britain

HERBERT MAXWELL.

Monreith.

The Actinium Series and the Lead Ratios in Rocks.

PROF. JOLY in his beautiful work on pleochroic haloes in mica has stressed the importance of a small discrepancy in the observed position of the first halo ring. The discrepancy was shown to vary with the age of the rock It was recognised that the influence of actinium in the formation of these uranium haloes had not been taken into account, but it did not seem possible that the actinium series could have any appreciable effect since it is regarded as only a 3 per cent. off-shoot from the main uranium series. Certainly it could not account for a *shifting* inner ring, and Prof. Joly suggested that the type of thing needed was a variable decay-constant for uranium—such as would arise if uranium had an isotope of considerably shorter life than uranium I. But it can be shown that more than one additional α-ray is needed to account for the observed shifts.

I hope in a more extended article to explain these discrepancies by assuming a different origin for actinium. Dr. A. S. Russell has proposed such a theory by placing AcU_I and AcU_{II} as parent isotopes in the actinium series. He assigned a half-period of 8×10^9 yr. to AcU_I—a period considerably longer than that of U_I. The theory here proposed would indicate a half-period of about $2 \cdot 5 \times 10^8$ yr. (only about $\frac{1}{18}$ that of U_I). The usual connexion between range and decay-constant would assign a range of 3·2 cm. to the α-ray. Such a quick rate of decay leads to some marked contrasts with the assumption of a longer rate of decay. The activity of AcU_I, once as great as that of U_I, is now but a few per cent. On this theory AcU_I would be of no assistance in explaining the departure of the atomic weight of uranium from an integral value, for while the activity of AcU_I is still a few per cent. of that of U_I, the relative mass of it is negligible. An explanation of the atomic weight would have to be sought elsewhere. AcU_{II} also turns out to be necessary, and apparently a range of about

3·4 cm. is prescribed, as will be shown. Equilibrium of AcU_1 and U_1 seems indicated about 10^9 years ago.

These assumptions have a very important bearing on the ages of rocks found from lead or helium ratios. A variable fraction of Ur-Pb would be AcD—the proportion varying from about 40 per cent. in Archaean rocks to 10 per cent. in Devonian. If this is so, a varying atomic weight of Ur-Pb should be found, and in very old rocks a 40 per cent. reduction in ages determined from Ur-Pb ratios would follow. Other interesting consequences and curves showing the shifting of the inner halo ring will be presented later.

An attempt to secure direct experimental evidence of these two α-rays is being made. T. R. WILKINS.

Cavendish Laboratory,
Cambridge, May 5.

Plastic Deformation of Single Metallic Crystals.

IT is a remarkable and characteristic feature of single metallic crystals that when loaded in tension the plastic deformation produced leads to the production of a wedge, the final fracture taking place along the thin edge formed. From the angle of this wedge it is possible to deduce valuable information regarding the actual nature of the mechanism of the plastic flow.

Goucher (*Phil. Mag.*, 48, p. 800, Nov. 1924) has considered the question in relation to his single crystals of tungsten, the relation given being:

$$\phi = 2\tan^{-1}(\tfrac{1}{2}\tan\theta),$$

where ϕ is the included angle between the sides of the wedge and θ is the angle made by the planes on which slipping occurs and the axis of the test-piece.

Although this is given as a general solution, it does not appear to be so, since it is based on the assumption that the point of fracture is distant $D\cot\theta$ from the plane, normal to the axis of the wire, at which the wedge commences to form, D being the diameter of the wire. In the particular case examined by Goucher, however, the formula agreed well with about one-half of the results.

It is possible, however, to treat the problem more generally and, as the result may well become of considerable value, this has been done here. Let ACE and DF (Fig. 1) be successive planes on which slip occurs and p be the perpendicular distance between them. For a uniform wedge the distance through which each plane of atoms moves, *i.e.* AC and DF, will be the same, say q. With ϕ and θ bearing the same meanings as above,

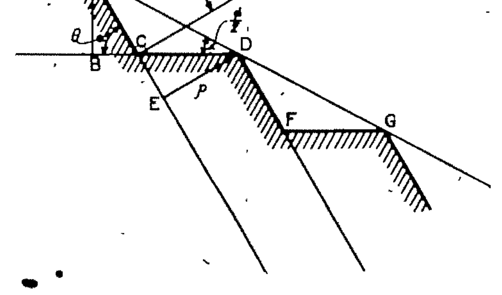

FIG. 1.

$$\cos\frac{\phi}{2} = \frac{q\cos\theta + \dfrac{p}{\sin\theta}}{\sqrt{(q + p\cot\theta)^2 + p^2}}.$$

This relation is now a perfectly general one applicable to any uniform wedge formed by the fracture in tension of a single crystal of any ductile metal. By its use it is possible to extract from the experimental results obtained on these single crystals of tungsten information with regard to the distance through which the atoms move and the number of planes involved which has hitherto remained unrealised.

Of the fractures dealt with in his paper, Goucher points out that they fall into two sharply defined groups with 'sharp' and 'blunt' wedges respectively. About half gave a wedge angle very near to 39°, while the remainder, though giving a mean angle of 54° 12′, varied from about 50° to 60°. For movement on the {112} plane, the one shown to be operative at any rate in the case of the sharp wedges, for the body-centred lattice of tungsten, and for an orientation such that the axis of the wire crystal is perpendicular to the $\{\bar{1}10\}$ plane, θ is $35\tfrac{1}{4}°$ and $p = \frac{\sqrt{2}}{3}d$, where d is the atomic diameter, *i.e.* the distance between the centre of atoms in 'contact.' Putting $q = cd$, the following values of ϕ are obtained:—

c	2/3	1	2	3	10
$\phi/2$ ϕ	15° 50′ 31° 40′	19° 36′ 39° 12′	25° 10′ 50° 20′	28° 15′ 56° 30′	32° 26′ 64° 52′

The significance of Goucher's wedge angle of 39° is now clear. It is almost exactly that which would be produced by slipping on every successive {112} plane through a distance exactly equal to that of the nearest approach of the atomic centres. It is true, of course, that the same wedge angle would result if slipping took place on alternate planes but through a distance of two atomic diameters, but it is certainly less likely that the latter are the conditions than that the movement is through one atomic distance on each plane.

With regard to the more variable blunt wedges, hitherto no very convincing explanation has been offered. Slipping on two symmetrical cube faces would give a wedge with an angle of about 53°, but the wedge itself, if this were the movement, would be at right angles to that actually found. Movement on the {223} plane would also give an angle very near to the mean value for all the tests in this group, but slipping on this plane cannot be regarded as likely. The obvious explanation, however, is seen from the values of ϕ just recorded. Among the values obtained by Goucher there is no angle between 41° and 50°, a fact which is of value in suggesting very strongly that movement takes place on every plane. A movement, for example, through three atomic distances on alternate planes would lead to a wedge angle of 46° 42′, and nothing within 5° of this is mentioned. Now if the explanation of these blunt wedges is to be found, not in a different plane of movement, but in varied degrees of movement on the same—the {112}—plane, and if the movement on every plane is through a multiple of the atomic distance so that the space lattice remains unaltered, the next wedge angle higher than 39° should be 50° and the next higher about 56°. Now 50° is, as we have seen, the minimum angle recorded by Goucher among his blunt wedges and there are six results within 1° of 56°. The largest angle of 60° corresponds with movement through five times the atomic distance.

The results thus suggest that the plastic deformation has taken place by atomic movement on the {112} plane in all cases, on every one of these planes of atoms and by an amount which is in almost every case equal to, or a definite multiple of, the atomic distance, the space lattice thus remaining essentially unaltered and the atoms in their new positions slipping into the depressions left by the removal of other atoms just as would happen if the atoms behaved as hard spheres.

On Imperfect Crystallisation in certain Long Chain Compounds.

A SMALL rectangular crystal flake of behenolic acid, $CH_3(CH_2)_7C\;C(CH_2)_{11}COOH$, was mounted on an X-ray spectrometer in such a way that the long edge of the flake was parallel to the spectrometer axis. It was anticipated that this long edge should be parallel to the *b* axis of the crystal, in analogy to the previously investigated stearolic acid.[1] The revolving crystal photograph obtained with this setting was, indeed, almost identical with the corresponding photograph of stearolic acid. It gave, within the limits of experimental error, the same value for the *b* axis. One difference, however, was the extreme faintness of the long spacing. A second exposure obtained with a random setting gave an entirely unexpected picture. Most of the reflected spots on this second photograph were drawn out into arcs of circles. The picture was very similar to certain powder photographs which show orientation effects. It showed that the sample, in spite of its transparency, its smooth surface, and its straight edges, is not a single crystal. The first photograph leads to the conclusion that the small crystal elements from which the flake is built up cannot be orientated completely at random. The only possible orientation of these elements which is compatible with the observations is the following: All the elements have their *b* axes in common. The degree of freedom which is required to explain the powder effect consists in a rotation round the *b* axis (Fig. 1).

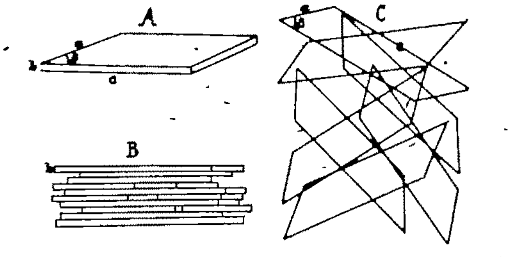

FIG. 1.—A: crystal element, B: arrangement of layers having *b* axis in the plane of the paper; C: another view of the same arrangement having the *a* and *c* axes in the plane of the paper.

An optical investigation of the crystal flake which was made afterwards confirmed the X-ray evidence of an anomalous structure. A true single crystal of either stearolic or behenolic acid shows in convergent polarised light the typical dark bands and coloured fringes. One of the dark bands which lies in the symmetry *b* plane persists in this anomalous crystal. The coloured fringes disappear. It was found later that some of the stearolic acid crystals showed the same phenomena.

An interesting fact is that very similar X-ray photographs to those described here can be obtained from crystals which have been bent. Rocksalt is a well-known example. Another example is maleic acid, the bending of which has been studied in this Laboratory. Supposing a crystal plate is bent in such a way that one of the crystal axes remains undistorted (Fig. 2). The crystal is fixed on an X-ray spectrometer with this axis parallel to the rotation axis. Both rocksalt and maleic acid give under these conditions perfectly normal rotation photographs. For any other setting they show powder effects. The explanation is obvious. The bending produces an internal breaking up of the crystal. The small crystal elements keep the undistorted axis in common—a rotation photograph round this axis shows no signs of this breaking up. The small elements have, after the bending, a random orientation round this axis—a random setting of the crystal gives rise to powder rings on the photographs.

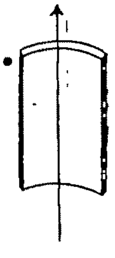

FIG. 2.—Crystal plate of maleic acid bent so that the axis is not distorted.

Behenolic and stearolic acid and most likely many of the long chain compounds grow from the solvent in this abnormal way. The crystallisation seems to go in two steps. The first step consists in an orientation of small crystal elements in parallel layers; the second step is an orientation of these elements parallel to a definite direction in the layer. The fact that these substances can exist in either the degenerate form or in the form of a true crystal illustrates again the instability of their crystals.

ALEX. MÜLLER.

The Fundamental Level of the Iron Atom.

IN a paper on the under-water spark spectrum of iron in *Phil. Mag.* (February 1926) and in a letter to NATURE (March 13, 1926, p. 380), Mr. N. K. Sur raises objections against the main result of the writer's classification of the iron spectrum (*Zeit. f. Phys.*, 23, 135, 1924; 26, 1, 1924), namely, the fact that a ^5D term is the lowest term in the energy diagram and that consequently ^5D corresponds to the normal state of the iron atom.

In spite of the fact that this conclusion was confirmed and independently arrived at by Angerer and Joos, as well as by Gieseler and Grotrian's absorption experiments (*Ann. d. Phys.*, 74, 746, 1924, and *Zeit. f. Phys.*, 22, 245, 1924), Mr. Sur maintains that a still lower term (X) must exist—the real normal state of iron—and that the alleged ground level ^5D is going to play only the rather subordinate rôle of a metastable state. Mr. Sur does not state clearly what the character and the quantum numbers of this hypothetical term X should be, although he intimates on p. 447 of his paper in the *Phil. Mag.* and in par. 2 of his letter to NATURE that he means a quintet or septet S term. But even these would be "at variance with the experiments of Stern and Gerlach on the directional quantisation of atoms." Only a $^1S_0$ would be in agreement with Gerlach's results, and obviously singlet terms cannot occur at all among the low terms of iron. (Comp. the last paragraph.)

A comment by Gerlach (*Ann. d. Phys.*, 76, 197, 1925) that some strong absorption lines around

---

[1] The samples of stearolic and behenolic acid investigated are monoclinic. Their space group is C_{2h}^4. A more detailed description of their crystal structure will be given shortly. In a note to NATURE, vol. 116, p. 45, July 11, 1925, it was suggested that stearolic acid was triclinic. This statement was made at a time when only very poor photographs were available. Photographs from very much better crystals have been obtained since. It was found that the preliminary conclusion with regard to the stearolic acid was erroneous.

2100 Å.U., which were not included in the writer's classification, probably involve this hypothetical low level, is also quoted by Mr. Sur. Unpublished observations of the under-water spark spectrum of iron made in this laboratory show, indeed, a conspicuous group of absorption lines in the region in question, the strongest being λ 2166·79. But these lines involve the differences of ^5D and form a multiplet with a new high $^5P_{1,2,3}$, which has the relative term values 13862·90; 13686·40; 13589·58 cm.$^{-1}$ (if we put according to general custom $^5D=0$). The reality of this term is confirmed by combinations with the low metastable $^5P'$ and an (unpublished) $^3P'$ term in two groups at 3500 and 4200 Å.U. respectively.

We shall show at first that no other term lower than ^5D can exist, and then that *only* ^5D can be the fundamental lower level of the iron spectrum.

In order to illustrate his point, Mr. Sur compares the iron energy diagram with the neon diagram, emphasising that, although neon possesses a complete spectrum of more or less strong lines in the visible and near ultra-violet, it is entirely unjustified to draw any conclusions as to the *raies ultimes* of neon and its normal state; on the contrary, only the investigation of the Lyman region by Lyman and Saunders as well as by Hertz revealed the true normal state of neon. This conclusion, although correct for neon, does not apply to iron, for two reasons. (1) An upper limit of about 9 volts for the ionisation potential of iron is suggested by the general chemical similarity and by the ionisation potentials of the neighbouring elements, while from the behaviour of the iron lines in the sunspot spectrum we know that it must be larger than 6 volts (according to a letter of Prof. H. N. Russell to the writer). The difference $X-{}^5D$ must therefore be rather small, since we know that ^5D is already 8·15 volts = 66,000 cm.$^{-1}$ distant from the surface of the atom. Consequently, Mr. Sur's alleged ultimate lines arising from X should also lie in the near ultra-violet region, as do the strong lines involving ^5D; (2) the other reason for assuming the difference $X-{}^5D$ to be but small, is the appearance of the first iron lines in absorption at 1250°, and on the other hand the—at least approximate—absoluteness of King's scale in classifying the iron lines. If there were a much lower level than ^5D, King would not have assigned the designation "I" or "IA" to most of the lines which are found to be combinations of ^7P ^7D ^7F, ^5P ^5D ^5F with our ^5D. Their behaviour in the furnace would have been characteristic for Class II. or III., since a difference of about 10,000 cm.$^{-1}$ is equivalent to the interval between adjacent classes.

Assuming the difference $X-{}^5D$, or rather $S-{}^5D$, to be even so large as 14,000 cm.$^{-1}$, the combination with ^7P (1) should give a strong doublet or triplet not farther down than 2600 Å.U. We therefore reject Mr. Sur's point that in order to find this term "the spectrum in the Schumann region must be very thoroughly investigated, and then only can the point be settled." Such an investigation cannot possibly offer anything new concerning the low level of iron.

We are now going to show that *only* a ^5D term can be the lowest term in the iron atom, and for this proof we shall use the recent theory of spectra with several valence electrons, which was brought into final shape by Hund (*Zeit. f. Phys.* 33, 345, 1925). The iron atom with its eight valence electrons has for its low term set the choice between three more or less stable electron configurations, which furnish the following low terms:

Two 4_1, six 3_3 electrons: ^5D ^3H ^3F — — —
one 4_1, seven 3_3 " ^5F ^3F ^5P ^3P — — —
eight 3_3 " ^3F — — —.

The theory thus accounts for all the terms of the low metastable set up to a distance of about 20,000 cm.$^{-1}$. None of these three arrangements furnishes a ^7S or ^5S, and others are of course not possible. It furthermore seems entirely impossible to understand how any S term might arise from the normal state of Fe$^+$ ^6D (according to Russell, *Astr. Jour.*, 61, 223, 1925), since, according to a rule given by Kiess and the writer (*Science*, 63, 234, 1926), the transition from the higher to the lower stage of ionisation always amounts to a removal of the 4_1 electron. How this connexion of the arc and spark terms in iron can be traced is shown in a paper of the writer which is going to appear in *Journ. Opt. Soc. Am.*

The writer cannot agree with Mr. Sur that chromium and iron are comparable to any extent. The fact that in both spectra two prominent ^5D terms occur cannot warrant any conclusions of analogy between atoms of six and of eight valence electrons. The occurrence of S terms, only caused on account of five 3_3 electrons giving as a most prominent term (among others) a ^6S, is rather the exception than the rule in complex spectra. Only Cr$^+$, Mn^{++}, and consequently Cr, Mn$^+$, and Mn have S terms. If Mr. Sur doubts that ^5D is the low term of Fe, does he also question the low D and F terms of Sc, Ti, V, Co, Ni and their analogues in the next period?

Peter Mark Roget and the Voltaic Cell.

The transformation of energy from one form to another was realised in a general way before the middle of the nineteenth century, although it was not until the researches of Joule during the years 1838–1848 and the later work of Kelvin and of Helmholtz that the principle of the conservation of energy became an established doctrine of physical science. It is of interest, therefore, to find the principle of energy applied to the study of the voltaic cell by Peter Mark Roget (1779–1869) so early as 1829. This was before the experiments of Faraday on electrolysis, and nearly ten years before the work of Joule on the energetics of a voltaic cell.

In a work on natural philosophy published under the auspices of the Society for the Diffusion of Useful Knowledge, there is a section on galvanism by Roget. He discusses the chemical and contact theories of the voltaic pile, and brings forward powerful arguments in favour of the chemical theory. He explains that chemical action is always accompanied by a "disturbance of electric equilibrium, in consequence of which a certain quantity of electricity is developed, or, in other words, converted from a latent into an active state." He distinguishes between quantity of electricity and its "degree of intensity or tension," which we now call electro-motive force.

Roget then shows that certain conditions are necessary for galvanic action to take place. Denoting the three essential substances of a galvanic cell by A, Z, C, he explains that between A and Z some chemical affinity must exist and that the same action is not exerted between C and either A or Z. A must be a liquid, C a liquid or solid and Z a solid. If these conditions are satisfied he asserts that a continued stream of electricity will circulate in the direction CZA. If A, Z, C represent acid, zinc and copper, it is evident that Roget's conditions do apply to the ordinary voltaic cell. He goes on to say:

"The absolute quantity of electricity which is thus developed and made to circulate, will depend

> upon a variety of circumstances, such as the extent of the surfaces in chemical action, the facilities afforded to its transmission; . . . but its degree of intensity or *tension*, as it is often termed, will be regulated by other causes, and more especially by the *energy* of the chemical action . . . the energy of the galvanic power will depend altogether upon that of the chemical action, and can never be excited when the latter condition is wanting "[1]

Roget then discusses Volta's contact theory of the pile and says:

> " There are several facts which appear so totally at variance with the immediate consequences of its fundamental hypothesis as to warrant us in rejecting it Chemical action between some of the elements of a galvanic combination is so invariably connected with the production of electrical effect that it would be a violation of all just rules of philosophy not to consider these two classes of phenomena as standing to each other in the relation of cause and effect. . . . If there could exist a power having the property ascribed to it by the hypothesis, namely, that of giving continual impulse to a fluid in one constant direction, it would differ essentially from all other known powers of nature. All the powers and sources of motion with the operation of which we are acquainted, when producing their peculiar effects, are expended in the same proportion as those effects are produced; and hence arises the impossibility of obtaining by their agency a perpetual effect, or in other words a perpetual motion. But the electro-motive force ascribed by Volta to the metals when in contact . . . continues to be exerted with undiminished power in the production of a never-ceasing effect. Against the truth of such a supposition, the probabilities are all but infinite."

Thus Roget makes out a good case for the chemical theory. It was not until many years later, after the work of Arrhenius, Van't Hoff and Nernst, that the rival chemical and contact hypotheses were both included in a wider theory.

Roget is an interesting figure in nineteenth century medical science. He had a varied career and lived to a ripe old age. He was in France when hostilities with England broke out again after the Peace of Amiens and was among the unfortunate *détenus*. After a time he obtained his release, as his father had been a citizen of Geneva. After a period spent in private practice he held various official positions as a medical man. He was the first Fullerian professor of physiology at the Royal Institution and was for a time secretary to the Royal Society and editor of the "Proceedings." Among his publications besides his work on Galvanism we may note the following:—

Animal and Vegetable Physiology considered with reference to Natural Theology. Two vols. Bridgewater Treatises. Treatise 5. 1834, etc.

Third edition with additions, etc. Two vols. 1840.

Vol. 2 of the Library of Useful Knowledge. Natural Philosophy, 1829, etc., contains Treatises by P. M. Roget on Electricity—Magnetism—Electro-Magnetism

An introductory Lecture on Human and Comparative Physiology, etc. 1826.

Tentamen physicum . . . de Chemicæ Affinitatis Legibus, etc. 1798.

Thesaurus of English Words and Phrases, etc. *First edition*. 1852.

An 'Eolith' Factory.

PROF. BOULE'S wash-mills are now rivalling the conjuror's hat—from which all sorts of strange things can be taken by an experienced hand. Years ago they produced what were declared to be typical Harrisonian eoliths; now they have given us "a collection of characteristic types, rostro-carinates, etc." (NATURE, April 24, 1926, p 602), such as are found beneath the Red Crag of Suffolk, while, already, a crushing machine has "produced flakes, some of which . . . might have been taken for scrapers of an Upper Palæolithic or even Neolithic culture." From this it would appear that, with a little less stringent selection on Prof Boule's and Mr Etienne Patte's part, these wash-mills and crushing machines of France will soon be shown to be turning out 'typical' flint implements of all prehistoric periods, and the much-discussed Stone Age thus be made to disappear into the limbo of forgotten things.

Before, however, this dire result is brought about, it may perhaps be as well to consider for a moment or two the evidence upon which this latest wash-mill claim is based. Unfortunately, the illustrations accompanying Mr. Etienne Patte's paper in *L'Anthropologie* (Nos. 1, 2 of vol. 36) are of the indifferent order, but, even so, it appears reasonable to state that the specimens figured bear no real resemblance to those found below the Red Crag, and the claim that this resemblance does indeed exist is, it must seem, due to the fact that Prof. Boule and Mr. Patte have failed to distinguish between the type of flaking exhibited by their wash-mill flints and that of those from the Sub-Red Crag detritus-bed.

Such mistaken comparisons are by no means uncommon in prehistoric archæology, for there are still some observers who, for example, are unable to distinguish thermal flaking on a flint from that produced by human blows. That this conclusion is not unjustified is made clear by a letter which I have received recently from Prof. Henri Breuil, who has examined the actual specimens upon which Mr. Etienne Patte bases his case. It may be said that Prof Breuil does not himself regard the Sub-Crag rostro-carinates with a favourable eye, yet he states that the cause of fracture of these wash-mill specimens is not the same as that exhibited by the Sub-Crag flints, and that the ensemble (of the wash-mill specimens) resembles in nothing the tertiary flints, or even those of the ancient palæolithic period.

History is repeating itself in this matter. In the days when the now accepted palæolithic flint implements were not universally regarded as examples of man's handiwork, a book was published in 1880 entitled "The Antiquity of Man," by Thomas Karr Callard and others, and I would ask those interested in this question to compare the statement published in NATURE (April 24, 1926, p. 602) with the following extracts from this book. On p. 33 we read: "We have said that these Palæolithic implements have a *certain* resemblance to the weapons of the modern savage; but instead of drawing the inference that because man made the latter therefore man made the former, *the resemblance we attribute to a natural cleavage in the flint which gives to it a tendency, however struck or crushed, to break into these particular forms . . .*" (my italics). Putting this thought to experiment, the writer has spent some hours in roughly breaking flints with a sledge-hammer, and the result has been that he has found amongst the broken flint forms sufficiently *resembling* the supposed arrow-heads, spear-heads, serrated edged saws, etc., to convince him that as many years spent in this way as M. Boucher de Perthes and Dr. Rigollot have occupied in their research at Abbeville and St. Acheul, would be likely to result in finding among the broken flints the choice specimens that they have treasured up: "*for it must be borne in mind that they simply made a selection*" (my italics).

Again, on p. 35 we find "Mr. Whitley has shown at the Victoria Institute *specimens of flint broken by Blake's patent stone-breaker, in which a cast-iron jaw is worked by a steam engine, which flints, selected from the broken mass, could not be well distinguished from those which, in the ossiferous caves, are the reputed knives and scrapers of Palæolithic man*" (my italics).

Further comment is unnecessary.

Frictional Forces in Liquid Surfaces.

WHILE working with a suspended system in which the bottom of the system consisted of a fine wire dipping into a solution of salt in water, it was found that frictional forces existed which resisted rotation of the wire. The suspending fibre was of phosphor-bronze, 0·0015 cm. in diameter and 1 m. long. On this was hung a disc, 4 cm. in diameter, and weighing 10 gm. Fastened to the bottom of the disc was a short piece of No. 30 copper wire dipping a few millimetres below the liquid surface. The liquid was 4 cm. deep.

It was found that often the top of the suspending wire could be turned two or three complete revolutions without any resulting motion of the disc, but when the disc once started to move it would move a considerable distance and with some rapidity.

The Disposal of Scientific Journals.

I EXPECT there are many people like myself who are embarrassed by the accumulation of scientific journals, which remain unbound and are so seldom referred to afterwards that they amount to little more than an incubus. I think many of us would be glad of some help towards getting this literature disposed of to the best advantage. I have myself a large accumulation of unbound issues of the *Proceedings of the Royal Society*, the *Journal of the Chemical Society*, *Chemistry and Industry*, etc. After inquiry in likely places I have found no trade market for these. I scarcely like to part with them as waste paper, yet it is difficult to find any better destination.

Perhaps some readers of NATURE may have found a solution of the difficulty, and could give others the advantage of their experience.

S.

Ultra-Violet Photometry.

THE use of optical wedges in photometry is so convenient and accurate that they are now being largely employed, but their use is, at present, mostly confined to the visible region. Dr. Toy (*Phil. Mag.*, 1920) showed that wedges of neutral grey gelatine between quartz plates could be used down to about 3000 Å.U., but the absorption coefficient, and hence the wedge-constant, was increasing so rapidly with decreasing wave-length, that they would probably become useless beyond about 2900 Å.U.

Having recently had facilities for measuring the constants of such wedges on an accurate spectrophotometer, using a sodium-in-quartz photo-electric cell, we found that the constants actually increased but slowly beyond 3000 Å.U. Messrs. Ilford, Ltd., kindly made another new wedge embodying certain suggestions indicated by previous work. The change of wedge-constant with wave-length for this new wedge is considerably smaller than that of a wedge of the standard type, and either type of wedge can easily be used down to 2380 Å.U. at least. (Beyond this there are no lines which we could use in the mercury spectrum, and the mercury arc is the only convenient source of illumination for this work.) The following table shows the change of wedge-constant with wave-length for both of Messrs. Ilford's standard wedges between quartz plates, and also for the special wedge they recently made for us—the wedge-constant for 3655 Å.U. being taken as unity in each case.

The change of wedge-constant with wave-length seems to be a gradual one, and is a very small disadvantage in practice, as it is easily allowed for. The writers have employed Ilford gelatine wedges between quartz plates for photometry of the ultra-violet end of the solar spectrum—*i.e.* to about 2950 Å.U.—for two years with excellent results.

λ.	Wedge-Constant.		λ.	Wedge-Constant.	
	Standard Type.	New Type.		Standard Type	New Type.
Blue	0·7	0·7	2893 Å.U.	1·62	1·30
3655 Å.U.	1·00	1·00	2804	1·65	1·36
3342	1·28	1·10	2752	1·68	1·40
3131	1·50	1·19	2655	1·78	1·45
3022	1·37	1·23	2536	2·00	1·55
2967	1·53	1·26	2480	2·10	1·57
2925	1·60	1·28	2378	2·30	1·63

In the booklet on "Photographic Photometry" recently published, we have stated that neutral gelatine wedges cannot be used for wave-lengths shorter than about 2900 Å.U. as indicated by the earlier results. This now needs correction, since such wedges can be very conveniently used to 2380 Å.U. and probably somewhat further.

A Substitute for Microscope Cross-Wires.

IF a microscope or other apparatus fitted with cross-wires is not available, a convenient substitute may be made by placing a coverslip carrying two filaments of seccotine at right-angles between the lenses of an eyepiece.

The coverslip is placed on the end of a cork, which makes a convenient 'bench.' A small quantity of seccotine is squeezed out of a tube; this is touched with a pin or match, and the fine filament produced when the pin is drawn away is manipulated on to the coverslip. The cork is rotated through 90° and the operation repeated. The degree of fineness to which a filament can be drawn depends on the consistency of the seccotine. At ordinary laboratory temperature in winter it was in a suitable condition almost as soon as it had left the tube.

The Next Task of Astronomy.[1]

By Prof. R. A. SAMPSON, F.R.S.

A VERY large amount of work is in progress at present upon astronomical photometry. The older branches of astronomy, astrodynamics and measures of position, are far from being exhausted, and it is a matter for great regret that the former, especially, with its splendid traditions of great workers, of discovery and invention, should have fallen into relative neglect. The middle branch, astrophysics, has so far been based, almost exclusively, upon measures of position, namely, precise determination of spectral lines. Beyond that it has been little more than a descriptive branch—an avenue to science rather than a part of it. But lately from every direction it is being forced to address itself in earnest to the problems of photometry—that is, to face directly and with as much science as it can command, the question of measuring quantity of light-emission.

One is apt to forget that the estimation of stellar magnitudes is coeval with our earliest measures of position. It is found in Ptolemy's "Almagest," accompanied even by a few notes on colour. The six magnitudes into which we divide the naked-eye stars are a legacy from his sexagesimal arithmetic. The subsequent development of the two is in curious contrast. The edifice of positional astronomy is the most extensive and the best understood in all science, while light measurement is only beginning to emerge from a collection of meaningless schedules.

Measures of positional astronomy were originally nearly as meaningless as magnitudes. Successively the position of the observer, the phase of the earth's rotation, precession, the atmosphere, stellar aberration, nutation, the solar motion, stellar parallax, and finally relativity-shifts, required to be discovered, measured and eliminated, before we got down to clean results that referred to the stars and nothing else. To these may be added personality and the theory of instruments, or the allowances that are necessary before measures made by different persons in different circumstances can be combined. All this has been done with a success that is very nearly complete and permits one to remark, first on the extreme complexity and variety of unknown troubles by which simple geometric measures proved to be actually embarrassed, and secondly, on the enormous collateral advantages that accrued to knowledge in general by their solution, including unforeseen conquests of theory, necessity for invention of new methods, new instruments and new outlooks.

Now the place of a star is certainly the datum that matters least about it—except perhaps in statistical grouping. Its mass, its size, its surface temperature, the state of its atmosphere, its radiative emission—if we can get them—are all intrinsically a great deal more significant. All these are absolutely basic data or quæsita of physics. They relate to circumstances of Nature which we cannot imitate in any experiment of our own, owing to the quantities and the temperatures involved, and the isolation. These are Nature's experiments, in her own laboratory, and their variety is for our purposes endless and may be called complete. Our only access to them is by parcels of starlight, and our only treatment for these parcels, after a certain amount of general description, is to measure them, and to cast out from our measures what is irrelevant, personal to ourselves, our situation or our instruments. Difficult and laborious as the prospect may seem, it will falsify all experience if our labours do not yield us unexpected stores of gain, new and unforeseen relations, besides what we set out to master.

I would repeat that the measurement of radiation is a physical question of absolutely basic importance. Every step matters on the road to its elucidation. This is the question I refer to as "The Next Task of Astronomy," because a large part of it, and necessarily a critical part of it, falls in the astronomer's field. In spite of all the work that has been done upon it up to now, it is still, in the main, in a crude stage, much behind where we might, with proper effort, place it, and out of all comparison behind the position of measures of place. Therefore it offers a field which both astronomer and physicist can be sure they will not cultivate in vain.

Very few years ago there was but a single star for which a photometry that was physically significant was attempted. This was the sun. Here all the necessary allowances that were known were made, the first being a very elaborate and difficult determination of the effect of the earth's atmosphere, and the elimination of it. Then there was the measure of the sun's own radiation. This might be done in bulk, or separately for each wave-length. In either case the true measure is taken as a heat measure, an energy measure. As to that, there is more to say than used to appear. Questions of fundamental interest suggest themselves, and will certainly call for investigation hereafter. For the sun, the standard detecting instrument at present is the bolometer, which in principle is a Wheatstone's bridge, balanced upon a pair of exceedingly fine short strips of platinum, one of which receives the selected radiation and responds to it by an increase of resistance. Increase of telescopic power has made it possible to extend this method to certain stars, employing as detector either Nichol's radiometer or Coblentz's vacuum thermocouple. C. G. Abbot, with the 100-inch telescope at Mount Wilson, has been able to record the actual distribution of heat-radiation of nine stars, over the whole visible spectrum and far into the infra-red. Coblentz has obtained results nearly equal to these. Deflexions corresponding to integrated radiation for the whole spectrum are readily obtained by the same means for far fainter stars.

Interesting though this is, personally I regard it as a *tour de force*; like the interferometer measures of stellar diameters, it does not hold out any promise of general use, and gives measures which serve only to confirm results that are more conveniently and as certainly obtained otherwise.

Besides the interest attaching to a new feat, however, such measures are true physical photometry, as absolute as we can make them. The same cannot be said of our chief standard, the north polar sequence. Perhaps nothing speaks more clearly of the detached, inconclusive and essentially unscientific position of stellar photometry than the labour spent upon establishing and verifying this work, without reference to its subsequent physical interpretation. If my words are depreciatory, this does not mean that I undervalue those who worked at it, or what they have given us; it is to remind workers of to-day that we have got into a different era, in which astronomy has definitely and finally joined hands with physics, each serving and responsible to the other, for mutual profit.

---

[1] From a paper read before the Optical Convention, 1926, on April 13

The north polar sequence was devised by E. C. Pickering at Harvard, as his ultimate standard of photometric reference. It consists of a carefully graded series of stars within 4° of the north pole.

The accepted scale for magnitude is Pogson's, which he derived from J. Herschel, defining increment of magnitude as proportional to increment of log (intensity), so that an increment of magnitude, dm, varies as $-dI/I$, where I is the intensity. This is in accordance with Fechner's law, by which a physical intensity is translated into a sense-measure; its significance is the escape from introducing an arbitrary external unit to measure dI—the instantaneous value I serving for that purpose. To establish a standard sequence in accordance with this definition, Pickering deliberately employed a variety of instruments and methods, relying upon their mean to cancel the comparatively large discrepancies. Such a plan may have been the best to use at the time it was devised, but it is obvious that it may leave a residue of systematic error. It was ascertained to do so by F. H. Seares of Mount Wilson, and this was confirmed by H. Spencer Jones at Greenwich. But these are no more than the incidents in fixing a critical standard, and one can scarcely suppose equal results could have been better or more readily obtained.

What I criticise in the investigation of 'magnitudes,' of which the standard sequence is merely the best, and one of the least extensive, examples, is that the measure is a measure of a mixed phenomenon, which has never been analysed to its physical basis, and which it is usually impossible to complete afterwards. There are always and obviously three elements that contribute to the measure—the actual radiative emission of the source, losses in transit by dispersion, absorption and reflection in the instrument and the atmosphere, and finally the peculiar sensitivity characteristic of the receiving apparatus. One form of the latter is the eye, supposed reduced to a standard, and equivalent to a photovisually corrected lens used in conjunction with an isochromatic photographic plate and a rather ill-defined yellow filter. The result can be made sensibly the same and sensibly uniform.

The position is decidedly more unsatisfactory when we deal in photographic magnitudes. Apart from such investigations as I advocate below, which have not yet received a recognised place in astronomy, the basis of the adopted treatment is frankly empiric, and empiric in a way that holds out no promise of a better foundation. After numerous experiments a formula has been settled on, $m = a + b\sqrt{d}$, where d is the measured diameter of the photographed image, and a, b turn out to be sensibly constant over considerable ranges. It is a very convenient rule, and it has turned out a great deal of very useful work, but in a physical sense it is hopeless.

Now if we accept the heat radiation as standard, it is of course familiar that the estimate of intensity made by the eye, whether analysed or summed, is distorted. Abbot, for example, extended his bolometric measures beyond wave-length 2μ, to which the eye is perfectly blind. We require an equation of conversion and a different equation according to the partition of emissive energy along the spectrum. We can imagine then a reduced 'bolometric' magnitude, as introduced by Eddington, which corresponds to the true heat emission of the star, the correction that produces it being a function of the spectral class of the star. This correction is large, exceeding a magnitude at both ends of the scale. Equally a photographic magnitude, derived from an ordinary photographic plate, would require a different, similar correction, but it is more usual first to reduce the photographic magnitude to the photovisual, by estimating the difference between the two known as the 'colour correction,' and itself an index of the spectral class.

Thus, apart from instrumental and atmospheric difficulties, photometry is helpless without at least two measures, to give, between them, the total heat emission and the spectral class, or in other words the size and the shape of the Planck radiation curve. This statement assumes that the star radiates as a black body, which is sufficiently though not closely or invariably verified. So many ways are known for finding spectral class that it is sufficient merely to mention them. They are designed to apply to different cases, according as we want detail or collective summary, and can dispose of much light or little. The slit spectroscope, the prismatic camera, effective wave-lengths determined by the position of the secondary images formed by a very coarse grating, photographs with different colour screens interposed, and even eye estimates of colour.

To speak first of one of the desiderata, it has been verified beyond any doubt that the temperature indicated by the shape of the Planck emission curve of the star, which is taken as the 'effective temperature,' or the surface temperature of the star, implies quite strictly the spectral class, with its intricate detail of absorption lines. It remains only to confirm the fact by defining the relation more closely and better cleared from impurities, to examine how nearly the black body radiation actually applies to a star, and finally to search out exceptional cases.

As this branch of the research has been carried out with fair success and with general agreement in result for different methods of treatment, some detailed reference may be made to the questions it has evoked. The investigation proceeds from the evident fact that the balance of intensity of a star's radiation shifts from the blue to the red as we cross the spectral series. Presumably this is a temperature effect which may be interpreted by means of Planck's radiation curves. If we assume that the star's radiation is itself black-body radiation, it would suffice to use Wien's law and determine the summit or maximum of the curve, but it is preferable to make no assumption and attempt to determine the whole curve. In any case we require to calibrate our apparatus of reception by seeing what it records when exposed to a standard source. It is possible to make such a source terrestrial. Wilsing employed as his standard an electric oven, constructed as a black body, against which he calibrated a glow lamp, which in turn was compared with the stellar spectrum. His work was visual. The method requires the subsequent elimination of instrumental and atmospheric losses. The latter vary rapidly and greatly. Accordingly Wilsing's measures show a rather wide dispersion, and there are some improbable results for individual stars. Besides, the general scale seems low, so that systematic error has not been avoided. But these are minor criticisms by which one tries to learn the lesson of the difficulties. The whole work, including that of his collaborators Scheiner and Münch, is a monument of skill and care.

To vary the method as Wilsing's experience suggests, I have photographed the spectra upon panchromatic plates sensitive up to Frauenhofer's (B), and in place of the terrestrial source as standard I have made comparison with a similar spectrum of Polaris, taken first and last on each plate, to guard so far as possible against atmospheric vagaries. Apart from altitude effect, it is assumed that both stars are equally affected by losses, so that there is no allowance to be made in the relative measures. We have then before us an interesting problem of interpreting the photographic deposit in terms of the active light. Different times of exposure and different wave-lengths enter with the changing sensitivity of the plate. It is in fact the basic problem of sensitometry. One might say that little can be said of it, except that it is enormously complicated. What the star contributes is merely a 'latent image' that cannot be examined, and the outcome depends on the chemicals used, their handling and temperature. The material employed is none too uniform. It is altogether a region that has hitherto been avoided, and that one would rather avoid if the gain were not so manifest of reducing it, even partially, to order. Besides, what is the alternative? There are exactly the same obscurities in using the eye, but it gives no permanent record that one can experiment on and cross-examine. Two other detectors of the same order of sensibility are offered—the selenium detector and the photo-electric cell. Whether photography may be more or less obscure than these, in a metric sense, it is certain we are more familiar with its troubles, and are in any case bound to use it for other purposes. Hence it appears to me, the sooner the discussion of the photographic deposit is reduced to a standard for scientific purposes, the better.

My own effort has been confined to reducing the complexity by defining the circumstances. If the temperature, chemicals and handling are kept the same, and if the photographic constants p and γ are separately determined in the laboratory for each batch of plates and for each wave-length used, then it would appear that the blackening of the plate can only depend on the intensity of the light and the time of exposure, or alternatively, the intensity is a function of the blackening and the time. The last two are measurable, so that to derive the former requires merely the establishment of a calibration curve in the laboratory as indicated above. Departures must be treated as accidental anomalies. It can be shown that a manageable theory may be built on this basis, applying at any rate to the case when the desideratum is the shape of the radiation curve, leading to an easy equation between the relative temperatures of two sources, as indicated from any wave-lengths at which their spectra are compared.

It will be noted that this method fails to provide an absolute standard temperature unit, as basis. This, however, may be supplied by taking the temperature of a 'Go' star the same as that of the sun; but in fact when a great many stars are used, the indeterminateness is distributed over them all, and it is found that a coherent treatment permits of very little latitude, without thrusting very improbable figures upon one or other of the extremities.

A parallel treatment of the area of the radiation curve, giving the total bolometric emission of the star, should not present any insuperable difficulty. We should then have by direct determination the two fundamental elements of the star's radiation, temperature and quantity.

. . . .

The measurement of the intensity of individual lines in the spectrum promises at least as much interest as a treatment of the whole. But in writing this summary directed to a special object, I have omitted many points which mean a great deal to those conversant with astronomical literature. If we want to pass from the 'magnitude' of a star to its radiative emission, we require to know the magnitude of the sun and the distance of the star. A few decades ago the number of stellar distances known was so insignificant that no general treatment was possible. It was the want of this knowledge that really accounts for some of the deficiencies of which I have spoken above. But that is now past. Some thousands are now determined, and their number is still rapidly increasing. Of stellar masses we still have only a very few determined directly; but a well-credited theory permits us to calculate these too, even for individual stars. These are necessary adjuncts if astronomy is to unite itself with physics, and the astronomer may be relied upon not to fail in supplying them.

The Active Principles of the Pituitary Gland.

SINCE the discovery by Oliver and Schafer of the blood-pressure raising or pressor effect of extracts of the posterior lobe of the pituitary gland, a number of other phenomena caused by injections of this material have been described; thus although in mammals the blood-pressure is raised, in birds it is reduced; in the former the extract also stimulates the uterus to contract, and produces an increased flow of milk and an increased secretion of urine, under certain conditions, but under others the urinary flow is markedly diminished. In frogs the extract stimulates the pigment-carrying cells or melanophores to dilate, producing thereby a darkening of the skin of the animal. It may be noted that these active principles are all obtained from the non-glandular posterior lobe of the organ, which is composed chiefly of neuroglial tissue, although it has a partial investment of glandular cells from the *pars intermedia.* The glandular anterior lobe, which is essential for normal growth, has not yet yielded for certainty an active extract to the labours of the biochemist.

Are these various active principles, designated in the present state of our knowledge by an adjective descriptive of the effect produced, all different, or is there only one, or possibly only two or three? Subject to the isolation of one (or more) in a chemically pure condition, we can only attempt to reach an answer to this question by consideration of the indirect evidence which is available. Before reviewing some recent work on this subject, attention may be directed to one or two points. It is generally held at the present time that the diuresis observed after injection of a posterior lobe extract intravenously into an anæsthetised animal is caused by the rise of blood-pressure simultaneously produced, with perhaps a dilatation of the kidney blood-vessels, and that the galactogogue effect is due to the same principle stimulating the smooth muscle fibres in the walls of the ducts of the mammary gland, and so leading to an expression of the milk already secreted; in neither case is it considered that the extract stimulates the kidney or mammary gland cells to increased activity. It appears almost certain that some of the effects must be pharmacological rather than physiological; the usefulness of a principle which will produce a flow of milk and an expulsion of a fœtus from the uterus to a fish or frog is obscure.

Evidence as to the identity or otherwise of the active principles has been sought by an examination of the glands of different species for the presence of the various activities associated with gland extracts. According to a table given by L. T. Hogben and G. R. de Beer (*Quart. Journ. Exper. Physiol.*, 1925, vol. 15, p. 163), extracts of the pituitaries of elasmobranch and teleost fish, amphibia, reptiles, birds and mammals produce all the effects obtainable from such extracts, except that there is some doubt as to the presence of a pressor and diuretic principle in the gland of the skate. The authors have made quantitative comparisons of the contents of the skate's and cod's glands in the pressor and oxytocic (uterine-stimulating) principles, and have found that the latter contains twenty to thirty times as much oxytocic activity as the former, tested on the virgin guinea-pig's uterus, whilst the pressor activity of the cod's gland is at least five times more than the skate's, tested on the spinal cat. Unfortunately, the doses of skate's gland extract used failed to produce any rise of blood-pressure; it is possible that with larger doses some rise might have been obtained, seeing the great difference in their relative oxytocic activities. Hence the experiments are inconclusive, but afford no evidence that the two principles are separate chemical compounds.

Since the principles are so widely distributed throughout the animal kingdom, the differentiation between them must be made, if at all, by other means. Is there any difference in their distribution in the gland of a single species? That is, can differences be detected between their concentrations in the *pars nervosa* and in the *pars intermedia*, both of which structures are included in the posterior lobe? Hogben and de Beer have also investigated this question and find that in the pituitary gland of the ox the *pars intermedia*, although containing roughly only one-fifth of the amount of the principles in the *pars nervosa*, yet consistently contains more of the oxytocic principle than of the pressor, although usually the difference is not great. The authors favour the view that these two principles are probably different chemical substances.

Further light is shed on the problem by greater knowledge of the chemical properties of the active substances, and of their specific or non-specific nature. Thus Hogben (*ibid.* p. 155), investigating the depressor effect of injections of extracts of the posterior lobe in birds, finds that other tissue extracts fail to give this response; moreover, the chemical properties of the active principle are, so far as investigated, the same as those of the other principles and different from those of a non-specific depressor such as histamine. The compound is localised mainly in the *pars nervosa.*

The principle influencing the secretion of the urine has been investigated in some detail by N. S. Craig (*ibid.* p. 119). The *diuretic* action of posterior lobe extracts was the first to be discovered, and it was only later found that in the disease *diabetes insipidus*, characterised by great thirst and the passage of large volumes of urine, subcutaneous injections abolished temporarily both the thirst and the polyuria, thus exerting an *antidiuretic effect*. It appears, therefore, that one of the functions of the posterior lobe of the gland is to maintain the concentration of the urine; if this function is deficient, polyuria and thirst result. Craig finds that, injected subcutaneously into unanæsthetised cats, the extract delays the diuresis produced by giving water or saline solution by mouth, but has much less effect on that following the exhibition of a solution of urea. No evidence of a delayed absorption of the fluid from the gastro-intestinal tract was obtained, so that it must be retained in the body after absorption; certain observations on the hæmoglobin percentage in human blood after the administration of fluid by mouth and the injection of pituitary extract confirm this result. The author inclines to the view that the principle exerts its influence by an action on the cells of the kidney.

It is usually stated that extracts of the posterior lobe stimulate all forms of smooth muscle. A. D. Macdonald (*ibid.* p. 191), as the result of an investigation of their action upon isolated strips of smooth muscle from the mammalian ileum, disagrees with this statement. He finds that not all commercial extracts stimulate this preparation, that the stimulating substance can be preferentially extracted from laboratory-desiccated posterior lobe by alcohol, which extracts the non-specific depressor compound, and also to a certain extent by ether, which extracts neither the pressor nor the oxytocic principles, that it is present in other tissues, and hence is not a specific principle of the pituitary gland, and that it is not destroyed by boiling in dilute alkali, which treatment deleteriously affects both the pressor and oxytocic activities. It is probable, therefore, that the stimulating substance is histamine, which occurs in most tissue extracts, and that it is not quite completely removed from desiccated posterior lobe preparations by alcoholic extraction; although a preparation thus treated may show no depressor effect on injecting a second dose into a mammal, yet sufficient histamine may have been left behind to stimulate the smooth muscle of the intestine, since the latter is about one hundred times more sensitive to histamine than it is to pituitary extract. It is possible, from some experiments on the heart of the dogfish, that small quantities of choline are also present in most posterior lobe extracts. Hence it must be concluded that any gut-stimulant action which pituitary extracts possess is very largely or entirely due to the presence therein of the non-specific stimulants histamine and choline.

Finally, reference must be made to the attempted chemical separation of the active principles. As W. Schlapp (*ibid.* p. 327) points out, the identical behaviour of the different principles through a large number of chemical manipulations is not sufficient evidence of their chemical identity, more especially as the non-specific histamine apparently accompanies them in many cases. On the other hand, a separation of two by a single chemical treatment would argue very strongly in favour of their non-identity. The author finds that the pressor, oxytocic and melanophore principles are all destroyed at the same rate by boiling in dilute acid, but that the pressor and melanophore activities are not extracted by butyl alcohol, whereas the oxytocic largely passes into this solvent; furthermore, lead sulphide adsorbs almost all the pressor and melanophore material present in a solution, but only about half of the oxytocic. He concludes that the pressor (and melanophore) and oxytocic activities are mediated by two separate and distinct substances, thus agreeing with Hogben and de Beer, who by a different method reached a similar conclusion. Now the melanophore principle appears to exist in greater concentration in the *pars intermedia* than in the *pars nervosa*, thus resembling the oxytocic but differing from the pressor principle. Hence it appears probable that these three activities of posterior lobe extracts are due to the presence in them of three different chemical compounds. Their relationship to the avine depressor and antidiuretic principles requires further research for its elucidation; whilst Macdonald's results throw doubt on the specificity of the galactogogue effect. The conclusions reached from a consideration of the work mentioned above agree in general with those which may be drawn from the experiments of other investigators.

Vital Statistics of Scientific Academies.[1]

A COMPARISON of the life statistics of such bodies as the Royal Society of London and the scientific academies in other countries is interesting, because the efficiency and influence of these institutions depend to some extent on the average age of their membership. Unless they contain a sufficient sprinkling of the younger generation and elections are not delayed until a man has done his best work, the institution will cease to command confidence and be hampered in the fulfilment of the object for which it was founded. We welcome the publication of the statistics collected by Prof. Raymond Pearl, and published by the National Academy of Sciences of Washington, because it allows us—so far as the limited material permits—to form a judgment of the effects of the conditions of election, which differ materially from those applying to the Royal Society. The latter, as is well known, has elected since 1848 fifteen members every year, while the leading scientific body in the United States has followed the practice of Continental academies and limited its total membership.

A statistical inquiry was first made in England by General Strachey (*Proc. Roy. Soc.*, vol. 51, 1892) in the latter part of the last century, primarily for the purpose of forecasting the ultimate membership of the Royal Society, which had fallen from 768 in 1848 to 427 in 1891 (not including 36 fellows elected under a special rule). There were then still 26 members alive who were fellows in 1848, when the statutes were changed.

In the United States the problem is reversed, the question being, what the number of elections per year should be so that the Academy might settle down at the maximum membership fixed by charter in 1863 at 250.

The National Academy started with a membership of 48, and, anxious no doubt to set a high standard, it was slow in making any substantial additions. During the first twenty years of its existence ninety-five new members—that is, less than five per year—were elected, and the number of elections diminished still further in the second period of twenty years, when the annual average of new members fell to a fraction more than three. Since 1905 the Academy increased more rapidly "under pressure of an arbitrary rule which virtually forced the election of 15 per annum." Reference to this rule occurs twice on the same page in Prof. Pearl's publication, but its exact terms are not stated.

The average age of members of the National Academy on May 1, 1925, was practically identical with that which I found for fellows of the Royal Society at the beginning of 1923, being 60·7 years in one case and 60·9 years in the other. But there is a great contrast in the admission of men below middle age. During the sixty years that have elapsed since the first nominations under the charter, Washington has elected only one man below the age of thirty, while the Royal Society has elected twenty-nine in the course of seventy-five years. The same tendency is shown in elections below the age of forty years. The percentage of elections under that age was 33·9 at the Royal Society and only 19·9 at Washington. The further fact emerges that the election of younger men to the National Academy has very markedly and steadily decreased since its foundation. On this point Prof. Pearl makes the following startling remarks:—

> "It is easy to attribute the changing habits of the Academy relative to the election of young men to a growing conservatism of that body itself. That this is the sole cause I doubt. It is at least possible, and I incline personally to think it probable, that the increasing organization, standardization, mechanization, and constant striving for efficient mediocrity in all our academic life, which every thoughtful person has seen going on during the past 30 years, and which some have deplored and vainly endeavoured to stop, is showing as one of its most dreadful effects the curbing and fettering of the progress of the really brilliant student."

---

[1] Vital Statistics of the National Academy of Sciences: By Raymond Pearl. *Proceedings of the National Academy of Sciences* (vol. 11, No. 12, 1925).

It is not for us to comment on this formidable indictment.

At the Royal Society the decline in the number of elections of young men appears to a much smaller extent, and may be accounted for without assuming a decline in intellectual power. The statistician had better confine himself to his job; and if he ventures on explanations it is safest to assume that the general intelligence of a country is less likely to change than the state of science, which at different stages of its progress requires different types of intellectual activity.

One factor affecting the average age of admission is the greater competition due to the enormous increase in the scientific output of the British universities. This is strikingly illustrated by the increase in the number of men presenting themselves for election. The assistant secretary of the Royal Society has kindly supplied me with the relevant figures. I have collected these in the following table, in which the columns headed '*N*' give the five-year averages of the numbers of candidates.

Period	*N*	Period.	*N*	Period.	*N*
1848–1852	30	1873–1877	53	1898–1902	86
1853–1857	36	1878–1882	53	1903–1907	84
1858–1862	42	1883–1887	60	1908–1912	96
1863–1867	50	1888–1892	68	1913–1917	116
1868–1872	52	1893–1897	73	1918–1922	113

I have not ascertained the ages of the candidates, but am under the impression that they would show a slight increase in the last twenty years. Since 1922 the number has been 112 on the average.

ARTHUR SCHUSTER.

Obituary.

MR. JOSEPH LUCAS.

MR. JOSEPH LUCAS, who died on April 20 last at the age of seventy-nine years, was educated at Westminster School and in 1867 joined the Geological Survey of Great Britain. During his nine years in the service he was employed in mapping the Carboniferous rocks in the West Riding of Yorkshire, and, later, the area in north-east Yorkshire, within which the Cleveland ironstone occurs. While in the West Riding he was much impressed with the great amount of water yielded by the Lower Carboniferous sandstones, and this probably led to his taking up the study of water supply and the profession of water engineer on his retirement from the Geological Survey.

Although his investigations covered many parts of England, Mr. Lucas concentrated on the area of the Thames Valley, and all his more important publications dealt with this region. His work was marked by a distinct originality of thought and at once brought him into public notice. He was probably the first to publish a hydrogeological map with artesian contours, which he defines as a series of lines drawn through a number of points at which the water rises to the same height above Ordnance Datum. He gave much additional evidence of the steady fall of the underground water-level in the Chalk and suggested that such maps should be prepared at intervals, as by them this fall in the water-level would be more clearly shown.

A fairly full summary of Mr. Lucas's more important publications and conclusions are given by Whitaker in his comparatively recent work on the water supply of Surrey (*Mem. Geol. Survey of England and Wales*, "The Water Supply of Surrey," by W. Whitaker (1912), pp. 14-17. See also Bibliography (*ibid.*), pp. 328-330). A brief account is here given of Mr. Lucas's first paper, "Horizontal Wells" (published privately in 1874), and of his second and better-known "Artesian System of the Thames Valley," published in 1877 in the *Journal of the Society of Arts*, vol. 25, No. 1277, p. 597. The second work contained the original and valuable "Hydrogeological Map" showing the underground contours of the water-level in the Chalk, but referred only to the area south of the Thames. In 1878 he published privately a complete map of these underground water contours both north and south of the Thames. This proved so instructive that it was republished by the Geological Survey together with two other similar maps showing their position first in the period between 1890 and 1900 and later in 1911 (*Mem. Geol. Survey of England and Wales*, "Records of London Wells," by G. Barrow and L. J. Wills (1913), p. 19).

Later on, Mr. Lucas turned his attention to the water supply that could be obtained from the Lower Greensands of Hampshire and Surrey, and a short résumé of the work was published in 1880. Though he continued to practise as a water engineer for some years, he ceased, after this, to make any further publications of general scientific interest.

DR. B. P. GRENFELL.

THE death is announced of Dr. Bernard Pyle Grenfell, honorary professor of papyrology in the University of Oxford, which took place at Eley, Perth, on May 17. Dr. Grenfell was born in Birmingham in 1869, and was educated at Clifton College and Queen's College, Oxford. After taking his degree with first-class honours in both Moderations and *Lit. Hum.*, he was elected to the Craven fellowship and a fellowship at his own College.

In 1894 Grenfell began work as an excavator under Sir Flinders Petrie, who confided to him the editing of a Greek roll which proved to contain enactments of Ptolemy Philadelphus I. of the greatest importance for the currency and fiscal systems of Egypt. It was in this year that there began his long association with A. S. Hunt, which was to prove so fruitful in the study of the fragments of papyri which they discovered in the course of their excavations at Oxyrhynchus. From these were derived the "Sayings of Jesus" and the many other fragments published in the Oxyrhynchus series, which have thrown a flood of light on many aspects of the social and religious life of Egypt, as well as much matter of literary interest and of importance to the scholar. Grenfell himself was especially interested in the intricate problems of finance and currency in Egypt—a subject in which he had early shown his competence in a masterly account of the ratio of silver to copper which had appeared as an appendix to his edition of the Ptolemy text referred to above.

In 1906, while excavating at Oxyrhynchus, Grenfell broke down through overwork. Though he recovered for a time, he broke down again in 1908, the year he was elected first professor of papyrology at Oxford, and it was only intermittently that he was able to resume work after that date. In 1913 he was appointed honorary professor of papyrology. He was an Hon. Litt D. of the University of Dublin, and Hon.D.Jur. of Graz, corresponding fellow of the Munich Academy, member of the Academia dei Lincei, and Drexel medallist of the University of Pennsylvania.

THE death of the eminent French entomologist the Abbé J. J. Kieffer occurred on December 30 last. For many years he was on the teaching staff of the College of St. Augustin at Bitche in Lorraine, where he devoted himself largely to entomological research. His earlier work was concerned with the taxonomic study of gall-making Diptera and Hymenoptera, but latterly he turned his attention to the Chironomidæ and became the foremost European authority on the family. His most enduring contribution is his "Monographie des Cecidomyides d'Europe et d'Algérie" (1900), which contains a wealth of biological and anatomical information, and is profusely illustrated. His death leaves a gap in the ranks of the few students of the difficult and obscure groups of insects among which he laboured so assiduously.

WE regret to announce the following deaths:

SIR Harry Brookes Allen, emeritus professor of pathology in the University of Melbourne, and president in 1908 of the Australasian Medical Congress, aged seventy-one years.

Dr. J. T. Bottomley, F.R S., for many years Arnott and Thomson demonstrator (experimental physics) in the University of Glasgow, and the author of elementary text-books on dynamics and hydrostatics and of papers on the thermal conductivity of water, permanent temperature of conductors, etc., on May 18, aged eighty-one years

Prof. L. A. Herdt, professor of electrical engineering at McGill University, Montreal, and president of the Canadian National Committee of the International Electro-technical Commission, aged fifty-three years.

News and Views.

IT is gratifying to note that a serious effort is being made in the United States to assist the development of research in pure science, and in that land of dollars, concentrated energy, and munificent benefactors we have little doubt that the scheme adopted by the National Academy of Sciences will meet with the success it deserves. The general purpose of this scheme is "to increase and strengthen American contributions to the mathematical, physical, and biological sciences by the creation of a national fund to aid skilled investigators." Universities and other higher institutions will be expected to co-operate by assuring complete sympathy with research, by relieving the professoriate from the excessive demands of teaching and administration, and by providing all necessary laboratory accommodation and facilities. The endowment fund which has now been launched, and by means of which it is hoped to raise twenty-five million dollars, will be controlled and administered by a board of trustees consisting of Mr. Herbert Hoover, as chairman, and twenty-five well-known public men, including some of the foremost scientific workers. In a brochure recently issued by the National Academy of Sciences, the trustees declare their conviction that the funds at present available for the support of research in pure science are far below what the population, education, and material resources of the country demand. The United States already occupies a leading position in industrial research, it should rank with the most enlightened nations in the advancement of pure science.

RUSSIA affords a field for research in so many important branches of knowledge that any indication of a revival of interest in scientific matters among her people is of more than local moment. Under the Empire the study of the archæology, ethnology, and cultural history of the vast territory included within its boundaries was actively pursued, but unfortunately the results were not made widely known. Publication was much delayed, and comparatively little appeared in languages other than Russian It is possible that under the Soviet Government conditions may be changed. It would appear at any rate that there is a strong desire to encourage the continuation of the scientific work which was carried on under the old regime and even to extend it. As an example, we may mention the development of the regional survey. The extent to which this form of activity has been encouraged and the proportions it has now assumed are described in a paper by Prof. P. D. Schmidt, of Leningrad, which was read at a meeting held in London in September last to celebrate the tercentenary of the Russian Academy of Sciences, and is now published in the *Sociological Review* for April. The movement began in 1921, when a Congress was held on the initiative of the Academy. A central bureau was organised in January 1922 at Leningrad with a branch at Moscow. By March 1923 there were 231 societies with 285 museums, 21 biological stations, and 16 natural reserves or parks, and in June 1925 it was estimated that there were more than a thousand institutions dealing with regional surveys. The museums have proved the most successful feature and are very popular among the peasantry; but a great deal of original work has been done in biology, geography, archæology, and the study of local history and culture, and most centres publish a periodical dealing with these activities.

MACHINE design has made during the last century enormous developments and shows no signs of having reached a standstill, but the designer as a rule considers primarily the work to be turned out by the machine and gives relatively little attention to the operator of the machine. Nor do operators, as a rule, complain when the construction of the machine induces bad posture, inconvenience, or fatigue, for with habit they become acquiescent to an existent state of affairs. The Industrial Fatigue Research Board in a recent report (H.M.S.O., price 1*s.* 3*d.*, No. 36) by Legros and Weston directs attention to this neglect. Investigations have been made into machines used in laundries, leather factories, sheet-metal trades, textile trades, etc., from the point of view of the worker, and it is found that much fatigue and faulty posture might be eliminated by altering the designs somewhat. Suggestions are made for improvements. The Board points out that the work is in a preliminary stage and deals only with a few examples of industrial machines. It is, however, a very important aspect and the report is timely in its insistence that the unit is not the machine but the worker and the machine.

A REPORT on the administration of the Meteorological Department of the Government of India in 1924-25, and a general survey of half a century's work since the establishment of the department, has recently been issued by Mr. J. H. Field, Director-General of Observatories. This is the fiftieth administration report of the India Meteorological Department, and records the completion of the first half-century of systematic observations on weather in India by uniform methods. The retirement of Sir Gilbert Walker, who for some twenty-one years ably directed the policy and work of the department, is an especial feature. During the year the services of cyclone warning to ports and shipping, and of flood warnings to officers in the irrigation, railway, and other departments, were carried out. The period was marked by heavy localised rainfall, causing destructive floods from time to time in various parts of India, but the sea areas were unusually free from severe storms. Upper air work has been carried out in association with Army Headquarters for the needs of artillery and Royal Air Force, and telegraphic forecasts of bad weather were sent throughout the year to these authorities. The probability of closer co-operation with the Royal Air Force as the development of civil and military aviation progresses, is alluded to. Marine meteorology is being actively advanced, and wireless weather messages from ships at sea are used to supplement the coast observations in cyclone-warning work. Rainfall registration is carried out at nearly 3000 stations scattered well over India. The historical survey of half a century's work is of considerable interest.

A PUBLIC lecture on "The Ethnographic Approach to the Native Problem" was delivered by Capt. G. Pitt-Rivers at the London School of Economics, Houghton Street, Aldwych, on Tuesday, May 18. The subject is one on which Capt. Pitt-Rivers is especially competent to speak. His experience of native administration in the Papuan area has given him a clear insight into the difficulties of the native problem, to which he has also devoted close study from the special point of view of the anthropologist. Current events in the Union Parliament of South Africa serve as a reminder that the native problem is an insistent one in any widespread association of peoples such as the British Empire. Those who are most competent to judge and are most closely acquainted with the conditions in British tropical and sub-tropical dominions and dependencies are convinced that the ultimate prosperity of the State and the well-being of the individual are largely dependent upon a fair and sympathetic solution of the problem—a solution which will take account of the mentality and culture of the native populations as well as of the modifications in custom and outlook which have been forced upon them by contact with European civilisation.

BESIDES detailing the work carried out in the Museum itself during 1924, the Report of the Director of the Bernice P. Bishop Museum (Honolulu, 1925) gives an account of several expeditions by sea. A party on the mine-sweeper *Tanager* made a re-survey of Necker and Nihoa Islands, especially of the ancient building sites. The mine-sweeper *Whippoorwill* made two trips: the first to Fanning, Christmas, Jarvis, and Washington Islands, near the Equator in long. 157°-165° W.; the second to Baker and Howland Islands, long. 175° W. Some of the same islands, as well as Malden and Toagareva Islands and Tahiti, were visited by representatives of the Museum on board the *Kaimiloa*, a four-masted schooner with accessory oil-power, as guests of Mr. and Mrs. M. R. Kellum. On these expeditions many ethnological observations were made and large collections obtained for future study in the Museum. A botanical survey of Hawaii and the preparation of a Hawaiian dictionary are among the more important works being undertaken by this active Museum.

ON April 15, according to an announcement of the Smithsonian Institution, Mr. Henry B. Collins, assistant curator of the National Museum, left Washington to explore the tract of the Louisiana coast westward from New Orleans, which was the camping grounds of the Attacopa and Chitimacha Indians, about whom it is stated nothing has ever been written. The Attacopa were one of the few cannibal tribes of the American continent, though it is not known whether the practice was followed for ceremonial or other reasons. The Chitimacha were a people of much higher culture than the Attacopa, and seem to have been related to the Natchez. They had the same caste system, which descended through the mother, and their language was similar to that of the Natchez. Mr. Collins's work will be directed specially to the investigation of the mounds with the view of ascertaining whether they are true mounds or shell heaps. On completion of his work here he will proceed to the Mississippi Valley to continue the work of exploring the Choctaw mound which he began last year.

DURING the past few years there has been much discussion concerning the merits of the Spahlinger treatment of tuberculosis. This treatment consists in the use of a vaccine, analogous to tuberculin, and of a serum consisting of a mixture of anti-serums prepared with various strains of the tubercle bacillus and other organisms The Science Committee of the British Medical Association has summarised the known details of the preparation of the agents and of the effects of the anti-serums in the *British Medical Journal* (April 24, 1926, p 755), and points out that the exact methods of preparation have never been fully published, and that, therefore, the remedy is of the nature of a "secret remedy." It is also pointed out that no investigations, carried out under strict experimental conditions which afford direct and convincing evidence of the curative action of the remedy, have been published.

THE inter-relationship of food, health, and strength is discussed by Sir Arbuthnot Lane in an article in the *Quarterly Review* for April. While fresh air is undoubtedly important, though animals and primitive natives disregard it, right food seems vastly more important to men and animals Much of our food nowadays is soft, de-vitaminised, de-mineralised, chemically-coloured and preserved, and highly spiced. Failure to use our strong jaws, powerful jaw muscles, and teeth by the consumption of soft stuff, swallowed without chewing, results in the receding jaw, the narrow nose, weak throat, decaying teeth, toxic gums and tonsils. The capacity of the stomach and bowel clearly indicates that man was intended to live on bulky, not concentrated, food. A 'tablet' diet is an absurdity. Only a well-filled bowel readily empties itself; a sluggish bowel means stagnation and putrefaction of its contents and absorption of poisonous products. A far-reaching reform is necessary; we must go back to sound natural food; and this is one of the objects of the New Health Society founded by the writer.

THE extensive development of agricultural planting enterprises in Ceylon during the last hundred years has been accompanied by a voluminous literature, much of which is widely scattered and difficult to trace without undue expenditure of time. This has led to the publication by T. Petch of a "Bibliography of Books and Papers relating to Agriculture and Botany to the end of the Year 1915" (*Peradeniya Manuals*, 3, 1925), consisting of a list of more than five thousand references to the two subjects, exclusive of entomological work. Much care has been devoted to its compilation, and it is believed that the list is almost complete. The literature is classified under subjects, but there is no general alphabetical list of all the references. The bibliography should be of special value to all interested in tropical agriculture and botany, as it is stated that the literature of Ceylon on these subjects provides a mass of information rarely equalled in any tropical country.

MR. HENRY WOODS, of the Sedgwick Museum, Cambridge; Dr. Cyril Fox, Keeper of the Department of Archæology in the National Museum, Cardiff, and Ald. Edward Wooler of Darlington, have recently been elected honorary members of the Yorkshire Philosophical Society.

AN International Congress for Applied Mechanics will be held at the Federal Technical University, Zurich, on September 12-18 Prof E Meissner will be glad to receive the names of those who propose to attend. The titles and an abstract (not exceeding 300 words) of any paper offered for presentation at this Meeting should be forwarded to him at the University not later than June 1. Lectures have been promised by Prof. P. W. Bridgman of Harvard, Prof. P Debye of Zurich, Prof. T. Levi-Civita of Rome, Prof. L Prandtl of Gottingen, and Prof. G. I. Taylor of Cambridge, among others.

THE report of the National Baby Week Council for 1925, recently received, gives an account of the finance and activities of the Council and the results of the competitions for that year. "Baby week" in Great Britain is being organised this year on July 1-7, and a leaflet instructing how to organise a baby week celebration may be obtained from the Secretary of the Council, 117 Piccadilly, London, W.1.

THE Smithsonian Institution of Washington has in view the preparation of a descriptive account of the plants of all Central America. Dr. Paul C. Standley, botanist of the National Herbarium, has just returned from Costa Rica with a collection of nearly twelve thousand plants, including two thousand orchid specimens He is now preparing a memoir on the flora of Costa Rica, whilst the Smithsonian Institution is seeking funds to prosecute botanical exploration in Honduras and Nicaragua, two regions as yet very inadequately worked.

THE next award of the Fondation George Montefiore, which is given triennially for the best original work bearing on scientific progress and on the advancement of technical applications of electricity, will be decided in 1927. The latest date for the receipt of competing works is April 30, 1927, and they should be addressed to the Secrétaire-archiviste de la Fondation George Montefiore, Association des Ingénieurs électriciens sortis de l'Institut électrotechnique Montefiore, rue Saint-Gilles, 31, Liége. The prize, which may be divided, will be worth 20,500 francs, and is awarded by an international jury of ten, five of whom are Belgian electrical engineers.

THE German Scientific and Medical Association met in 1924 at Innsbruck; last year there was no meeting. This year the Association meets at Dusseldorf on September 19-26. Preliminary announcements are dated April, and the detailed programme is expected in July. Invitations are extended to all scientific workers and doctors of German speech and to all who appreciate German character and learning. There is also to be an exhibition of hygiene, social welfare, and physical exercises. The general sessions and chief group sessions are already planned. The main topic is scientific research in relation to industry; other matters for discussion are vitamins, capillaries, goitre, non-ferrous metals, noxious animals, quantitative spectrum analysis, luxury-poisons, synthetic anti-malaria drugs. There are fifteen scientific sections, including physical chemistry, pharmacy, genetics, eugenics, mathematical and scientific education, as well as other titles familiar at the British Association. The medical sections are nineteen in number. Correspondence should be addressed to Buro der 89 Versammlung der Gesellschaft Deutscher Naturforscher und Aerzte, Dusseldorf, Schliesfach, Nr. 66.

THE Italian Ministry of Aeronautics has issued a small *Annuario* for the use of aviators. It contains tables of the rising and setting of the sun and moon and other astronomical information, besides tidal, magnetical, and meteorological information likely to be of value in aviation. The latter half of the book gives the position of wireless stations, wave-length, call letters, and times of transmission of weather bulletins. The book is well arranged in a handy form suitable for ready reference.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned :—A lecturer in philosophy in the University of Liverpool—The Registrar (June 1). An assistant lecturer in engineering at the Cardiff Technical College—The Principal (June 5). A lecturer in mechanical and structural engineering at the Regent Street Polytechnic—The Director of Education (June 7). A reader in mathematical analysis in the University of Leeds—The Registrar (June 9). Lecturers in palæontology, plant physiology, and comparative anatomy in the Egyptian University, Cairo—The Minister of Education, Cairo (June 14). A lecturer in tinctorial chemistry and dyestuffs, and a lecturer in bleaching, dyeing, printing, and finishing at the Manchester Municipal College of Technology—The Registrar (June 21). A lecturer in mathematics at the Northampton Polytechnic Institute, St. John Street, Clerkenwell, E.C.1—The Principal (June 26). A lecturer in biology at the Cheshire School of Agriculture, Reaseheath, Nantwich—The Principal (June 26). A principal of the L.C.C. School of Engineering and Navigation, High Street, Poplar—The Education Officer, (T.1.a), The County Hall, Westminster Bridge, S.E.1 (June 30). An assistant in archæology in the National Museum of Wales, Cardiff—The Director (July 9). A professor of Indian economics in the University of Madras—The Registrar, Senate House, Chepauk, Madras (July 30). A full-time teacher of physics and electrical engineering at the Leicester College of Technology—The Registrar. A lecturer in geography and nature study at the Bedford Training College—The Principal.

Our Astronomical Column.

SUN'S ROTATION PERIOD AS DETERMINED FROM AURORÆ.—It has long been recognised that auroræ and magnetic storms tend to recur after a synodic rotation of the sun. Mr. G. J. Burns, director of the zodiacal light and auroræ section of the British Astronomical Association, contributes a paper to the March issue of the journal of the Association, in which he discusses the auroræ from 1860 to 1921. When these are grouped in ten-year periods and separated into the four quarters of the synodic period (assumed after Carrington as 27.275 days), the maximum and minimum values shift one quarter of a rotation each ten years, indicating that the rotation period should be increased by 0.02 day. This is quite a small amount, considering the large variations in rotation period in different latitudes. It could be explained by assuming either a slightly different level or a slightly different latitude for the regions of the sun that contribute most actively to visible spots and magnetic disturbances respectively.

THE ROTATION OF VENUS.—The rotation period of Venus is still one of the enigmas of the solar system. Prof. W. H. Pickering in 1921 was led to announce a period of 68 hours about a highly inclined axis. Mr H. McEwen, director of the Mercury and Venus section of the British Astronomical Association, contributes a paper to the March issue of the journal of the Association, in which he describes some observations that support the Pickering period. Six drawings are reproduced, made between April 9 and 15, 1924; they show several light and dark streaks, which appear to turn about an axis near the centre of the disc. The periods deduced for the different markings varied from 66 to 77 hours. The definition was good on all the days. There is, of course, a large amount of evidence, notably that of Schiaparelli and Lowell, in favour of a longer period. The Mt. Wilson spectroscopic results were considered to indicate 15 days as a minimum. But the problem is such a difficult one to settle, that all evidence by skilled observers should be carefully considered.

MOTION OF SUNSPOTS IN LATITUDE.—A letter received from R. Sekiguti, Imperial Marine Observatory, Kobé, directs attention to a research on the motion of sunspots in latitude of which full details will be given in No. 2 of vol. 2 of the *Memoirs of the Imperial Marine Observatory*, now in press. An analysis of latitude motions of spots was recently published by the Royal Observatory, Greenwich, in *Mon. Not. R.A.S.*, Dec. 1924, in which no systematic drift so large as 0·1° per solar rotation was found, by considering long-lived spots during the period 1874–1923. Mr. Sekiguti, by limiting his analysis to spots of recent formation, considers that during the early phase of their life-history, spots in lower latitudes have an equatorward movement when their longitudinal drift (referred to the average motion of stable regular spots) is westward; *i.e.* in the direction of the sun's rotation. His conclusions are based on the following table from statistics of the last spot cycle:

Daily Motion in Latitude	Frequency.			
	Eastward		Westward.	
+0·5°	74	657	89	723
+0·4	58		68	
+0·3	133		135	
+0·2	162		180	
+0·1	230		251	
0·0	361		377	
−0·1	230	634	264	890
−0·2	152		215	
−0·3	149		182	
−0·4	39		89	
−0·5	64		140	

Such motions in latitude, Mr. Sekiguti says, besides throwing light on the properties of a spot vortex, may explain the equatorial inclination of the axes of bipolar groups pointed out by Hale and others.

Research Items.

A Tasmanian Aboriginal Skull.—A skull of a young Tasmanian aboriginal female discovered on the north-east coast is described by Mr. H. H. Scott, Curator of the Launceston Museum, and Dr. R. McClinton in the *Papers and Proceedings of the Royal Society of Tasmania* for 1925 The skull, which is in sound condition but lacks the mandible, indicates the age by the non-erupted wisdom teeth and the condition of the sutures. The inion is slightly developed only. Of several wormian bones the most striking is a divided "Inca bone." Like some skulls of other lowly races it shows a last relic of the external plate of the old pre-frontal in the "orbital process of the sphenoidal turbinate bone." The palate is a perfect horse-shoe shaped cavity, the lingual aspect of the tooth-line slightly widening as it goes backward, in marked contrast to the straight tooth-line in the gorilla. There are seventeen teeth in the skull, of which fourteen had erupted during life. The third pair of molars was on the eve of eruption. The effect of coarse food has begun to be apparent. Except for an abnormal molar, all the teeth are physically perfect and without structural defect. There are large pulp canals and an absence of bone absorption. The palatal arch of this and four other female and six male skulls available to the authors more nearly resemble the Mousterian outline given by Dr. W K. Gregory in his "Origin and Evolution of Human Dentition" than they resemble his Tasmanian palatal arch (Keith), though that of an eleventh skull, that of "Cobia," the lowest and most debased Tasmanian native, is more gorilla-like and generally conforms to Keith's figure.

The Jewish Calendar.—Mr. W. A Heidel contributes to vol. 61 of the *Proceedings of the American Academy of Arts and Sciences* a study of the Jewish calendar in which he arrives, by different methods, at conclusions virtually in accord with the results of the well-known authority, Dr. Julian Morgenstern. Taking it as axiomatic that the calendar is connected with cultus, there would appear to be three calendars, or preferably three phases of the calendar, in Jewish history. A convenient starting-point is the reform of Josiah in 621 B.C., which aimed at a centralisation of the cultus at Jerusalem, superseding a number of local shrines of primitive usage, each doubtless with different calendars. The first indication of a change in the calendrical system after Josiah is in Ezekiel, who dates his vision of the Temple on New Year's day, the 10th day of the month. This obviously implies an equation between two calendars—almost certainly one solar, the other lunar—the latter being the pre-exilic Israelite or current Babylonian calendar. In like manner the 10th day of a month equated with a first day of some 'New Year,' links up with the Jubilee, the Day of Atonement, Sukkot and Pentecost. The calendar to which the 'first day' belongs is clearly the sacred calendar *par excellence*. The new system of numbering of the months, the neglect of lunation in the Torah, and the Bible, and other considerations also point to a solar year In all probability it was introduced from Egypt somewhere between 610 and 605 B.C. After the Captivity there is evidence that proximity and similarity to the Babylonians led to the adoption of new festivals and of a luni-solar year, and the calendar of the Reformation was forgotten or misinterpreted It would appear, therefore, especially in the light of the evidence afforded by the dating for the feast celebrating the Exodus before the Reformation of Josiah, that the Jewish calendar was essentially luni-solar, became solar for a short time after the Reformation of Josiah, and then reverted to luni-solar, although the calendrical arrangements adopted under the solar calendar for the Church year have persisted down to the present day.

Hydrography and Plankton at Millport.—The Annual Report (1924-25) of the Scottish Marine Biological Association on the work done at the Millport Laboratory on the Clyde, drawn up by the executive of the Council, shows a satisfactory progress in all directions. The research carried on by the permanent staff includes hydrography by Mr. A. P. Orr and plankton investigations by Miss S. M. Marshall. Mr. Orr is investigating the Clyde Sea area systematically with regard to the hydrogen-ion concentration and oxygen, nitrogen, phosphate and silicate content throughout the year. Miss Marshall has published elsewhere three papers on her plankton work, including the description of the interesting new dinoflagellate *Protoerythropsis vigilans*, and a systematic study of the food of the copepod, *Calanus finmarchicus*. In the present report she describes the feeding and reproduction of the aberrant silicoflagellate *Ebria tripartita*, which is holozoic, and also gives notes on other members of the microplankton collected in the lochs. She finds that when diatoms and certain small dinoflagellates occur in a loch to any extent, they increase in numbers towards its head, where they may be very numerous. This seems to fit in with the abundance of silicates found at the loch heads, a rapid growth probably taking place where the silicates are poured in from the streams Mr. R. Macdonald, Carnegie research student, is working on the euphausiids of the Clyde area A table of the food of *Meganyctiphanes norvegica* during several months includes copepods, diatoms and other algæ besides vegetable debris.

Siliceous and Horny Sponges.—Prof. H. V. Wilson describes (*U.S. Nat. Mus., Bulletin* 100, 1925) the siliceous and horny sponges collected by the U S. Fisheries steamer *Albatross* during the Philippine Expedition, 1907-10. His account is also "something of a guide to the contemporary taxonomy of sponges, more especially of the tetraxonid sponges." He directs attention to the bearing of variations on classification in such genera as Donatia and Tetilla—the problem which meets workers on groups of plastic organisms In Donatia, for example, the various diagnostic features which have been picked out as characterising natural races all vary, and they vary apparently independently of one another, so that many kinds of combinations come into existence. Moreover, it is not a case of relatively unalterable characters (unit characters) which are present or absent, but any one feature varies so as to produce a series the extremes only of which contrast sharply; thus as the number of carefully studied individuals increases, the intergrading makes more and more difficult the customary method of classification, which is essentially a splitting method. He advocates the formation as sub-genera, not as groups into which all the species of a genus are divided, but rather as groups which are sufficiently homogeneous to be set off from a still heterogeneous remainder. If, therefore, a character or combination of characters is distinctly developed in a particular case the latter would find its place in a sub-genus in the sense proposed, but if such features are absent or not well marked, the specimen would be placed in the body of the genus (*e.g.* Tetilla).

Mitochondria in Opalina.—E. S. Horning (*Australian Journ. Exp Biol*, vol 2, Dec. 1925) has investigated the mitochondria which are present in large numbers in Opalina at all stages of the life cycle. In the asexual multiplicative phase of Opalina the mitochondria are bent, filamentous bodies and they multiply by longitudinal fission. Immediately before the Opalina encysts the mitochondria may divide transversely, giving rise to spherical bodies which persist in the cyst and in the gametes. In the zygote they appear to fuse into larger masses which later break up into small granules; these in turn elongate to form the filaments of the asexual stage. The author considers that his observations afford strong evidence for the view that the mitochondria are persistent, self-reproducing bodies, and not metabolic products of the cytoplasm, though the latter possibility has not been disproved. Further, he adds that synthesis of vegetative granules—storage products—appears to take place at the surface of the mitochondria, an observation which gives support to the speculation that the mitochondria are loci of protein and possibly of general protoplasmic synthesis within the body of the living cell.

Ice in the Baltic.—The Havsforsknings Institutet of Finland has published the annual report on ice in the Gulf of Bothnia and Finland (*Isarna Vintern*, 1922–23). From about 120 stations, including several on the Finnish coasts of Lake Ladoga, detailed observations are given for the winter months. Not until January did ice become a serious menace. By early February all the Baltic coasts of Finland were blocked and the Gulf of Finland was very congested. By the end of the month pack-ice extended past the Åland Islands across to the Swedish coast, and the head of the Gulf of Bothnia was inaccessible. Conditions were even worse in March, and the spring break-up was very slow. In the beginning of May there was still ice in the north of the Gulf of Bothnia and at the head of the Gulf of Finland. It was June before the former entirely disappeared. These conditions, except the slow disappearance of the ice, did not show a marked departure from the normal, but the winter was on the whole a severe one.

The Plant as a Measure of the Habitat.—The discussion of the 'phytometer' method by Clements and Goldsmith was recently referred to in this journal (Nature, Oct. 31, 1925, p. 656). Two recent papers record South African studies on these lines. Mr. J. F. V. Philips has been using the growth and structure of indigenous tree seedlings, both naturally sown and specially planted in selected quadrats, in order to obtain a quantitative expression of the effect of the habitat (*South African Journal of Science*, vol. 22, pp. 197–214, 1925. See also Nature, January 2, p. 16). Prof. J. W. Bews and Dr. R. D. Aitken, with the collaboration of advanced students of Natal University College, have issued a second series of the researches on the vegetation of Natal (*Memoir No.* 8, the Botanical Survey of South Africa, Pretoria, 1925), which includes a study of the water requirement and transferation of a common Natal weed, *Bidens pilosa* L. These studies were undertaken with the view that the behaviour of this universally distributed Natal weed under carefully controlled habitat conditions is a necessary preliminary to its employment as a 'phytometer.'

Silver Leaf Disease.—Mr. F. T. Brooks continues at Cambridge his investigations into this serious disease of fruit trees, especially apple and plum, and in association with Mr. W. C. Moore publishes a fifth paper upon the subject in the *Journal of Pomology and Horticultural Science* (vol. 5, No. 2, March 1926). One of the most striking results reported is the almost complete failure of inoculation with spores of *Stereum purpureum* upon freshly cut surfaces of healthy trees in the months of June and July, and sometimes in August. These results are in striking agreement with Mr. Swarbrick's investigations upon the natural processes of healing in such cut trees (Nature, May 1, p. 635), recorded in the same journal. As Mr. Brooks finds that the disease makes little entry, if any, by old wounds, or through diseased tissues produced by other pathogenic organisms, these results seem to be of great practical significance. Indeed, in discussing treatment, the authors conclude that there is now ample evidence that the winter thinning and pruning of fruit trees is fundamentally wrong from the point of view of plant pathology. The authors report further trials with various protective dressings, applied immediately to cut surfaces. Gas tar and Stockholm tar seem to be ineffective; soft grafting wax is most highly recommended. Apparently its great value lies in the fact that it does not injure the tissues; apart from this danger certain anti-fouling paints appear to be very satisfactory. In view of the inoculation experiments reported in the same paper, it would seem that if the cut surfaces are exposed at a suitable season, natural healing processes themselves are usually an adequate protection against the entry of *Stereum purpureum*.

Subsidence of Coral Reefs.—In the *Proc. Nat. Acad. Sci.*, Washington, for February 1926, Prof. W. M. Davis brings forward additional evidence in favour of the strong subsidence of certain reef-encircled islands. It is argued that during intermediate stages of the submergence of a maturely dissected volcanic island, the distance from the island top to the outer spurs (spur-radius) should be two or three times the distance between the heads of bays and the outer spurs. Some of the embayed islands of the Fiji and Society groups, tested by this new criterion, appear to have subsided 1000 or 2000 feet. Similarly, where the width of the lagoon and the spur-radius are of the same order, the encircling reef must have been built up from a considerable depth. It is also ingeniously shown that the rate of island submergence in the open Pacific is frequently not faster than that of reef upgrowth. This implies that the rate of reef upgrowth is significantly slower than that of coral upgrowth, since the growing corals are the chief source of supply not only for the reef face itself, but also for the reef flat, much of the lagoon floor, and the outbuilding of the outer talus slope. The relation of island subsidence and reef upgrowth to changes of ocean level during and after the glacial period is also briefly considered.

The Age of Uranium Minerals.—Analyses of pitchblende from Katanga, uraninite from the Black Hills of South Dakota, and asphaltite from Utah have been made by C. W. Davis, and they are recorded and discussed in the *Am. Journ. Sci.* for March 1926. The Katanga specimen is of particular interest in being quite free from thorium. It therefore helps to confirm the theory that thorium and uranium are not genetically related. The lead-ratio is 0·084, which is identical with that of polycrase from Brazil and with the higher ratios from Ceylon thorianites. The dolomite schists of the southern Belgian Congo are now known to be older than the age corresponding to this ratio, but unfortunately it is not yet certain whether that ratio characterises the older Palæozoic or the latest pre-Cambrian. Determinations on minerals of Keweenawan age now being carried out in the United States should definitely fill up this gap in our present knowledge. The Black Hills uraninite contains lead having an atomic weight of

206-07 (determined by Dr. A. L. Hall of Harvard). The geological age is pre-Cambrian, but the lead ratio, 0·24, is abnormally high. As the specimens are all somewhat altered to gummite and uranophane, the result is in accordance with the view advocated by Holmes, that altered uranium minerals tend to gain lead in greater proportion than they lose uranium (*Phil. Mag.*, May 1926). The asphaltite gives a low age and indicates, as deduced from geological evidence, that the deposit has been carried upwards and redeposited by thermal waters, during which most of the accumulated lead was dissolved and removed.

Diffraction Phenomena with Biological Structures.—Adrianus Pijper has demonstrated (*South African Med. Record*, October 24, 1925) that surface growths of various bacteria act as diffraction gratings, and a study of the spectra obtained by means of such ‘ gratings ’ leads to the conclusion that bacilli in the culture probably stand on end perpendicular to the surface. By projecting the spectrum obtained into a dark chamber and focussing on a screen, measurements of the circular images may be made which, by the aid of a simple formula, give the size of the structures forming the grating. In this way the diameters of the microbes constituting the grating may be calculated. Blood smears also act as diffraction gratings, and the average size of the blood corpuscles can be calculated in a similar manner. In pernicious anæmia there is an increase in the average size which can be demonstrated by the method, which, therefore, may be employed for certain clinical investigations. Full details of the technique are given.

Optical Effects in Invertebrates due to Guanin.—The recently issued *Verhandlungen des Naturhistorischen Vereins der preussischen Rheinlande und Westfalens* (82 Jahrg) is dedicated by his friends and pupils to Prof. Walter Voigt of Bonn, for many years secretary of the Verein, in honour of his seventieth birthday. It contains a score of zoological papers and three on geological subjects. Two of the zoological papers record the occurrence of guanin in reflecting structures in invertebrates. J. Schlicher describes the tapetum—using this term for the iridescent layer—in the eye of *Pecten jacobæus* as composed of crystalline quadratic plates, about 1·4 μ in diameter, which are arranged in superimposed layers and in rows. These plates consist of guanin. He states that the layer contains from three to six cell nuclei of characteristic structure. W. J. Schmidt has examined the iridescent males of two Mediterranean species of Sapphirina, and shows that the iridescence is dependent on the epithelium of the dorsal surface, the cells of which attain a large area but are very thin. These cells secrete the cuticle, and they also produce in their cytoplasm the layer which gives rise to the iridescent effects. This consists of hexagonal plates about 1 μ in diameter and 0·3 μ thick, arranged in three systems, and they are either composed of guanin or contain a guanin component.

Liquid Viscosity under Pressure.—The February issue of the *Proceedings of the American Academy of Arts and Sciences* contains a paper by Prof. P. W. Bridgman of Harvard on the effect of pressures up to 12,000 atmospheres on the viscosities of forty-three liquids, mainly organic, at 30° C. and 75° C. The method used is that of the falling weight, which in this case is a short cylinder nearly filling a steel tube 0·6 cm. internal diameter and about 6 cm. long placed vertically. The time of fall, 5 to 50 seconds, is determined by means of electrical contacts at the top and bottom of the tube, which can be inverted between each fall. Except for water, the viscosity increases with the pressure, at first according to a linear law, but at higher pressures the increase becomes more rapid. The total increase at 12,000 atmospheres may be 10-fold or 10-million-fold, the larger values being found for liquids with complicated molecules. The effect of temperature on the viscosity is several times as great at 12,000 atmospheres as it is at 1 atmosphere. The viscosity of water decreases a few per cent. as the pressure increases up to 1000 atmospheres, then increases, and at 12,000 atmospheres has about twice the value it has at 1 atmosphere.

The Lightning Flash.—Some fifty years ago a lightning flash was supposed to take place along the path of minimum electric resistance Afterwards Lodge gave reasons for supposing that it followed the path of minimum electric inductance, and this is the orthodox theory at the present time. In a paper communicated to the Washington Academy of Sciences (vol. 16, p 87), N. E. Dorsey describes in detail the effects produced by a flash striking a tulip tree. He considers that these effects could have been produced by a great rush of ‘ carriers ’ analogous to the well-known cathode stream. If an electron attain a sufficiently high velocity it may generate a ‘ dart ’ of electrons, the leading electrons gaining energy at the expense of the trailing ones. A high-speed dart possesses a considerable amount of momentum, and can strike a correspondingly powerful blow. In the particular case studied, the molecules were so crowded that they could not pass transversely to the grain without actually punching out the fibres ahead of them. Along the grain, however, in the direction of the flow of the sap, they could pass much more easily, but in so doing the fibres were torn into shreds.

What happens during a lightning flash Dr. Dorsey describes as follows. There is at first a rush of electrons. These blaze a conducting path along which flows a more leisurely current of the ordinary type. Possibly this conducting current conveys a far larger quantity of electricity than is carried by the dart of electrons. The direction in which the dart flies is the direction in which the blow is delivered. The effects produced where the stroke starts differ characteristically from those produced where it ends.

Electric Ignition of Firedamp.—The Safety in Mines Research Board has issued a paper by Prof. R. V. Wheeler on the electric ignition of firedamp which is of considerable interest. The results do not agree with the researches of some other workers in this field, and further experiments are being undertaken in an attempt to reconcile them. It is proved that the igniting current for a given mixture of methane and air varies directly with the volatility of the metal at the spark-gap, being lower the lower the boiling point of the metal. The igniting current also is lower the more rapid the break in the circuit. It is also lower the less the area of the surfaces which touch one another and are pulled apart. Prof. Wheeler was unable to find any simple law connecting the value of the igniting current with the inductance of the circuit. In a particular case, a simple particular law was found which seemed to indicate that the electromagnetic energy stored in the circuit was approximately constant for the minimum igniting current. With highly self-inductive circuits the magnitude of the current is of far greater importance than the impressed voltage when the voltage is low. But with high voltages the igniting current decreases with the voltage. Finally, the experiments seem to prove that the incendivity of the break flashes does not depend on whether the current is direct or alternating.

A Problem in South African Geology.

THE Vredefort Mountain Land lies to the west of Vereeniging and some eighteen miles south-south-west of Johannesburg; it is cut through by the Vaal River, which forms the boundary between the Transvaal and the Orange River Free State. Its striking topography, in marked contrast to the monotonously flat country of the northern Orange River Free State, is determined by an enormous circular boss of granite with some gneiss and schists, about twenty-seven miles in diameter. This granite boss is surrounded by a belt of sediments ranging from the Lower Witwatersrand beds (nearest to the granite) up to the Pretoria beds—in all some 13,000 feet of total thickness. Although in apparently conformable succession, the beds dip towards the granite instead of away from it, as they should do if the succession were normal; so that there is here an inversion of the strata on a very large scale. Near the granite the sediments are highly metamorphosed, the shales and slates being charged with contact minerals. These phenomena constitute a fascinating problem, which has exercised the minds of South African geologists since the earliest days of the Rand.

The granite (a quartz-orthoclase-oligoclase-biotite rock) is generally accepted as identical with the old granite occurring north of Johannesburg and near Heidelberg, and as older than the Witwatersrand beds It cannot therefore be intrusive in them, and the problem requiring solution is: What brought about the tilting and inversion of the sediments encircling the granite? And what is the cause of the contact-metamorphism shown by them?

The memoir under review[1] embodies the work done by Dr Molengraaf, professor of geology in the Technical High School, Delft, and Dr. Hall, assistant director of the Geological Survey of the Union of South Africa, to elucidate this problem The authors first review the various theories put forward in papers by Gibson, Molengraaf, Draper, Bunkell, Hatch, Sawyer, Jorissen, Kynaston, Mellor, and Penny, and then, after a detailed geological and petrographical description of the rocks and their tectonic history, they state their conclusions, which may be briefly summarised as follows:

(1) The granite is older than, and therefore non-intrusive into, the sediments.

(2) The over-tilting of the sediments is due to the up-doming of the central granite, which, it is suggested, was initiated by centripetal pressure. The relief of load resulting from this movement caused a younger magma below the granite to become active and to rise, thus assisting the upward movement of the heated but passive granite

(3) This up-doming called into play exceptionally powerful pressure which manifested itself both in the metamorphism of the encircling sediments and in the production, by compression, trituration, and local fusion, of a flinty crush-rock (pseudo-tachylyte) which occurs in countless veins both in the granite and in the encircling sediments.

(4) In the contact-belt are dykes of enstatite-granophyre, which contain numerous xenoliths of crushed quartzite derived from the Lower Witwatersrand beds. It is suggested that this apparently igneous rock is a flinty crush-rock originating from ultra-trituration and partial fusion of the sediments.

(5) The metamorphism of the sediments was, in part, *regional* and due to static pressure, accompanied by heat, and, in part, *local* and due to the emplacement of a large younger intrusion.

(6) The regional metamorphism is characterised by the production of hornblende-granulite and garnet-amphibole-hornfels; the local metamorphism, by cordierite-biotite-hornfels and andalusite-biotite-hornfels. Where the two are concurrent the reinforced metamorphism is indicated by the increased size and abundance of the contact-minerals

(7) The younger intrusion, referred to in (5), is, to a great extent, concealed, although exposed as three small bosses of alkali-granite (soda-granite) and accompanying nepheline-syenite dykes. Certain gabbroic marginal intrusions in the older granite and the nearest belt of sediments are regarded by the authors as the earliest basic differentiates of the younger magma

(8) The extension of the nepheline-syenite dykes northward across the Magaliesberg into the Pilandsberg (also a region of alkali-rocks) indicates the existence of channels of communication between the two centres of alkali-rocks and some community of origin with the Bushveld complex.

The Vredefort Mountain Land has, according to the authors, remarkable analogies with the Black Hills dome in Dakota and the Ries Kessel in Bavaria In the Vredefort area the up-doming movement originated at a greater depth than in the Black Hills dome; and this explains why the regional and contact metamorphism are so much more developed in the Vredefort area. Stress phenomena are much in evidence both in the Vredefort and the Ries domes, but in the former they attain a marvellous development, culminating in the genesis of flinty crush-rocks on a gigantic scale In all three cases the observed facts lead to the surmise that a hidden mass of igneous magma must be present below the central core of granite.

F. H. HATCH.

Sunspots and Terrestrial Magnetism.[1]

FOR a long time it has been known that sunspot frequencies have had their counterpart on the earth in the disturbances exhibited by the magnetic elements on its surface As the sunspot period is at least eleven years, and as the variations in sunspot phenomena in successive eleven-year periods are considerable, it follows that to get a comparison of normal means free from accidental effects, a large number of periods must be taken. The Kew magnetographs have been in almost continuous operation since 1858, and the connexion between sunspots and the absolute daily range of declination (the element most easily measured), for the first 42 years of their progress up to 1900 has already been discussed. The first of the memoirs under notice treats of the same phenomena and adds another 10 years to the comparison (1) The decade which is under discussion proved generally to be one of small magnetic disturbance and low sunspottedness. Anomalies were disclosed in 1903 and 1909, but were attributed to accidental magnetic disturbance enhancing what would otherwise have been normal years. The application of Wolf's formula, connecting magnetic range with sunspot numbers, also gives a small amplitude of the declination range corresponding to hypothetical zero sunspot numbers throughout the ten years.

---

[1] Air Ministry, Meteorological Office, London. (1) Geophysical Memoirs, No. 29 *The Absolute Daily Range of Magnetic Declination at Kew Observatory, Richmond*, 1901–1910, by J. M Stagg. 3*s.* net (2) Geophysical Memoirs, No 30. *Comparison of Magnetic Standards at British Observatories, with a Discussion of Various Instrumental Questions involved*, by Dr C Chree. 1*s.* 6*d* net (Published by the Authority of the Meteorological Committee.) H.M. Stationery Office, London.

Generally speaking, the results obtained are parallel with those for the previous longer series, especially in regard to the annual variation in daily range, and the incidence in the times of daily maxima and minima. The progressive change in time of the maximum daily value of declination was of the same sign, although not attaining the same order of magnitude as was suggested for the earlier periods. Confirmatory evidence is also shown of the 27-day period of recurrence of magnetic disturbance and calm, corresponding with the period of rotation of the sun.

The memoir concludes with a comparison between the inter-diurnal variability of sunspot areas and declination ranges, which does not remove the anomalies of 1903 and 1909. To facilitate examination, the numerous tables are represented diagrammatically. Mr. Stagg is to be commended on undertaking a task involving much tedious measurement of curves and a vast amount of laborious arithmetic.

(2) In order to get a correct idea of local variation and secular change in the components measured in terrestrial magnetism, one must be assured by careful comparison that the differences between individual standard measuring instruments do not confound the issues. Owing to his long experience in testing magnetic instruments, and his intimate knowledge of the standardisation of magnetographs, no one was better fitted than Dr. Chree for carrying out the comparison of the magnetic standards used at Kew, Greenwich, Eskdalemuir, Stonyhurst and Valencia, described in the second memoir. Taking the Kew instruments as ultimate standards, the instruments compared were Kew pattern unifilar magnetometers for measuring horizontal force and declination, and dip circles and inductors for the angle of dip.

Generally a travelling unifilar magnetometer and a dip circle served as intermediaries between Kew and the other stations. According to circumstances, the comparisons, extending in each case to about a week, were effected through direct simultaneous observations with two instruments, or indirectly through the medium of the magnetograph curves. Except at Stonyhurst, where the facilities for 'direct' comparison were rather limited, the differences obtained in declination and dip were trifling, and what might be expected of any two ordinary instruments over such a short period. The differences in the case of horizontal force measurements were more considerable, and no doubt had their origin in the variations of the 'constants' for which corrections have to be applied.

These 'constants' include (1) temperature, and (2) induction coefficients; (3) distribution of magnetism constants (P and Q), and (4) the moment of inertia of the collimator magnet. They have such an important bearing on the results, that the first part of the paper is devoted to a detailed discussion of the considerations which they involve. Temperature and induction coefficients are determined at the initial standardisation of the collimator magnet, and their variations are inappreciable. The 'constants' P and Q vary considerably with time, and the elimination of changes due to accidental causes is brought about by the use of means from large numbers of observations. Owing to attrition through constant use, the moment of inertia of the magnet is liable to decrease progressively, and fairly frequent determinations are desirable. The moment of inertia of the magnet is usually calculated from the mass and dimensions of its inertia bar (which should be a perfectly homogeneous right circular cylinder). Recent measurements of inertia bars at the National Physical Laboratory give the impression that modern methods of accurate measurement of length do not absolutely agree with those of the past, and the question should be investigated further.

After a perusal of the uncertainties liable to be introduced in the corrections applied, one is left with the idea that consistent true values of the horizontal force are hard to come by, but this idea is partly dispelled by an examination of the remarkably consistent base line values of the magnetograph curves obtained at Kew Observatory.

The memoir should prove of valuable assistance to all magneticians, and particularly to any one undertaking a similar investigation in the future.

R. E. Watson.

The Fauna of the Chatham Islands.

The Chatham Islands lie 536 miles east of the South Island of New Zealand and belong to that country both territorially and faunistically. They include three chief islands which are very fertile and are inhabited by a few hundred whites and natives. In *Records of the Canterbury Museum*, vol. ii, No. 3, 1925, seven out of the ten papers contained in that issue are devoted to various groups of animals occurring in these islands, and chiefly collected by Messrs. Archer and Lindsay.

The Lepidoptera are dealt with by Mr. E. Meyrick, who mentions that forty-three species have now been recorded. Of these, three are domestic insects undoubtedly introduced by the direct agency of man; one species, *Agrotis ypsilon*, is cosmopolitan; six are common to both New Zealand and Australia, but probably are all of Australian origin; twenty-four are New Zealand species; and nine species so far as known are endemic. It is believed that few of the non-indigenous species have found their way to these remote little islands by being blown out to sea, and they have probably taken advantage of human agencies in some way in gaining their entry.

The Trichoptera are described by Dr. R. J. Tillyard, and only three specimens were obtained. Two of these belong to new species that are closely allied to existing New Zealand forms, while the third specimen is of a more interesting character. It is a very remarkable short-winged caddis-fly which is referred to a new genus Chathamia and to a new subfamily of the Rhyacophilidæ, the Chathamiinæ.

Mr. A. E. Brooks discusses the Coleoptera, and remarks that, of the 110 species of beetles previously known from the islands, only twenty-four are represented in the collection made by Messrs. Archer and Lindsay. More than half the species recorded are also common to New Zealand, and only two endemic genera have been brought to light, namely, Thotmus and Hadramphus, both of which belong to the Curculionidæ. The Orthoptera and Dermaptera are very few in number, only six species being recorded by Mr. A. M. Lysacht. These include three species of so-called sand-crickets (Stenopelmatinæ), one of which is endemic; a phasmid *Argosarchus horridus* (White); a cockroach *Zonioploca brunni* (Alfk.); and the earwig *Anisolabis littorea* (White).

Prof. C. Chilton enumerates the Amphipoda and Isopoda, and of the first-mentioned order eight species are now known to occur. Of the Isopoda eight species likewise are listed, and of these the most notable is *Paravireia typicus* gen. et sp nov. This crustacean belongs to the family Sphæromidæ and is a fresh-water form. A remarkable fact concerning this type is that it is allied to the genus Vireia which occurs in underground waters in Europe. The spiders are discussed by M. Lucien Berland, who adds two species new to science, making a total of twenty species now recorded from the islands. The affinities of these spiders, he remarks, are entirely with New Zealand—they have no affinity with S. American forms.

Inheritance of Induced Melanism in Lepidoptera.

J. W. H. Harrison and F. C. Garrett (*Proc. Roy. Soc.*, B, vol. 99, p. 241, Feb. 1926) record the results of some eight years' observation and experiment upon the inheritance of melanism induced in Geometrid moths by the addition of lead and manganese to their diet. The increase of melanism among various Lepidopteran species in industrial districts of England and the Continent has excited the attention of the field naturalist and the general biologist for some time, and in 1920 Dr. Harrison made the suggestion (*Journ. Genetics*, 9, 3, p. 195) that the increase in melanism was due to the modification of the body pigments through various salts deposited on the food plants in areas where the atmosphere is charged with smoke.

This suggestion was submitted to experimental verification, and the result is the most unequivocal proof which has yet been obtained of the inheritance of an experimentally induced modification. Individuals of three species, *Selenia bilunaria* and *Tephrosia bistortata* and *crepuscularia* were used. Normal (non-melanic) individuals were obtained from rural districts of the south of England. Some of them were kept as controls on normal food and, though bred for several generations, showed no melanism. Others were submitted to experimental conditions, the *S. bilunaria* individuals being fed on hawthorn treated with lead nitrate and manganese sulphate, the *T. bistortata* being fed on roadside hawthorn gathered in an industrial district (north Durham) where there is an abundance of wild melanic forms. In both cases melanism appeared in the experimental animals, and was inherited in *S. bilunaria* and *T. bistortata* as a Mendelian recessive, in *T. crepuscularia* (p. 245) as a dominant.

The technical procedure in these experiments seems to leave no room for criticism; though we would like to hear the author's views as to why in certain cases (pp. 245 and 246) the number of animals which are experimentally modified is so low (22·1, 26:1, and 29:2). Further experiments are contemplated with the view of discovering the active agent which produces the colour change, the authors expressing a doubt as to whether it may not be the acid radical of the compounds employed instead of the metal.

A Journal of Marine Investigations.

The recent issue of the first number of the *Journal du Conseil* marks the start of a new and welcomed venture in publication by the Conseil permanent international pour l'exploration de la Mer. British readers in particular will find pleasure in the fact that Dr. E. S. Russell, the Director of Scientific Fishery Investigations of the Ministry of Agriculture and Fisheries, has undertaken the difficult task of editing this important work. The *Journal* will, it is hoped, appear quarterly, each number containing a general article on some aspect of the Council's work, one or two short scientific articles such as have hitherto been published in the *Publications de Circonstance* (which series will now be discontinued), notes on current work, reviews, and a current bibliography. The first number is a noteworthy commencement. The general article is written in English by Prof. Johan Hjort on "Fluctuations in the Year Classes of Important Food Fishes," and a résumé in French follows. The scientific article, also in English, on "The Relation between Cod-end Mesh and Size of Fish Caught" describes some preliminary experiments with the Trouser trawl, and should be of especial interest to the practical men of the trawling industry.

Thirteen papers in all are reviewed, the name of the reviewer in each case being given. It will probably be noticed that twelve of the thirteen papers reviewed were published in English, and of these nine were written by British investigators. Moreover, only two of the reviews were prepared by Continental writers. Many readers would be greatly assisted in their work if it could be found practical to include reviews of papers appearing in languages which are generally unfamiliar. If, also, the list of reviewers could be made to include representatives of the several nations interested in the work of the Council, a great store of experience and thought would become available to the readers of the *Journal*.

Part i. of a selected bibliography of marine bionomics and fishery investigation, compiled by Dr. E. J. Allen, will be generally welcomed. Part ii. is to appear in the second number of the *Journal*, and it is proposed to re-issue the bibliography, when complete, as a separate publication. Starting with No. 3 of the *Journal* the current bibliography will be issued to subscribers in the form of sheets printed on one side only, as well as being printed in the *Journal* in the ordinary way.

University and Educational Intelligence.

Cambridge.—The effects of the general strike were very marked. The Council of the Senate naturally made no recommendation as to the course which persons *in statu pupillari* should adopt. A tutors' committee dealt with instructions to those who wished to volunteer for service in various capacities; unfortunately, this committee gave instructions before an adequate organisation capable of dealing with masses of volunteers had been created. The result was semi-chaos, reminiscent of the early autumn of 1914.

The University ceased to give formal instructions between May 9 and 16. All triposes have been postponed, some for a week and some for a fortnight. As a result of this scheme the carefully devised plan on which the examinations are usually arranged in space and time has been dislocated, and the Board responsible for the organisation is faced with the prospect of providing for some 2000 candidates for university examinations on certain days (1600 is usually regarded as the maximum).

Edinburgh.—At the meeting of the University Court on Monday, May 17, an intimation was received from Prof. B. P. Watson, professor of midwifery and diseases of women, of his intention to resign upon his appointment as professor of obstetrics and gynæcology in Columbia University, New York. The Court received his intimation with regret.

LEEDS.—It has been decided to confer the honorary degree of D.Sc. upon emeritus Prof. P. F. Kendall, following professor of geology in the University.

Dr. F. M. Rowe has been elected to the chair of colour chemistry and dyeing as from October 1 next, in succession to Prof. A. G. Perkin. Dr. Rowe entered the University of Leeds from the Marling School, Stroud, in 1908 with a Clothworkers' Company's scholarship. He graduated with first-class honours in colour chemistry and obtained the Diploma in Dyeing and the Leblanc Medal in 1911. He held the Clothworkers' Research Scholarship for one year and a University Research Fellowship in the following year. After three years' experience with Messrs. Joseph Crosfield and Sons, Ltd., Warrington, he was appointed lecturer in dyestuffs in the University and the College of Technology at Manchester, and in 1926 was appointed reader in tinctorial chemistry and dyeing. He was awarded the Dyers' Company's Gold Research Medal in 1925. He is the author of a number of papers on pure chemistry, coal tar, intermediate products, dyes, and dyeing published in scientific and technical journals, and of articles in Thorpe's "Dictionary of Applied Chemistry." He is also the editor and compiler of the "Colour Index" published by the Society of Dyers and Colourists, Bradford.

LONDON.—The University chair of physiology tenable at the London School of Medicine for Women, now held by Dr Winifred C. Cullis, will henceforth be known as the Sophia Jex-Blake chair of physiology in the University of London.

Prof. J. A. Fleming, who occupies the University chair of electrical engineering at University College, will retire on July 31 next; the Senate has passed a resolution placing on record its sense of the importance of his achievements in this field of applied science.

A bequest by the late Sir John Rotton of books, bookcases, and bookshelves, and of 500*l.* for the creation of a fund to be known as "The Sir John Rotton Fund" in connexion with the Library of University College, has been accepted.

The following doctorates have been conferred:—*D.Sc.* (*Botany*) on Mr E. J. Collins for a thesis entitled "Variegation and its Inheritance in *Chlorophytum Elatum* and *Chlorophytum Comosum*," and other papers; *D.Sc.* (*Mathematics*) on Mr. G. C, Steward for a thesis entitled "Aberration Diffraction Effects," and another paper.

In consequence of the general strike, many of the University examinations have been postponed.

Dr. T. F. Sibly, vice-chancellor of the University of Wales, has been appointed Principal Officer in succession to Sir Cooper Perry, who retires on August 31.

DR. W. E. H. BERWICK, reader in mathematics in the University of Leeds, has been appointed to the chair of mathematics at the University College of North Wales, Bangor.

APPLICATIONS for grants from the Chemical Society Research Fund are invited. They should be sent, on a prescribed form, to reach the assistant secretary of the Society, Burlington House, Piccadilly, W.1, by Tuesday, June 1.

THE London School of Hygiene and Tropical Medicine, 23 Endsleigh Gardens, W.C.1, is prepared to consider applications for two whole-time research studentships, one in the Department of Tropical Pathology and one in the Department of Helminthology. Each studentship is of the annual value of 250*l.* The latest date for the receipt of applications by the Secretary of the school is June 30.

Contemporary Birthdays.

May 24, 1855.	Dr. Alfred Cort Haddon, F.R.S
May 24, 1861.	Sir Wyndham R. Dunstan, K.C.M.G., F.R.S.
May 24, 1860.	Prof. A. Smithells, C.M.G., F.R.S.
May 25, 1858.	Sir Henry Alexander Miers, F.R.S.
May 25, 1865.	Prof Pieter Zeeman, For.Mem R.S.
May 26, 1844.	Sir Daniel Morris, K.C.M.G.
May 28, 1861.	Dr. Hugh Robert Mill.
May 28, 1874.	Sir Rowland Harry Biffen, F.R.S.

DR. HADDON, reader in ethnology in the University of Cambridge, is a Londoner. He graduated at Christ's College, Cambridge. A former president of the Royal Anthropological Institute, he has received its Huxley medal for his services to anthropology

Prof. SMITHELLS, emeritus professor of chemistry in the University of Leeds, a Lancashire man, was born at Bury Educated at the University of Glasgow and Owens College, Manchester, he studied also at Munich and Heidelberg. Prof. Smithells' extended and valuable services to the University of Leeds, of which indeed he may claim to be one of the founders, have received special recognition.

SIR HENRY MIERS, vice-chancellor of the University of Manchester (an office from which he is retiring this year), was born at Rio de Janeiro. From Eton he graduated at Trinity College, Oxford. Waynflete professor of mineralogy in the University of Oxford from 1895 until 1908, he vacated this chair to become principal of the University of London Recently Sir Henry has been elected a trustee of the British Museum.

Prof. PIETER ZEEMAN, foreign member of the Royal Society, was born at Zonnemaire, Holland. He is an alumnus of the University of Leyden, and formerly held there the chair of physics. Thirty years ago Zeeman communicated a paper of prime value to the Academy of Sciences, Amsterdam, entitled "On the Influence of Magnetism on the Nature of Light radiated from a Substance." Later, in its applications to celestial physics, this contribution provided astronomers with methods for tracing magnetic effects at the surface of the sun. In 1902 Prof. Zeeman was Nobel laureate in physics, with Prof. Lorentz; in 1922 he was awarded the Royal Society's Rumford medal for his researches in optics. A medallist last year of the Franklin Institute, Philadelphia, reference may be made to Prof. Zeeman's suggestive address there, "Magnetisation of Spectrum Lines: Reminiscences and Prospects."

SIR DANIEL MORRIS, economic botanist, was born at Loughor, Glamorgan, and was educated at Cheltenham and the Royal College of Science, London. From 1886 until 1898 he was assistant director of the Royal Botanic Gardens, Kew, and afterwards Imperial Commissioner of Agriculture, West Indies

DR. MILL, geographer and meteorologist, was born at Thurso. He is a graduate of the University of Edinburgh. Librarian of the Royal Geographical Society, 1892–1900, Dr. Mill is an authority on rainfall data and meteorological statistics in general. He is the author of valuable works on polar exploration

SIR ROWLAND BIFFEN, professor of agricultural botany in the University of Cambridge, graduated there at Emmanuel College. He has actively pursued (notably in conjunction with the late Dr. W. Bateson) the general problems of heredity and variation in plants, particularly with reference to the breeding of new and valuable races of wheat. Sir Rowland was Darwin medallist of the Royal Society in 1920.

Societies and Academies.

London.

Royal Microscopical Society (Industrial Application Section), April 28.—J. H G. **Monypenny**: Some microstructural features of modern rustless steel. During the last few years several special types of stainless steel have been developed to meet special requirements. After referring briefly to the characteristic structures of ordinary stainless steel, the effects of raising still further the chromium content was described. The properties of low carbon material containing 16 to 20 per cent. chromium were discussed, particular attention being given to the solution of the carbide, the grain size, and the hardness and toughness of such material. Adding increasing amounts of nickel to such alloys restores to such high chromium steel the capacity for hardening by quenching from high temperatures and of producing tough ductile material when suitably treated. The austenitic steels produced by adding large amounts of nickel to high chromium steels were also described.

Cambridge.

Philosophical Society, May 3.—Sir Joseph **Larmor**: Insular gravity and oceanic isostasy.—W. A. D. **Rudge**: A mechanical model of the Rutherford-Bohr atom. An attempt is made to show that a rotating electron or electrons can map out a portion of space which represents the volume of the atom. This is effected by using for the electron a small electric lamp, which may be made to rotate about two axes simultaneously. Owing to persistence of vision, the track of the moving lamp appears as a continuous line, mapping out a spherical or ellipsoidal figure somewhat resembling a hollow globe with luminous lines for the meridian of longitude. A second lamp indicates the position of the nucleus. In another arrangement vacuum tubes are arranged in a plane, and by rotating about an axis parallel to the plane, the anode glows of the tubes are concentrated at the centre of a spherical space, and the cathode glows are distributed in the space surrounding the centre. This realises the usually accepted structure of the atom.—Miss C. A. Scott. On the higher singularities of plane algebraic curves. Expansions can be used to prove the numerical relations for singularities without any reference to small quantities. This is based on the theorem that if the lowest terms in $F_1(x, y)$ and $F_2(x, y)$ are of degrees r and s, then the conditions for $rs+q$ O-solutions of $F_1=0$, $F_2=0$, involve only the first q groups of terms in each, here proved by examination of the resultant of F_1, F_2 By means of this it is shown that for determining the number of O-solutions either F may be replaced by a factored form. This factored form is then applied to the proof of Plucker's equations; in particular, the number of intersections of a curve and its Hessian, at a higher singularity, is found by a direct process. No use is made of power-series and convergence.—J. A. Ratcliffe and M. A. F. **Barnett**: On the attenuation of wireless waves in short distance overland transmission. The attenuation of wireless waves of wavelengths 1600 m. and 360 m. has been measured over land up to distances of 70 miles. The results, on the whole, confirm the theory worked out by Sommerfeld, but departures from the theory are noticed at short distances. The value 10^{-8} E.S.U. is deduced for the resistivity of the ground.—Ž. **Marković**: Sur la non-existence simultanée de deux fonctions de Mathieu —C G. F. **James**: On the multiple tangents and multisecants of scrolls in higher space.—E. V. **Appleton**: On the diurnal variation of ultra-short-wave wireless transmission.—R. **Vaidyanathaswamy**: The $(a; 1)$ correspondence.

Dublin.

Royal Irish Academy, May 10.—J. **Doyle**: Observations on the staminate cone of Larix. The vascular strand of the stamen of Larix becomes mesarch distally and develops such an arrangement of transfusion tissue as to support the claim that the tissue itself is, phylogenetically, a modification of centripetal xylem. Evidence from a study of the stamens of Larix and related forms supports the claim that the stamen is not a leaf, but that the primitive stamen of the Conifer and Ginkgo phyla was a radially symmetrical structure, carrying sporangia distally attached, and of a non-foliar, axile, or sporangiophoric nature. This conception allows an easy and direct homology to be drawn between the microstrobili and megastrobili of Conifers, a point of great importance; between the different megastrobilus types themselves; and between both strobili and primitive Palaeozoic forms such as Cordaianthus. Homologising thus directly, living structures with known structures in the Palaeozoic, it renders the brachyplast conception, in any but the most refined form, untenable.—D. R. **Pack-Beresford**: The harvest spiders of Ireland. One of a series of reports submitted by the Fauna and Flora Committee. Twelve species and one variety have so far been discovered in Ireland. Almost all these have a wide range in the country. Only *Nemastoma chrysomelas* seems to be confined to the south-east. The classification adopted is that proposed by Dr. Roewer.—A. W. **Conway**: The dynamics of the spinning electron. A spinning spherical electron rotates about a fixed nucleus. The six first integrals of the equations of motion are obtained without approximation, and the motion is described. The variables are quantised, leading to a type of series term.—A. W. **Conway** and G. **Keating**: Two-electron orbits. Two electrons rotate about a nucleus of charge $+2e$, the law of force between the electrons being that of the inverse cube. Symmetrical orbits of two types are considered and quantised, leading to enhanced series terms of Rydberg type. A supplementary field of force is obtained which will give the series terms of a selected Ritz type for the helium atom and also the proper value of the ionisation potential.

Edinburgh.

Royal Society, May 10.—A. P. **Laurie**: Modern research on the methods of painting oil pictures as illustrated by the technique of the fifteenth century. The media used by artists are gum-arabic for water-colour painting, size principally for scene painting, the yolk of egg known as the tempera medium, and the three drying oils, linseed, poppy, and sometimes nut oil. The refractive indices of the drying oils are much higher than those of the other media. Brilliancy is largely due to reflection of white light, and as a pigment is immersed in media of higher and higher refractive index, the amount of white light reflected from the surface diminishes and the pigment is deeper and lower in tone. It is therefore impossible to paint in so high a key in linseed or poppy oil as in these other media. As the oil dries and the oil film gets older it turns a brownish yellow and its refractive index increases, causing a lowering of tone in the oil picture. It is therefore necessary for the painter to distinguish between the properties of the opaque and the transparent pigments and use them accordingly.

Cape Town.

Royal Society of South Africa, March 17.—A. **Ogg**: X-rays and crystal structure (Presidential address).—H. O. **Monnig**: (1) On some strongylid nematodes of the African elephant. The specimens were collected from elephants shot in the Addo Bush, Cape Province. Seven different species were found, of which four are new, namely, *Murshidia brachyscelis*; *Pteridopharynx brevicapsulatus*; *Bunostomum brevispiculum*, and *Bunostomum hamatum*. (2) Three new helminths. These are (1) *Moniezia pallida* from the horse, (2) *Spirostrongylus australis* from the red kangaroo, and (3) *Cordophilus sagittus* from cattle, koodoo and bushbuck.—A. D. **Stammers**: (1) Some observations on certain pathological changes resulting from inanition. The changes, especially in the adrenals, resulting from vitamin deficiencies in the diet, are discussed. (2) Glycolysis in blood. A discussion of the fate of sugar in the blood after the removal of the latter from the body, and an account of experiments on normal and diabetic blood. (3) On the presence of α-hydroxy-acids in blood. Saccharic and mucic acids are formed by bacterial action in blood preserved *in vitro*; if the latter be inhibited, this oxidation process apparently does not occur.—F. G. **Cawston**: Variations in the shells of *Isidora africana* (Krauss) and closely allied species. It is difficult to divide this genus into species by the appearance of the shells, and the radulæ afford no better means of determining the species.—Sir Thomas **Muir**: Hadamard's approximation theorem since 1900.—Edith L. **Stephens**: A new sundew—*Drosera regia* (Stephens) from the Cape Province. This plant requires a moist and comparatively cool atmosphere such as is provided by the south-east cloud at the height of 3000 feet, where it flourishes. Possibly this may be connected with the very copious secretion of the tentacles, which is so viscid as to snare even grasshoppers and small beetles. It belongs to a section (Psycophila) hitherto unrepresented in South Africa. Its appearance is striking; a long peduncle, topped by a cluster of conspicuous pink flowers, being surrounded by linear leaves a foot or more in length.

WASHINGTON.

National Academy of Sciences (Proc Vol 12, No. 3, March 1926).—Carl **Barus**: Resonant acoustic and electric oscillations released by the relatively slow spring break.—William **Duane**: On the reflection by a crystal of its own characteristic radiation. Irregularities in the ionising current produced by the reflection of X-radiation (from a molybdenum target) by a crystal of potassium bromide have been observed which correspond to the bromine *K*-series lines. The increase, at any rate at the $K\alpha$ line of bromine (second order), seems to be due to an increase of fluorescent radiation at these points caused by slight imperfections of the crystal.—S. K. **Allison**: Note on the 'selective reflection' of X-rays by crystals of potassium bromide. The curve on which the preceding paper is based shows that a slight excess of radiation occurs only where reflection of the bromine $K\alpha$ line in the second order would be expected.—Robert S. **Mulliken**: (1) Systematic relations between electronic structure and band-spectrum structure in diatomic molecules (Part 1). The occurrence of features of band spectra can be explained on certain postulates. The first of these is that the electronic state of every molecule can be characterised by a term-designation associated with an electronic quantum number identical with Sommerfeld's atomic inner quantum number for the given term-type. (2) Part 2. The ZnH, CdH, and HgH molecules and their spectra. (3) The electronic states of the helium molecule.—Lee A. **DuBridge**: Variations in the photo-electric sensitivity of platinum. A platinum strip was heated for various periods in a vacuum and exposed to radiation from a quartz mercury arc lamp. For short or long heating periods, the photo-electric current decreases with temperature to a definite minimum which is not changed by prolonged heating or by further baking and out-gassing of the containing tube.—G. E. M. **Jauncey** and A. L. **Hughes**: Radiation and the disintegration and aggregation of atoms. A detailed statement of the arguments of a letter in NATURE of February 6, p. 193; $\lambda = 0{\cdot}0018$ Å.U. is corrected to $\lambda = 0{\cdot}00043$ Å.U.—Richard C. **Tolman** and Richard M. **Badger**: A new kind of test of the correspondence principle based on the prediction of the absolute intensities of spectral lines.—Roscoe G. **Dickinson** and Miles S. **Sherrill**: Formation of ozone by optically excited mercury vapour. Ozone is formed when oxygen at atmospheric pressure is passed over mercury and exposed to radiation from a water-cooled mercury lamp. Radiation of wavelength less than 2000 Å.U. was filtered out. Activated mercury atoms can give up energy to oxygen molecules as well as combining with it to form oxide.—George **Glockler**: Diffusion of electrons. The number of collisions which an electron makes in traversing a layer of gas, when the electron is not acted on by a field, is independent of its velocity and equal to $3a^2/2\lambda^2$, where a is the distance traversed and λ is the mean free path of the electron.—Lilian V. **Morgan**: Correlation between behaviour and shape of a chromosome.—Leonell C. **Strong**: The genetic basis of susceptibility to tissue transplants. Two relatively homozygous races of mice were used, in one of which a transplantable tumour showed progressive growth while the other race was resistant. The races were crossed and eventually synthetic races were selected which were susceptible and non-susceptible respectively, thus reproducing the original significant genetic constitution. Two factors seem to be concerned in producing susceptibility.—Joseph Miller **Thomas**: On various geometries giving a unified electric and gravitational theory. Einstein's new equations can be obtained by direct generalisation of his earlier equations of the gravitational field.—Sophia **Satina** and A. F. **Blakeslee**: (1) Studies on biochemical differences between (+) and (−) sexes in Mucors. (2) A preliminary report on the Manoilov reaction and other tests. Races of Mucor differ biochemically even when of the same sex; the (+) and (−) races show significant average biochemical differences, the (+) corresponding to the male of higher animals and the (−) to the female. (2) Biochemical differences between sexes in green plants. Average sex differences were found in respect to the Manoilov reaction, colour of leaf extract, presence of oxigenase, peroxigenase, and total acidity. (3) The Mucor parasite Parasitella in relation to sex. *Parasitella simplex* is a Mucor usually parasitic on other Mucors, when it forms galls. There may be some sex-relation between parasite and host.—Cecil D. **Murray**: The physiological principle of minimum work (1). The vascular system and the cost of blood volume. Calculations from the equations of flow through cylindrical tubes and the assumption of maximum economy of work, give values for the 'cost' of blood which accord well with the energy requirements of active tissues of the body. This 'cost' seems to be operative in determining conditions in the vascular system.—Curt P. **Richter**: The significance of changes in the electrical resistance of the body during sleep. Measurements were made of the resistance from hand to hand to an imperceptible electric current. During sleep the palm-to-palm resistance increases markedly, and this increase is some measure of the 'depth' of sleep, being very marked for heavy sleepers. On awakening gradually or suddenly, the resistance immediately becomes normal. Resistance measured between the backs of the hands increases a little where the sleep is tranquil and decreases with restless sleepers, possibly while dreaming. Patients in catatonic stupors resembling sleep do not show these characteristic changes of resistance.

Ethnographical Studies and Colonial Administration.

IN a recently published work by a resident in East Africa of many years' standing, it is stated that the native regards with profound mistrust all white men excepting only British officials and missionaries. This observation, perhaps a little too sweeping and perhaps too flattering to our vanity if assumed to be of universal application, lends support to the view, with which we have been made familiar since the British Empire became self-conscious, that members of the British race are pre-eminently successful as settlers and administrators in strange lands. In so far as this is borne out by the facts, it is in large part due to a certain ability to handle a backward people with a degree of sympathetic understanding. Although it is true that the British record in this matter has not been spotless in the past, and even now is not always above reproach, yet judged by results our methods may perhaps bear comparison, not entirely to their disadvantage, with those of other nationalities.

Lest such a comparison may appear invidious, it is possible to appeal for justification to facts which were forced on the attention of British officers in the former German colonies in Africa after the War. In the official reports, reference is frequently made to behaviour on the part of the natives which certainly seemed to indicate that their former rulers had inspired them with anything but confidence in the white man.

There is, however, less reason for diffidence on our part in instituting such a comparison now that in France, the power with a stake in tropical Africa second only to that of Britain, an appeal has been made to British methods to explain and justify action which has recently been taken by the University of Paris.

The pre-eminence of France in the study of prehistoric man and his handiwork has to a certain extent overshadowed the achievements of those of her men of science who have devoted themselves to other branches of anthropological investigation. To say this is not to ignore the claims of the distinguished human anatomists who have done so much to systematise the study of physical anthropology; or of the distinguished sociological group, with the late E. Durkheim at its head, which founded and carried on *L'Année Sociologique*, now happily revived after an intermission of some years owing to the War. Perhaps only those who follow specialist publications are aware of the extent to which ethnographical investigation has been carried on in the French colonies. Of the results, comparatively little has appeared in the more widely read publications devoted to the study of anthropology. A conspicuous example is the work which has appeared in the valuable and scholarly publications of the École d'Extrême Orient, dealing with the cultures and peoples of the French possessions in Further Asia. It ought, perhaps, to be unnecessary to emphasise the value of much of the work which has been done in Madagascar and the colonies of North and West Africa.

On more than one occasion in these columns, stress has been laid on the practical value of anthropological training in the administration of the affairs of backward races, or, to use the more general term, of peoples of non-European culture. It has been of interest to those who take this view to note that in the courses of lectures on ethnology and other departments of anthropology which were advertised at the opening of last winter's session of the University of Paris, there was a distinct bias in the direction of the possible practical application of the instruction to be given. Even courses of a general character in the study of religion and social anthropology frequently had special reference to the native races of some or all of the French colonial possessions. The study of Moslem custom and religion was naturally capable of more directly utilitarian treatment; while a large number of courses in linguistics covered many of the more important native languages under French jurisdiction.

A more significant development, however, is the foundation within the University of Paris of an Institute of Ethnology. The object of the Institute is, in the first place, to create a body of professional ethnologists and to give to any residents or intending residents in the French colonies who have an inclination for linguistic or ethnological studies, such instruction as will enable them to carry on these studies intelligently and in accordance with methods which will render the material collected of scientific and practical value. Secondly, to direct attention to recently discovered facts or newly developed methods with the view of their verification, and the testing in the field of any hypothesis under discussion. Thirdly, to publish ethnographical works which, owing either to their length or the amount of illustration they require, cannot be published in the usual periodicals. Fourthly, in conjunction with the colonial authorities, to send expeditions into the field and not to leave to foreigners the exploitation of the ethnography of the French colonies, as has happened in the past.

The idea of such an Institute was first put forward by M. Marcel Mauss in 1914; but its realisation has only recently been attained, the project having been revived in 1924. As a teaching body the Institute will in no way conflict with any existing interests. On the contrary, its primary function will be to act as a co-ordinating body for the courses already provided, or to be provided, at the University, the Collège de France, the Museum, the École des Hautes Études, the École Coloniale, and the École des Langues Orientales Vivantes. It will provide, in addition, in courses such as cannot be obtained elsewhere, a small number of lessons in technical matters with the view of giving an orientation to the future ethnologist. The Institute will grant a diploma in anthropology and, if or when the necessary ministerial permission has been obtained, a certificate of Licencié ès Lettres.

It is not without interest to note that Prof. Lévy-Bruhl, in an account of the Institut d'Ethnologie and its organisation and objects, which appears in the *Revue d'Ethnographie et des Traditions Populaires*, 4me trimestre, 1925, Nos. 23-24, indicates to what an extent the founders have been influenced by British methods in defining the scope and methods of the Institut. He opens with a reference of some length to Capt. Rattray's book on Ashanti, pointing to the incident of the 'Golden Stool' there related as an example of the way in which a serious conflict with the natives, and very possibly a punitive expedition, were averted by the advice based on expert knowledge which the newly constituted anthropological service was able to place at the disposal of the administration. Had it not been for the official anthropologist's knowledge of native customs and ways of thought, action in connexion with the Stool which it had been decided to take, without thought of its possible effect on the religious susceptibilities of the native in view of the sacred character of the Stool, would almost certainly have caused a serious uprising. Prof. Lévy-Bruhl goes on to express the hope that a similar anthropological service may one day be instituted in the French colonies. It will then be the aim of the Institut d'Ethnologie to turn out officers competent to man it, not necessarily highly trained ethnologists, but men with a sufficient knowledge of anthropological method to enable them to collect material of both scientific value and practical utility. He pertinently adds that in the study of the resources of the French colonies which is necessarily a preceding condition of their full development, the greatest asset of all, the native population, should not be overlooked.

However flattered we may feel at the compliment implied in Prof. Lévy-Bruhl's reference to the work of Capt. Rattray and his department, British anthropologists have still to regret that the principle that all administrative officials in British dependencies with backward peoples under their jurisdiction should be trained in anthropological methods is an ideal which has yet to be officially adopted in practice. An argument which is applicable to the case of the French colonies should, it is permissible to say, apply with immensely greater cogency to that of the British Empire.

Man at Great Altitudes.

The Respiratory Function of the Blood. By Joseph Barcroft. Part 1: *Lessons from High Altitudes.* Pp. x+207. (Cambridge: At the University Press, 1925.) 12*s.* 6*d.* net.

WHOEVER reads this book—and every physiologist who deals at all with the hæmato-respiratory functions must read it—will gain one certain result: he will conceive a sincere liking for the author, as the ideal companion under low barometric pressure. In a style intimate, as between comrades in adventure, Prof. Barcroft here sets forth his experiences in his various invasions of the regions of low oxygen, the Peak of Teneriffe, the Capanna Margherita on the summit of Monte Rosa, Cerro de Pasco in the Andes, and last but not least the glass chamber in his laboratory where for six days he breathed the oxygen down, and himself thus virtually up, to the physiological equivalent of an altitude which proved too much of a strain even for his bold and cheerful spirit.

Prof. Barcroft reminds us that the modern sport of mountaineering originated in such essentially scientific expeditions to the upper regions as those of de Saussure on Mont Blanc. It is quite proper, therefore, that the scientific treatment of the physiological effects of low oxygen, mountain sickness, and acclimatisation should retain something of the zest of a noble sport. In this field the investigator is himself the subject observed, and in his own person suffers discomfort and overcomes hardships as great as any explorer of a new country. Yet it is also in this field that physiology has most nearly emulated the precision of physics and chemistry. It requires literary art to bring out the sporting aspects of oxy-hæmoglobin dissociation curves. Prof. Barcroft imparts 'human interest' (to use the journalistic term) even to the gas laws.

As it happens, although mountaineering is not a competitive sport, the physiology of altitude is just now almost as competitive as football or rowing between two of the universities of England. It was shown by Paul Bert in France in the last century by means of a low-pressure chamber, and by the late Prof. Zuntz of Berlin by his expeditions to the Alps, that the one essential factor in the decrease of barometric pressure at great altitudes is the lower partial pressure of oxygen in the lungs and in the blood. The condition induced is essentially asphyxia.

During the first decade of this century, Haldane and his co-workers at Oxford carried out experiments which were so fundamental and so illuminating that they may be said to have created the physiology of respiration. To follow up the principles of vital regulation thus revealed, the next step was the study of the adjustment which respiration may make to the decreased oxygen pressure at high altitudes. Accordingly, Haldane and Douglas from Oxford, accompanied by Henderson and Schneider of Yale, spent five weeks during the summer of 1911 on the summit of Pike's Peak, Colorado, altitude 14,100 feet. Their observations were supplemented by Miss M. P. FitzGerald, who determined the alveolar carbon dioxide and the hæmoglobin of people resident at various altitudes between sea-level and 11,000 feet. The fundamental principle was thus established that the adjustment of respiration in states of complete acclimatisation is strictly quantitative. The basic controlling factor is the partial pressure of oxygen in the lungs. To this factor (*a*), the alveolar carbon dioxide (*b*) and the blood alkali (*c*) come gradually at every altitude into the relation $a:b:c=100:40:60$ (for example, 50:20:30 at about 17,000 feet, bar. 390 mm.); and the volume of breathing during rest is the reciprocal of the alveolar carbon dioxide.

In addition to this law, Haldane postulated an active secretion of oxygen by the tissues of the lungs, so as to raise the pressure of oxygen in the blood above that in the air in the lungs: a process analogous to that by which the kidney may produce urine of higher concentration in respect to salts than in the blood from which the salts are drawn.

At this point Barcroft takes up the story; and the book before us is in the main an account of the investigations of the Cambridge-Harvard expedition to the Andes which he organised and led. On the basis of the results obtained by that expedition, Barcroft accepts in the main the first part of the conclusions of the Pike's Peak expedition; but he rejects now absolutely the hypothesis of oxygen secretion in the lungs. It must, indeed, be admitted that the direct determinations of the pressure of oxygen in the arterial blood in relation to that in the air of the lungs, which he and his co-workers achieved, afford strong evidence that the former never exceeds, indeed never quite equals, the latter. Thus the passage of oxygen from the atmosphere into the blood must be dependent, according to the view of Prof. Barcroft and his co-workers, wholly upon the physical process of diffusion. The adjustments constituting acclimatisation do not then include oxygen secretion.

How great a problem is thus presented to physiology is evident from the fact which Prof. Barcroft points out that healthy men who go in a day, even by railway and with no exertion in comfortable, well-heated cars, from sea-level up to 14,000 feet in the Andes, are rendered acutely ill. Men who ascend direct from sea-level to 23,000 feet in a balloon lose consciousness and die. Yet a large population in the Andes and Tibet spend their entire lives at 14,000 or 15,000 feet, and the members of the two expeditions above referred to were quite comfortable and well when acclimatised at Cerro de Pasco and on Pike's Peak. Furthermore, the members of the Mount Everest expeditions became acclimatised to 23,000 feet, and in some cases ascended even to 26,000 feet without mountain sickness, as is described in an appendix in this book by Major R. W. G. Hingston, Medical Officer to the Everest expedition of 1924.

The utmost value attaches, therefore, to Prof. Barcroft's observations and discussions bearing upon different aspects of the problem of accounting for so extraordinary a power of adjustment in the living organism. Prof. Barcroft would himself be the first to recognise that if oxygen secretion is ruled out (and Dr. Haldane is still to be heard in reply at the meeting of the British Association at Oxford next August) the problem of acclimatisation stands out only the more imperatively. Thus, if the reviewer may be allowed to instance facts which the conception here presented seems scarcely as yet adequate to cover in detail, attention may be called to the rapidity with which a person acutely mountain-sick may develop a comfortable degree of acclimatisation. Such cases of rapid acclimatisation were easily explained on the theory of oxygen secretion. They still require much study to show how they are possible as results of the comparatively slowly developing changes in the blood. Indeed, the shift of the oxy-hæmoglobin dissociation curve to the left which Prof Barcroft now postulates was not found in any previous investigation, either by the Pike's Peak expedition (using Barcroft's method) or by himself at Teneriffe. It affords one of the strongest grounds for seconding Prof. Barcroft's expressed hope that others may carry further the study of altitude at Cerro and on Pike's Peak.

Attention may also be directed to the proven efficiency of inhalation of dilute carbon dioxide in overcoming the ill effects (which are essentially mountain sickness) following carbon monoxide asphyxia, and following anæsthesia. Such beneficial effects are presumably due to an adjustment of the blood of the same general character as that which Prof. Barcroft postulates in acclimatisation; but in this case probably the shift is to the right.

It is especially to be hoped that the unique opportunities of observing acclimatisation between 15,000 and 25,000 feet afforded by expeditions to Mount Everest will hereafter be utilised to the full. In future expeditions to Tibet it should be possible to combine this object without impairing the chances of attainment to the highest point in the world. For science the value of this accessory service would certainly equal the primary object of expeditions to Mount Everest.

In closing, a few words may be permitted on the general importance of the problem of asphyxia to the solution of which Barcroft and Haldane in their friendly controversy are making fundamental contributions.

The most universal and characteristic process of life lies in the exchange of oxygen, combustion in living cells or, as physiology terms it, respiration. When we understand asphyxia and the adjustments which the living body makes to combat it, we shall have solved a problem which is the reciprocal of that of the nature of life. We may fairly hope that, at least to a considerable extent, mere inversion of the terms in which the solution of the problem of asphyxia will be stated, will afford a solution of the inner nature of respiration, and thus far of life itself.

YANDELL HENDERSON

The Geology of West Lothian.

The Rocks of West Lothian: an Account of the Geological and Mining History of the West Lothian District. By Henry M. Cadell. Pp. xvi + 390 + 32 plates + 2 maps. (Edinburgh and London: Oliver and Boyd, 1925.) 18*s.* net.

THE county of West Lothian is of exceptional interest in Scottish geology, as it forms the connecting link between the two ends of the Midland Valley, and affords the most trustworthy evidence for the correlation of the dissimilar Carboniferous sequences in the western and eastern basins. The county is also of interest as the seat of the Scottish oil shale industry.

The geological and physiographic history of the county has been summarised by Mr. H. M. Cadell in an interesting and beautifully illustrated volume. Mr. Cadell knows the county intimately; he understands its relations to the rest of Scotland from knowledge gained during his service on the Scottish Geological Survey; and he brings to the interpretation of its rocks observations made during world-wide travels. Many of the illustrations are drawn from his foreign experiences, such as below a reproduction of von Humboldt's famous view of Jorullo in 1803, his own sketch taken from the same point of view in 1906. Much of the information in the volume has been previously published in technical journals, but it has been re-written in a simpler and more popular form.

The book is most concerned with the Scottish Carboniferous system; it gives an excellent account of the geology and economics of oil shale, and of some of the associated rocks such as the Houston marls, which the author shows are not of volcanic origin. He records the result of the bore at West Calder, 4000 ft. deep, put down in the search for mineral oil; instead of finding oil, it passed through an unexpected thickening of the volcanic rocks below the Burdiehouse limestone. The chapters on the Lower Carboniferous rocks describe their successive limestones and volcanic phenomena, which in this district are exceptionally well displayed, partly in surface outcrops, and partly in the evidence as to the deep-seated structure of some ancient volcanoes revealed by bores put down during mining prospecting. During the Carboniferous, according to the author, the country was broken across by an east-to-west rift valley, between the Ochiltree fault on the north and the Calder and Middleton Hall faults on the south; he illustrates this valley by one of his graphic reconstructions of the scenery, due to his combination of geological insight and artistic skill.

Mr. Cadell was one of the first Scottish geologists to recognise the importance and significance of the buried river channels that lie deep below the present sea-level; he brings the knowledge of those in West Lothian up-to-date in chapters dealing with the development of the present topography during the Kainozoic era, of which the only local evidence is physiographic.

The last three chapters are devoted to the history of mining in the county from that at Carriden about 1165 by the monks of Holyrood; he describes the condition of coal mining in the seventeenth century during the wars of the Commonwealth, gives an account of the early Scottish salt industry, and tells the story of the Hilderston silver mine, which was worked early in the seventeenth century and was unsuccessfully re-opened in 1873 and 1896. The author, owing to his descent from the founder of the Carron Co., has been able to draw on unpublished records in his interesting account of the mining and iron industry of the Bo'ness district since 1760.

Nematode Parasites of Vertebrates.

The Nematode Parasites of Vertebrates. By Prof. Warrington Yorke and Dr. P. A. Maplestone. Pp. xi+536. (London: J. and A. Churchill, 1926.) 36s. net.

THE outstanding spirit of the early study of helminthology was the search for knowledge for its own sake; whereas the motive underlying the activities of workers of more recent years has been, partly unconsciously perhaps, its potentiality for human and animal welfare. The literary output on the subject of the structure and relationships of the Nematoda during the last hundred years was enormous, and the position would doubtless have been chaotic had not Diesing, in 1866, summarised the knowledge of that time in his "Revision der Nematoden," and Stiles and Hassall, in 1919, provided the materials for a similar revision in the invaluable subject-index on the roundworms, in their "Index Catalogue of Medical and Veterinary Zoology." During the past ten years the labours of Railliet, Skrjabin, and Travassos have resulted in a classification of the parasitic nematodes which has met with considerable acceptance, though of course, in points of detail, there remains room for adjustment. The volume issued by Yorke and Maplestone is therefore to be welcomed as marking the present position of the classification of the Nematoda in the same significant way as did that of Diesing half a century ago.

The authors have handled the vast mass of material in a masterly manner. Accepting Railliet's classification in the main, they have provided a series of definitions and keys which should enable those acquainted with the structure of the Nematoda to place many, if not all, of the known species in their proper genera. Each genus is illustrated and defined, the definition being based largely upon the type species; other species which in the authors' view can be reasonably allocated to the genus are listed alphabetically.

As generic definitions based too closely upon the type frequently contain characters of specific value only, this method is likely to entrap the unwary. Moreover, those who prefer to rely upon text-books rather than consult the original publications, should note that many of the older and probably legitimate species have been omitted, and there is a distinct danger that these may be recorded again as new species. It is perhaps regrettable that some provision, such as the compromise recently suggested by Stiles, has not been adopted whereby collective group names, *e.g.* Fusaria, Sclerostoma, and so on, would have been given some taxonomic place to species which, although probably valid, have not yet been sufficiently fully investigated to admit them to modern and more restricted genera.

With each species the 'type host' in which it has been found is listed, but no indication is given of the almost equally important 'type locality,' although the subject of geographical distribution is one which is likely to interest many of those who turn to this work for information. The same may be said of intermediate hosts. In these days, when the bionomics of animals is attracting more and more attention, the omission of all reference to the life-history in a book with such a comprehensive title is, to say the least, unfortunate.

In the course of their revision the authors have found it necessary to create a number of new genera, many of which are based on new species, of which brief descriptions are given in the form of footnotes.

More than three hundred genera are illustrated in the text, and in most cases the type species has been used. Many of these are original, but the goodwill of other workers has been relied on for this purpose to a surprising degree.

In spite of these criticisms, the authors are to be congratulated not only on having produced a work which is likely to become a standard book of reference, but on having also made a definite contribution to the classification of the order Eunematoda.

The Composition of Milk.

Variations in the Composition of Milk: a Study of the Results of Analysis of Six Hundred and Seventy-six Samples of Milk (each Sample being the Milk of one Cow) from Cows of various Breeds throughout Scotland in 1921–22. By Dr. J. F. Tocher. Pp. 195. (Edinburgh and London: H.M. Stationery Office, 1925.) 21*s.* net.

THE Inter-departmental Committee appointed to report on the regulations, etc., governing the sale of milk in Scotland arranged for a large number of samples of milk taken at random from individual cows to be analysed. No particular breed was selected, nor was any account paid to the period of lactation, feeding, age of animal, etc., the only consideration being to ensure proper and thorough milking and the taking of a representative sample. In all, 676 samples of milk were dealt with, the samples being both from morning and evening milkings, with a small proportion of midday samples (the latter, however, not included in the statistical analysis). The examination of the samples covered the usual determinations of specific gravity, fat, solids not fat, and in addition the estimation of nitrogen, lactose, ash, refractive index and freezing-point.

The report which Dr. Tocher has drawn up gives a very exhaustive account of the manner in which the inquiry was conducted, the results of the determinations, the statistical analyses of the results and the conclusions which may be drawn from them.

Whilst the object of the inquiry was to collect data upon which legislation could be based, the information which has been gained is of considerable scientific interest, and some important facts concerning the composition of milk and the extent to which the constituents vary in the case of individual cows has been brought to light. The milk of single cows is shown to vary widely, in the case of butter fat from 1·7 per cent. to 7·5 per cent., whilst the solids not fat may be from 6·9 per cent. to 10·6 per cent. In the case of composite samples there were found to be wide differences according to the number of cows from which the milk sample was taken. Thus herds of five cows fell below the present standard for solids not fat (8·5 per cent.) in the proportion of six groups out of a hundred, whilst larger herds of twenty cows only fell below the standard in one group out of a thousand.

On the practical side of the subject, Dr. Tocher advocates that milk should be supplied from a large number of cows so as to reduce the variations; that good cows should be selected and that the inheritance of butter-fat yield should be completely studied. Some other matters of interest in the report are the lactose content and freezing-point of milk, the influence of the lactation period and the effect which this may have upon the interpretation of the results of feeding trials.

Our Bookshelf.

Handbuch der Arbeitsmethoden in der anorganischen Chemie. Gegründet von Arthur Stähler. Fortgeführt von Prof. Erich Tiede und Friedrich Richter. Zweiter Band: *Physikalische und chemische Operationen.* Zweite Hälfte: *Physikalische und chemische Operationen besonderer Art.* Herausgegeben von Prof. Erich Tiede und Friedrich Richter. Pp. x+655+1648. 54 gold marks. Vierter Band: *Ausgewählte Kapitel der präparativen Chemie.* Zweite Hälfte. Pp. x+315-572. 14·50 gold marks. (Berlin und Leipzig: Walter de Gruyter und Co., 1925 and 1926.)

THE special operations described in the second part of the second volume of this work include micro-chemical methods, membrane-filtration, electrometric analysis and electrolytic purification, decomposition with a silent electric discharge and in the arc, the use of radio-elements as indicators, identification of crystals and X-ray analysis, the use of high vacua and of high pressures, mass-spectrography, the use of liquid ammonia, sulphur dioxide, hydrogen chloride and hydrogen sulphide as solvents, and the general operations of photochemistry. The technique of these diverse operations has been described by fifteen authors, in a volume of about 1000 pages. It will form a most valuable work of reference for those who may have occasion from time to time to make use of one or other of the special methods with which it deals.

The first part of the fourth volume had already appeared when the present editors took charge of the "Handbuch." They did not regard it as necessary to carry to completion the original plan for the volume on preparative chemistry, but have concluded their work by adding to Part 1 of vol. 4 an abbreviated Part 2, dealing with thermite-reactions, phosphorescent materials, mineral synthesis and the growing of crystals. They have also included a very interesting catalogue of some hundreds of substances which can be prepared in a state of great purity (*e.g.*, as required for determinations of atomic weight), with references to the original papers in which the methods of preparation of these pure elements and compounds are described.

The Engineer and the Prevention of Malaria. By Henry Home. Pp. x+176+14 plates. (London: Chapman and Hall, Ltd., 1926.) 13*s.* 6*d.* net.

The object of this book, as mentioned by the author in the introductory note, is to help engineers engaged on anti-malarial works to obtain the necessary information without reference to numerous publications on public health, entomology, and parasitology which is otherwise essential. It is furthermore believed that medical officers will find material of value within its pages.

The book deals with the various engineering problems which so frequently arise in malaria prevention in a clear and concise manner. There are fourteen plates and numerous text figures which contribute to the value of the work. The first three chapters are devoted to the economic aspect of the disease, the malarial mosquito, and to anti-malarial schemes. The eight following chapters deal with the varied aspects of lowland drainage, hill drainage, details of construction, oiling, larvicides, vegetation, natural enemies, the question of housing, and possible biological methods of control.

There are four appendices, the first of which, by Lieut.-Colonel MacArthur, deals with mosquito netting from the point of view of the right determination of the apertures and the gauge of wire or the size of cotton thread used by the manufacturers.; Dr. P. A. Buxton contributes the next two appendices dealing with applied entomology as regards anophelines and the house fly. The final appendix contains an account of the hydrogen-ion concentration of waters and methods of estimation.

The engineer and the sanitarian are, or at least should be, frequently associated in endeavours to combat disease, and this is especially the case in anti-malarial schemes. To formulate a successful campaign on sound practical lines demands a close co-operation between the two services. In this little book both should find much of common interest, and its study will undoubtedly tend to foster that spirit of co-operation with and sympathy in the work of the two which is essential in so many of the efforts directed to the control of disease.

G. E. F. STAMMERS.

Rothamsted Experimental Station Library. Catalogue of the Printed Books on Agriculture published between 1471 and 1840; with Notes on the Authors by Mary S. Aslin. Pp. 331+22 plates. (Harpenden, Herts: Rothamsted Experimental Station, 1926.) Paper, 10*s.*; cloth, 12*s.*

Not the least notable feature of the Rothamsted Experimental Station is the library, containing as it does probably the most complete collection in existence of ancient and modern books (in all languages) on agriculture. The number of ancient books, in particular, is remarkable, including, it may be noted, copies of such treasures as Crescentius' "Liber ruralium commodorum," the first printed book on agriculture. Of this the library possesses a fine illuminated folio, bearing the insignia of Sigismund II. of Poland, and a unique early edition of Fitzherbert (*circa* 1523).

As the director, Sir John Russell, points out, the dates 1471 and 1840 are both significant in relation to the history of agriculture; the first marks the appearance of Crescentius, and the latter the definite break with empiricism which followed the foundation of the Rothamsted Station by Lawes. The catalogue, therefore (relating to 1500 books published between these dates), may be said to record the empirical stage of agriculture, and it speaks much for the enterprise and, may we add, the culture of the governors of Rothamsted and their director, that such a collection—largely of bibliographic interest—should have been added to the institution. Their interests in the art, which it is their mission to inspire with science, are conceivably more limited, but, as the director, in the words of Comte, aptly says: "No idea can be properly understood apart from its history."

Volumetric Iodate Methods. By Dr. George S. Jamieson. (New York: The Chemical Catalog Co., Inc., 1926.) 2 dollars.

The "iodate method," first proposed by L. W. Andrews in 1903, depends on the formation of iodine monochloride, and the disappearance of the iodine colour imparted to an immiscible solvent such as chloroform or carbon tetrachloride. Since the last traces of free iodine are collected in a small volume of immiscible solvent, the sharpness of the end-point is remarkable; and when a titration has been completed, there is no return of the iodine-colour even after keeping the solutions for a day. These factors, together with the great stability of the solutions of potassium iodate and the absence of interference by many kinds of organic matter, make the use of this method very advantageous in many forms of analysis. The author has therefore put together a description of a dozen different determinations (*e.g.* of Sb, Cu, Hg, Mo, Sn, Mn, N_2H_4, H_2O_2, PbO_2, etc.) in which the method can be employed with advantage. He has further increased the value of the book by giving details of the application of the method to the analysis of arsenic and copper in insecticides, of antimony, copper and tin in alloys, etc. The book should be of considerable value in giving publicity to a new and valuable method of analysis, as well as in providing precise directions for applying it.

Wellenlangenmessungen des Lichtes im sichtbaren und unsichtbaren Spektralbereich. Von Prof. Dr. Paul Eversheim. (Sammlung Vieweg, Heft 82.) Pp. v+111. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1926.) 7 gold marks.

The object of this book is to give a concise survey of the present state of our knowledge concerning the exact determination of standard wave-lengths. The author first gives a short general description of early measurements, together with Rowland's normal system, and refers to the necessity for its revision. He then deals with the more recent methods of determination, briefly referring to Millikan's work, and considering in detail the measurements of Benoît, Fabry and Perot. Succeeding chapters discuss the establishment of international standard wave-lengths, and many tables of standard lines in the visible region are given, attention being paid to the results of individual workers in order to indicate the accuracy of the standard data.

The ultra-violet and infra-red portions of the spectrum are treated in separate sections, due reference being made to the work of Lyman and Millikan. In the final chapter on X-rays, the work of the Braggs, of

Siegbahn and of others is described, and two clear diagrams of modern X-ray tubes for spectroscopic purposes are given.

The book may be thoroughly recommended to all interested in the matters with which it deals.

Adventures of Exploration. Book 4: *Africa.* By Sir John Scott Keltie and Samuel Carter Gilmour. Pp. iv + 180. (London: George Philip and Son, Ltd.; Liverpool: Philip, Son and Nephew, Ltd.; n.d.) 2*s.*

THIS volume is the most recently published of a series of six supplementary readers designed to quicken interest in geography by stories of adventurous travel. They do not claim to give a coherent history of exploration, but serve to direct attention to the great steps and prominent names in the story of discovery. In this respect they form valuable supplements to the orthodox geographical text-book. After a general chapter on early voyages the story begins with Bruce at the Blue Nile, moves to Mungo Park and the Niger, and after a chapter on the seekers for Timbuktu, takes the reader to the great lakes, the Nile sources, with chapters on the work of Burton, Speke, Baker, Thomson, Livingstone, Stanley, and others, and finishes with some of Selous' adventures and Hassenein Bey's recent journey. The stories are admirably told, and well illustrated with maps and pictures. The series deserves to be widely used. R. N. R. B.

Macmillan's Secondary School Atlas. With an Introduction by T. Alford Smith. Pp. iv + 64 + 8. (London: Macmillan and Co., Ltd., 1926.) 5*s.*

THE 64 pages of coloured maps in this atlas include physical and political maps of every part of the world, with enlarged maps of Europe and the more important parts of other continents. There are also January and July temperature maps and annual rainfall maps of all continents and the British Isles, geological maps of the British Isles and Europe, and a number of distributional maps of the world. The physical maps are particularly good, and not overcrowded with names. On all maps the projection is given. Although the scales vary a good deal, an attempt has been made to use simple multiples of the scales of the maps of Great Britain. An index of some two thousand names gives reference by latitude and longitude. The world-pressure maps would be improved by southward extension to show the Antarctic high-pressure area, and in the current and vegetation maps some revision is required on the coasts of Greenland. Murmansk, and not Alexandrovsk, is the terminus of the Murman railway.

The Story of Minerals. By Herbert P. Whitlock. (The American Museum of Natural History, Handbook Series No. 12.) Pp. 144. (New York: American Museum of Natural History, 1925.) n.p.

IN this book the author has aimed at a popular exposition of the elements of mineralogy, his declared intention being "to answer questions rather than to rehearse facts." In preparing it, he has taken advantage of his experience as Curator of Mineralogy in the American Museum of Natural History, and has fashioned the book to answer questions usually put by visitors to the Museum. About a third of the book is given to the principles of mineralogy, including chapters on "Nature's mathematics" (crystallography), "the mimicry of minerals," "water as a maker of minerals," and "change and decay in minerals." The remaining chapters describe some of the commoner minerals and groups of minerals. The book is very well illustrated, and should prove interesting as well as useful to those numerous visitors to the Museum who have not previously studied the science of mineralogy.

Introduction to the Study of Organic Chemistry: a Theoretical and Practical Text-book for Students in the Universities and Technical Schools. By Dr. John Wade. Revised by Dr. Henry Stephen. New and enlarged edition, with an Appendix containing Supplementary Practical Detail, forming with the text an Illustrative Laboratory Course. Pp. xx + 646. (London: George Allen and Unwin, Ltd., 1925.) 8*s.* 6*d.* net.

WADE'S "Organic Chemistry" is a book which has enjoyed a deserved popularity for some years. It is therefore only necessary to say that the new edition appears to have been carefully prepared, and that the appendix of laboratory experiments, occupying 65 pages, makes the volume a self-contained guide for students preparing for honours degrees. Dr. Stephen has added a new chapter on derivatives of pyrone, chromone and xanthone, and some new matter at the ends of various chapters. The price of the book brings it within the reach of students, and it may be warmly commended.

Gems and Gem Materials. By Prof. E. H. Kraus and Dr. E. F. Holden. Pp. vii + 222. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 15*s.* net.

THIS is a well-illustrated account of gem minerals, in two parts. The authors remark in a brief introduction that the study of gem minerals has been named "gemmology," but it is a great relief to have their assurance that this term is not widely used. Part 1 (pp. 9-104) deals with the general properties of minerals, including chapters on the genesis, cutting and polishing, naming and manufacture of gem stones. Part 2 (pp. 107-213) gives descriptions of the various minerals used as gems, and includes numerous tables in which gem minerals are classified according to their properties. The last of these tables gives a summary of the properties of gem minerals described in the text, the arrangement of the minerals being alphabetical. The book concludes with a useful index.

Le mouvement scientifique contemporain en France. 3: *Les sciences physico-chimiques*; 4: *les sciences mathématiques.* Par Dr. Georges Matisse. (Collection Payot.) Pp. 320. (Paris: Libr. Payot, 1925.) 10 francs.

THIS volume constitutes a small guide-book which indicates the main contributions of French chemists, mathematicians, and physicists to modern scientific knowledge. Since the work of about thirty scientific workers is summarised, that of any individual worker is only outlined in a very brief manner.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Magnetic Properties of Single Crystals of Iron.

FORMERLY the preparation of single crystals of iron has been made by Goldschmidt's method, by which means crystals ranging from one to two centimetres in linear dimensions can be obtained, but the production of larger crystals by the same method is almost impossible In 1924, however, Prof. C A. Edwards obtained large crystals of iron by using Prof. Carpenter's method of preparing single crystals of aluminium, and thus opened to us an important route for the investigation of the true nature of the metal. Hitherto we have been able to measure only the mean of the properties differing in various orientations of the crystal; but we are now in a position to study the property of an individual crystal in different directions relative to its orientation

Since the beginning of last year the present writers have used this method and obtained crystals of iron, for which the magnetic properties have been measured. The first communication of ours dealing with this investigation was published at the autumn meeting of the Denki Gakkai, Tokyo (Institute of Electrical Engineering), on Oct. 24, 1925 The present note contains the results of the investigations we have made during last year

The magnetisation was measured with a rod of a single crystal of iron of the dimensions, 68 1 × 2 4 × 1 81 mm³, the axis of the rod being inclined at angles of 21° 10′ and 70° 10′ to the tetragonal axis of the crystal The ballistic method was used for the measurement of magnetisation. The curve of magnetisation plotted against the effective field is given in Fig. 1

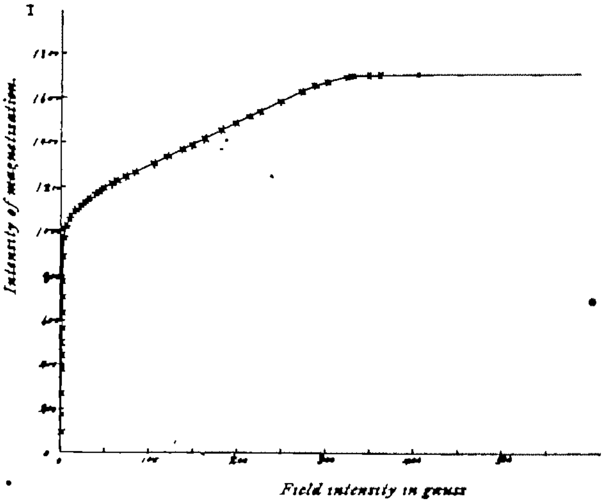

FIG 1.—Magnetisation curve of a single crystal of iron.

The characteristic features of the magnetisation curve are as follows:

(*a*) The curve is almost straight up to an intensity of magnetisation of 1000 c g s. units

(*b*) Then the curve shows two sharp breaks or bendings.

(*c*) The saturation of magnetisation is much more easily attained than in the case of polycrystals, its value being 1710.

The hysteresis loss of a single crystal of iron is very small, amounting only to one-tenth of that of ordinary sheet iron containing silicon It increases very rapidly with the numbers of grains or crystals in a specimen, as is shown in Fig 2. It is therefore to be concluded that the hysteresis is considerably affected by an irregular distribution of molecular magnets at the grain boundaries

The initial and maximum permeabilities also decrease with the number of grains. The following table contains the numerical results of our observations in this direction:

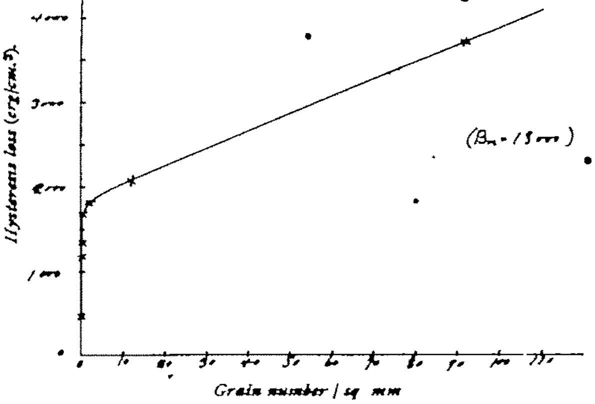

FIG 2.—Curve showing the relation of hysteresis loss to number of grains or crystals in the specimens

Grain Number per mm².	Initial Permeability	Max. Permeability	Hysteresis Loss.	Demagnetising Force.

0·0067	1700	4300	460	0·063

Five rods of single crystals and of dimensions 2 × 2 × 40 mm³, of which three had their axes approximately lying in plane (100) and other two in plane (110), were next prepared; their axes had the following orientations with respect to the principal axis of the crystals

Specimen.	Orientation	
No. 1	14°	
„ 2	25°	nearly in plane (100),
„ 3	33°	
„ 4	27°	nearly in plane (110).
„ 5	41°	

With these rods the magnetic expansion was measured up to an effective field of 500 gauss by the method usually employed in our institute (*Sci. Rep*, 9, 1920). The results of measurement are graphically given in Fig 3 and may be summarised in the following terms:

1. The magnetic expansion of single crystals of iron is generally very large as compared with that observable in ordinary iron, its magnitude being about ten times greater than that in the latter iron.

2. In specimen No 1, the axis of which subtends a small angle with the tetragonal, the magnetic expansion rapidly increases in weak fields and then slowly, tending to an asymptotic value, as the field increases (Fig 3, *a*).

3. In specimen No. 5 the axis subtends a small angle with the trigonal. A very small magnetic expansion is observable in weak fields; above a field of 50 it is always negative, the amount steadily increasing with the field (Fig. 3, *c*).

4. In specimen No. 3, subtending a small angle with the digonal axis, the course of the curve is similar to that in specimen No. 5; the maximum elongation and the inversion field are a little greater, but the contraction in strong fields is about ¼ of that in specimen No. 5 (Fig. 3, *b*).

From the above results it is to be concluded that the magnetic expansion in the direction of the tetragonal axis is always positive for all magnetising fields, and that the expansion in the direction of the trigonal axis should always be negative, the small initial expansion actually observed being due to the deviation of the axis of the specimen from the trigonal axis. The expansion curves in specimens Nos. 2, 3, 4 may be considered as the combined effect of the above two. The magnetic expansion in ordinary iron consisting of microcrystals is a differential effect of the expansion and contraction above referred to, the crystal axes being distributed at random. The smallness of the magnetic expansion of ordinary iron as compared with that of the single crystal, as well as the course of the expansion-curve, are all explained on the above view.

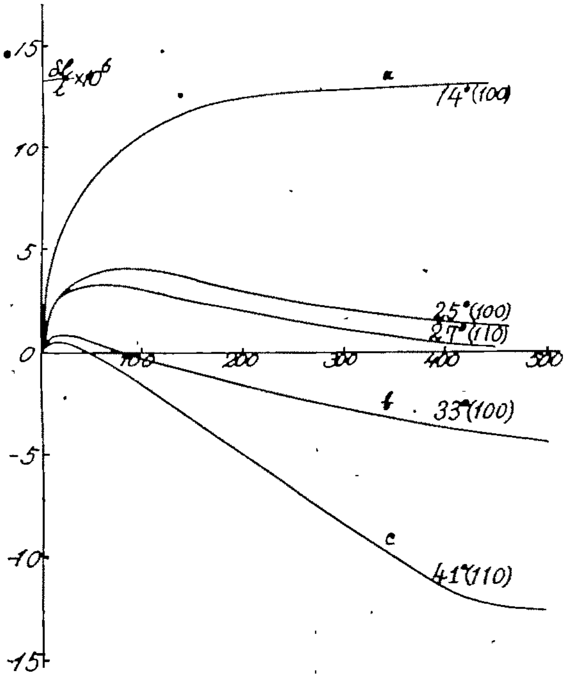

FIG. 3.—Curve showing magnetic expansion of single crystals of iron differently oriented with regard to the principal axis of the crystals.

The result obtained for the magnetic expansion agrees with that obtained by Heap (*Phy Rev.*, 24, 1924) in the case of magnetite. The sharp breaks in the magnetisation curve can be expected from the theory of crystal magnetisation put forward by Dr. J. Okubo and one of the present writers (*Sci. Rep.*, 5, 1916) ten years ago. This theoretical part, together with new interesting facts, will be dealt with in a further communication.

The Physical Basis of Insect Drift.

THE writer in the issue of NATURE for September 5, 1925, summarised available data in regard to insect drift and only incidentally alluded to the meteorological phases. Very recently the occurrence of hundreds of thousands or even millions of black aphids, *Dilachnus piceæ* Panz., and a flower fly, *Syrphus ribesii* Linn. (C. S. Elton, *Trans. Ent. Soc. Lond.*, pp. 289-299, 1925), on the ice-covered wastes of North-East Land, Spitsbergen Islands, north latitude 80°, has renewed interest in the subject, particularly as these insects must have drifted more than 800 miles near the extreme north. This could scarcely have been a movement in response to some strong instinct, and the same is very probably true of the Coccinellids recorded very recently from the crater of Vesuvius (*Ent. Record and Journ.*, Variation 37, 143, 1925).

There are physical explanations for these movements and many others noted in our earlier cited paper. A moderately strong favourable wind is all that is necessary to account for widespread transportation of insects capable of sustaining themselves in the air. The latter may or may not be correlated with what we know as a strong flight. It is well known that ordinarily air currents near the surface of the earth, during the milder season when insects are abroad, are usually more or less unstable, and therefore we do not expect extensive drifts in this manner, and the general tendency has been to explain any widespread movement as a migration, that is, a somewhat determinate or purposive movement by hosts of insects. This attitude is due in part to our very limited knowledge as to the movements of the upper air currents, and secondly to the assumption, based largely upon lack of data, that insects remain near the surface.

The recent development of aerial navigation has demonstrated the occurrence of convectional currents at considerable heights, 1000 feet to even 3000 or 4500 feet. A velocity of 2000 feet per minute has been recorded for such currents. The significance of these is that they may, and undoubtedly do, serve as elevators, as it were, to carry insects into the upper air, and once at a considerable height, it is not difficult to realise that horizontal currents of great velocity might carry these insects possibly thousands of miles before they descend to the surface. This latter is rendered more probable by the fact that wind velocities increase greatly as one ascends in the free air to 100, 200, or even 300 miles per hour. The 5¼ in. of dust swept from the Sahara Desert during the past thirty years and deposited in Europe and also over parts of Africa, Asia, and the Atlantic Ocean, and the transportation of dust 1500 miles from Australia to New Zealand, are concrete examples of what winds may accomplish (*Monthly Weather Rev.*, U.S. Dept. Agr., 50, 301, 1922).

It is well known that there is a somewhat definite circulation of warm air from the tropical or subtropical regions toward the cooler sections of the north. Such a movement of warm air means a return near or at the surface of the earth of cooler air. We readily see what is in the latter, because it is within easy vision. We know nothing about the upper air except the extremely few observations made by airmen in balloons, dirigibles, or aeroplanes, at a time when they are concerned mostly with problems of navigation and can give only incidental attention to such minor matters as birds, insects, and other forms of life.

The large desert areas in Arabia and northern Africa are undoubtedly sources of convectional currents which ascend to considerable heights and move northward, carrying with them, presumably, any light objects which might be in the air, including wandering insects, and possibly millions from nearby localities producing enormous broods. It is easy to see how hosts of the thistle butterfly, *Vanessa cardui* Linn., might be picked up by such convectional currents, carried to considerable heights, drift northward at such elevations, and thus supply all Europe north of a line through the middle of France and south Germany or Switzerland with these insects, a movement suggested by Mr. C B. Williams, some being carried (we believe this is drift rather than flight) even to northern Scotland, Scandinavia, the Shetland Islands, and distant Iceland.

Such a drift would suggest that the warm air currents might extend even nearer to the Pole, and the record of plant lice and flower flies which are given above is conclusive evidence that such must be the case, to a limited extent at least. It is quite possible that other insects are carried into remote northern areas, sometimes in considerable numbers. The mere fact that there are no records counts for little, owing to the impossibility of obtaining from such sections anything which might be considered approximately complete data.

Turning to the western hemisphere, there are several records of enormous swarms of this butterfly, *Vanessa cardui*, being observed in apparent migration in southern California in 1924 and 1926, the movement being from the south-east to the north-west. One of the observers suggests that the source or the origin was either the foothills of the Sierras or the Sierras proper. There is a possibility that these swarms originated at a considerably greater distance. They may have been carried into the upper air in regions bordering desert areas considerably farther south or south-east, in much the same way as suggested for this insect in the eastern hemisphere, since we have in both extensive desert areas constantly producing convectional currents, and after a certain altitude is attained, the probabilities of extensive drift are certainly excellent.

There are interesting records which, while they undoubtedly represent extremes for wind currents near the surface of the earth, may be taken as reasonably suggestive of conditions at some elevation where air movements are not hindered by friction These are the notable gales at Point Reyes Light, Calif. (*Monthly Weather Review*, U.S. Dept. Agr., May 1903, p 227), in May 1902 and 1903, the first lasting six consecutive days, with an average velocity of 50 miles an hour and an extreme velocity of 120 miles an hour, and the second of nine days' duration, with an average velocity of 54 miles an hour and an extreme velocity of more than 90 miles per hour There can be no doubt regarding the ability of the winds to transport insects and other drifting objects long distances, and with a multitude of areas favourable for the development of convectional currents of moderate to considerable intensity, it seems quite probable that many insects are raised to somewhat high altitudes and carried long distances, some species in large numbers, and presumably many are represented only by scattered specimens, owing to their seldom breeding locally in great abundance.

It is believed that a recognition of these forces and an understanding of the agencies involved will assist materially in solving problems in connexion with the extensive movements of flying or drifting insects.

The 'Gas Laws' in Surface Solutions.

IN a letter to NATURE (April 3, p. 484), Messrs. Adam and Jessop disagree with the findings of MM. Marcelin (*Ann. de Physique*, November-December, 459) and Delaplace (*C.R.*, 180, 2020), concerning the relation between the pressure, (F), of the surface films of oleic acid and the area per molecule, (A). The latter investigators find the relation $FA = kT$, while the former find A largely independent of F. It should be noted that Langmuir (*J. Am. Chem. Soc*, 39, 1868) obtained two types of FA-curves: when the films were formed on distilled water the FA-curves were steep like those of Adam, and represented *irreversible* conditions, when expanded on acid solutions the films gave flatter FA-curves, more like those of Marcelin, and were (presumably) reversible. Evidently there exists a disturbing factor and it will repay to inquire into its probable nature.

A little consideration will show that attempts to express the energy relations of surface films as a function of temperature alone cannot be successful, and that Delaplace's formula $FA = kT$, while true for dilute surface solutions with area per molecule greater than 5000 sq Å.U., cannot be applied to more concentrated films; on the other hand, Marcelin's original formula, $FA =$ constant, may be correct under specified conditions. Since molecular surface films are composed as a rule of heavy, highly polar, oriented, molecules which have relatively little freedom of movement, changes in their energy content will not involve changes in heat energy to any large extent. In fact, it has been shown by Einstein (*Ann. der Physik*, 4, 543), and by Harkins (*J. Am. Chem. Soc.*, 39, 354), that the relation between the specific heat of surface (S) and the free surface energy, or surface tension (γ) is $S = -T\, d^2\gamma/dT^2$, and when $d\gamma/dT$ is linear, which is generally the case, *the surface contains no heat, its energy being in potential form*. This is only what may be expected, seeing that heat energy is closely connected with volume and with free movement in three dimensions, and that oriented molecules, in a two-dimensional continuum, can possess but little energy of translation.

It seems much more rational to express energy relations of films in terms of surface (A), of surface pressure (F), and of (E), the *potential of the surface energy*,—these three variables corresponding to the familiar p, v, T, of thermodynamics Unfortunately, we know very little about the real nature of the potential E. It is probably an electro-chemical potential depending on the chemical nature of the film and on the electrical potential. We do know that in disperse systems certain ions have great influence on the degree of dispersion, and therefore on the surface energy; we know that there is a close connexion between potential difference and surface tension (Lippmann-Helmholtz equation); that the surface tension of mercury may be calculated, with certain assumptions, from the energy of the double layer formed by the positively charged atomic nuclei and the negatively charged electrons (Frenkel, *Phil Mag.*, 33, 6, 297); and the writer has shown that electrical energy may be changed into surface energy ("Electrical Dispersion of Liquids," *J. Phys. Chem.*, 29, 1289). Consequently the area of the molecular surface film may be expected to be a function of an electrochemical potential (E), just as the volume of gases is a function of the heat potential (T). By analogy we should expect a 'law' of the form $AF = kE$ (or kE^2, if the potential is to be expressed in units of ordinary electrical potential). Below a certain value of the potential E the molecular surface film will behave like a 'liquid' and steep FA-curves, like those of Adam, will be obtained; above that value, the film will behave like a gas above its critical temperature, giving FA-curves like those obtained by Marcelin and by Langmuir. The fact that experiments were carried out sometimes under (electrically) adiabatic conditions and sometimes under 'isoelectric' (corresponding to isothermal) conditions, possibly explains the 'hysteresis' of the curves obtained by Langmuir with films on water, and the (presumable) reversibility when acidified water was used.

Naturally, only 'ideal' cases follow the relation $FA = kE$. One may define an 'ideal film' or 'ideal colloid' as *a system all surface and no volume*, in the sense that *its energy is a function of the potential E only*. The 'ideal colloid' is, no doubt, as difficult to find as the 'perfect gas' is. Perhaps some of the body colloids come nearest to the ideal state, for we know, much to our discomfort, that they claim the temperature to be a constant, and a variation of a few degrees is as much as they will stand without 'giving up the ghost.' Yet the human organism is an extremely efficient machine, and its efficiency is due to the fact that it does not derive its energy from wasteful heat changes, more and more we come to consider it as an electro-chemical machine working under nearly reversible conditions. It is known, for example, that muscular action is accompanied by changes in the hydrogen-ion concentration (formation of lactic acid); if we had an ideal colloid composed, for the sake of simplicity, of closely packed molecular films of thickness, say, 1×10^{-6} cm, a variation in their potential due to a change in the hydrogen-ion concentration would readily produce a difference of 10 dynes in their surface tension (as in some of Langmuir's experiments); that would enable each square centimetre of cross-section of the ideal colloid (in this instance, the muscle) to lift a weight of approximately 20 lb. To conclude: let us follow Nature's lead and, assuming the temperature to be a constant, determine the electro-dynamic laws which govern the energy relations of 'oriented' molecules.

The Oxidation of Ammonia.

IT is regretted that there is an error in the second equation of those suggested in NATURE of April 24 which makes the scheme there given impossible. The writer still considers that nitrohydroxylamic acid is a possible intermediate product, as will be explained below, but it cannot be derived as previously given. Before giving alternative schemes it may be interesting to review briefly the facts to be explained.

A suitable scheme of reactions should explain some such set of data as the following, which is taken from records of experiments made for the Munitions Inventions Department during the period 1917–1919. These records have been in proof for two years but have not been published.

(1) The platinum catalyst, consisting of gauze of 0·1 mm. diameter wire with 80 meshes to the linear inch, through which the mixture of air (or oxygen) and ammonia is passed, exhibits an activity increasing from a very small value with unused metal to a maximum attained, in the case of a single gauze, after 14 hours running with an amount of ammonia oxidised of about 1 gram per sq. in. a minute. This is accompanied by a change in the appearance of the platinum from bright to grey, and has been shown by other experimenters (see Rideal and Taylor, "Catalysis," fig. 10) to be due to a remarkable efflorescence on the surface. This is similar to that observed by Newbery in experiments on overvoltage and seems to suggest that it is due to the expulsion of gases which have been dissolved in the platinum and have perhaps interacted there.

(2) The rate of oxidation is very great With two gauzes and ammonia-air mixtures containing from 9·1 to 13·8 per cent. ammonia by volume, a time of contact of not more than 0·000155 sec. was sufficient to ensure an oxidation of 82·6 to 94·2 per cent. in various experiments. The results were practically the same (87·6 to 94·4 per cent.) with a time of contact of 0·00062 sec., whilst with a longer time of 0·00093 sec. there was some falling off in the yield (63·7 to 89·1 per cent.). The higher yields usually correspond with lower ammonia content of the initial gas. In the case of mixtures with oxygen and steam, with a time of contact of 0·000155 sec. the oxidation was 98·3 per cent and the output greater than with air. With very slow rates, both in the case of air and oxygen, the yield fell below 70 per cent.

(3) The conversion was practically the same with mixtures in which the air varied from the amount required to form nitrogen trioxide, N_2O_3, to that required to form nitrogen pentoxide, N_2O_5, although the best working appeared to correspond with the former. Below N_2O_3 the yield is smaller, and it appears that more oxygen is required than for $4NH_3 + 5O_2 = 4NO + 6H_2O$, both with air and with oxygen and steam. In only two experiments yields of more than 90 per cent. were obtained with the nitric oxide ratio, but generally lower conversions were found with this ratio.

(4) In the experiments with pure oxygen (diluted with steam) the sole products of combustion appeared to be nitric oxide and water, since the gas coming from the converter could be completely condensed by cooling into liquid nitric acid. No nitrous oxide is formed and it is reasonable to assume that none is formed with air, although this was not tested.

A reaction scheme must therefore conform with the following conditions.

(*a*) Reactions of order higher than bimolecular are improbable.

(*b*) Hypothetical intermediate compounds should not be capable of rapid direct decomposition into nitrous oxide. This makes the formation of NOH improbable.

(*c*) Excess of oxygen above the amount to form nitric oxide, NO, seems necessary.

(*d*) Reactions between gases condensed on or dissolved in the platinum, or labile oxides of platinum and dissolved gases, seem not improbable.

The fact that unconverted ammonia, when it does not appear as such, is accounted for as free nitrogen, makes it possible that such substances as NH_4NO_2 can be formed.

The necessity for excess of oxygen seems to indicate that the primary product is one containing more oxygen than nitric oxide, and since the reaction becomes complete at the nitrogen trioxide ratio it may be that this, or $N(OH)_3$, or nitrous acid may be formed It is also possible to assume the formation of nitric acid, since the decomposition of this could be a slower reaction after the catalyst. Very recent work on heterogeneous catalysis will also allow us to make use of atomic oxygen, and hence the following schemes are possible:

A. (1) $NH_3 + O_2 = NH(OH)_2$.
(2) $NH(OH)_2 + O = N(OH)_3$
(3) $4N(OH)_3 = 4NO + 6H_2O + O_2$.
B. (1) $NH_3 = NH + H_2$
(2) $NH + O_2 = HNO_2$; etc.
C (1) $NH_3 + O_2 = NH(OH)_2$.
(2) $NH(OH)_2 + O_2 = HNO_3 + H_2O$; etc.

Schemes A and B also explain the formation of nitrogen, which would come from ammonium nitrite. A possible source of nitrogen in a gas rich in ammonia is combustion in the gaseous phase, possibly accompanied by flame, owing to local rise of temperature on the catalyst, as in the well-known lecture experiment.

It does not at the moment seem possible to connect the formation of nitrohydroxylamic acid with simpler reactions than those given. Although possible schemes are easily drawn up (*e.g.*, one involving the rapid reaction of $N(OH)_2$ and NH_2 followed by rapid oxidation of the product) they do not, in fact, appear very probable. East London College,
University of London.

Seasonal Sunshine in Great Britain.

AN article on "Seasonal Sunshine in Great Britain" by Mr. Charles Harding appeared in NATURE of March 20. The results were based on the 35-years' mean, 1881–1915. Comparing south-east England with south-west England and south Wales, Mr Harding says that "the average sunshine for the year in south-east England is 4·49 hours a day, and in south-west England and south Wales, including the so-called Cornish Riviera, it is 4·28 hours. In the winter, south-east England has an average daily sunshine of 1·92 hours, and in south-west England and south Wales the value is 1·91 hours a day; in spring the hours of sunshine for the two districts are respectively 5·50 and 5·36; in summer 6·88 and 6·41, and in autumn 3·46 and 3·31 hours."

An examination, however, of the Air Ministry figures, upon which these values are based, show that more sunshine is experienced in the south-west than in the south-east. The fact is hidden through the district being linked up with south Wales, which has different climatological characteristics. South-west England and south Wales have now been made separate districts by the Air Ministry for forecasting purposes, but the original larger areas are still retained for climatological investigation. The counties included in south-west England have an area of 6548 square miles, and those in south-east England 7224 square miles. As these districts are situated in approximately similar latitudes, there is but little difference between them for purposes of comparison of sunshine values. The addition of south Wales, however, with its additional 4762 square miles of country, brings the south-western district up to 11,310 square miles, and the lowering effect upon the sunshine values is apparent. The results for south-east and south-west England are as follows:

	S E England. Hours.	S.W. England. Hours.
Spring	5·50	5·66
Summer . . .	6·88	6·75
Autumn . . .	3·67	3·68
Winter . . .	1·92	2·61
Year	4·49	4·53

The seasons are:—Spring: March, April, May; Summer: June, July, August; Autumn: September, October, November; Winter: December, January, February. J. B. PHILLIPS.

The Observatory, Falmouth,
April 24.

THE criticism by Mr. Phillips, Superintendent of the Falmouth Observatory, is more a matter for the Meteorological Office than for me. In my article it is stated clearly that the sunshine records are taken from the "Book of Normals," published by the Meteorological Office. Exception is taken by Mr. Phillips to the paragraph he quotes from the article, where it is stated that the values quoted are taken from a "Book of Normals" (M.O. 236, Section 2) giving seasonal normals for several districts; in this the Meteorological Office has combined south-west England and south Wales in one normal. I am not at all sure that I agree with Mr. Phillips in thinking that the Meteorological Office should have separated south-west England and south Wales. I agree practically in the results obtained if these two parts are separated, and I will accept Mr Phillips' sunshine value 4·53 hours for the year for south-west England in which observations are taken for Newquay, Cullompton, Plymouth, and Falmouth. Taking all the stations as used by the Meteorological Office for the normal for south-east England, I obtain for the year 4·47 hours a day, in good agreement with 4·49 hours given by Mr. Phillips; this value is obtained from 9 stations By omitting observations from Kew and Marlborough, and using the remaining 7 stations, the normal for south-east England is 4·62 hours, which is a greater duration than the normal for south-west England.

There is clearly keen competition for a premier record, and without doubt much can be done by the choice of a good position for the sunshine recorder. In my judgment, however the records are considered, certainly for a single station or two south-east England has a higher value of daily sunshine than any station in south-west England, which includes the so-called Cornish Riviera. CHAS. HARDING.

The Original Home of the Banana.

I REGRET that in the notice of my recent discourse at the Royal Institution (NATURE, April 24, p. 597) it is stated that "the available evidence points to South America as the original home of the banana." Reference was made to the views that have been held by various authorities as to the original home of the edible banana, and it was pointed out that from all the evidence at present available the balance was in favour of Indo-Malaya as the probable home of the seedless forms now so widely cultivated.

These forms belong to the subgenus Eumusa, the species of which are all regarded as of Indo-Malayan origin.

There are ancient traditions that the banana existed in Central and South America before the arrival of the Spaniards, and edible bananas certainly existed in Sierra Leone in 1568, no doubt as introduced plants, as those alleged to exist in America may also have been.

Prof. Berry's recent discovery of fossil banana seeds in the Tertiary rocks of Colombia is of great interest, since they belong to a species of the subgenus Physocaulis, the species of which are nearly all African. This discovery proves, therefore, that the genus Musa was represented in South America in prehistoric times.

Whether, however, this fossil species, which is closely allied to *Musa Ensete*, from tropical Africa, is in any way related to the seedless bananas is very doubtful. Nor does it seem very likely that such a species as *M. Ensete* would give rise under cultivation to a form with edible fruits.

The seedless bananas have been so long in cultivation that it seems almost impossible to be certain of their place of origin, but the evidence I think on the whole inclines rather towards Asia than to America. ARTHUR W. HILL.

Royal Botanic Gardens,
Kew, Surrey,
April 29.

The Present Position of the Transmutation Controversy.

IF the genius of John Dalton gave the chemist a freehold title to the atom, the work of Becquerel and the Curies may be said to have transferred the title to the physicist, or at least to have granted him an indeterminable repairing lease of the property. The physicist has made good use of his tenure: he has determined the structure and conditions of stability of the atom, and by embellishing its parts with attractive and repulsive signs, he has thrown light upon many things that were previously obscure, and revealed new avenues of research for the investigator. Except for some tentative efforts to formulate an electronic theory of valency, the chemist has, for the most part, been out of the picture; and even when Rutherford used α-particles to disintegrate certain light atoms, the chemist was denied participation by the circumstance that the quantities of material involved were too minute to come within the range of his most delicate methods. In 1924, however, a vista of golden opportunity arose when Miethe and Stammreich announced that they had obtained from pure mercury gold in sufficient yield to be manipulated and determined by chemical means. The vista, although riddled by the barbed arrows of hostile criticism, is still above the horizon, and only the crucial test of further experimentation can decide its ultimate fate. Meanwhile, it may be of service to attempt a brief survey of recent happenings in this very interesting field of alleged transmutation.

It will be recalled that Miethe and Stammreich passed a strong current at 175 volts through a quartz mercury-vapour lamp containing, according to their statement, mercury free from gold, and that after working the lamp for 20-200 hours, gold to the amount of 0·1-0·001 mgm. was detected by chemical means in the mercury (*Naturwissenschaften*, August 1, 1924; NATURE, August 9, 1924). Afterwards, they found that the formation of gold was not bound up with any definite form of discharge, although a certain critical potential difference or electron velocity had to be exceeded; that the amount of gold produced was proportional to the current-strength and the time; and that the production was facilitated by a high pressure inside the apparatus. When they passed electric sparks between mercury poles in a paraffin dielectric, they found that gold was present in the mercury dispersed along the line of discharge, but not in the liquid mercury constituting the poles. Duhme and Lotz are reported to have observed the formation of gold when a sufficiently powerful current is passed between electrodes dipping into mercury; and investigators in the Siemens research laboratory to have produced gold by bombarding a mercury surface with electrons in a very high vacuum (*Naturwissenschaften*, July 17, 1925). In some of their experiments Miethe and Stammreich observed the production of a metal which resembled silver in its chemical properties. It is important to note that these authors have maintained throughout that the mercury they have experimented upon was in all cases proved to be free from gold by the very same tests which they used to prove its presence in the treated mercury.

In May 1925, Nagaoka reported in these columns that he and his co-workers had passed a discharge of P.D. about 15×10^4 volts/cm. for about 4 hours between terminals of tungsten and pure mercury, using paraffin oil as dielectric, and had detected gold in the resulting black mass of carbon, oil, mercury, etc., by the purple-of-Cassius test and by the formation of ruby glass. In a later communication (*Journal de Physique et le Radium*, 1925, 6, 209) he stated that on passing a discharge through drops of mercury falling between iron electrodes, he observed, in addition to gold, the formation of a complex white metal consisting mainly of silver.

Early this year, in a preliminary announcement to NATURE (January 2, p. 13), Smits recorded the transmutation of lead into mercury and into thallium by means of a quartz lead-vapour lamp consuming 40 amp. at 80 volts. The initial purity of the lead and the subsequent presence of thallium and mercury were attested by the spectroscope. The method was varied by substituting sparks of high current-densities for a continuous current; using 60-100 amp. at make, all the lines of the mercury spectrum were visible after 9½ hours' sparking. Another method, in which sparks at 100,000 volts and 2 milliamp. were passed between electrodes of highly purified lead, immersed in a liquid dielectric, showed the transmutation of lead into mercury, the presence of which was proved by conversion into red mercuric iodide.

A priori objections to these experimental results are not difficult to conceive. It might be thought that heavy atoms, like those of lead and mercury, would be more unstable and therefore easier to disintegrate than light atoms, because their nuclei contain a greater excess of positive over negative charges; but Rutherford's experiments with α-particles showed that the lighter atoms are the less stable. Most of the light elements which he decomposed have an odd atomic number; all, with the exception of nitrogen, have atomic weights that are multiples of that of helium plus 3 units; and none of them except boron exhibits isotopy. Now mercury and lead have each an even atomic number, their atomic weights do not follow the above-mentioned numerical rule, and both elements possess isotopes.

Aston, moreover, has advanced some weighty arguments against the probability of the alleged mercury-gold transmutations (NATURE, December 19, 1925). This transmutation might conceivably be effected by the addition of an electron to the mercury nucleus, or by the expulsion of a proton from it. The chance that an electron would hit a nucleus at which it was fired is remote; and if a mercury atom did absorb an electron its weight would not be sensibly increased. Hönigschmid, however, has determined the atomic weight of Miethe's gold and has found it to be 197·2 (the same as that of ordinary gold), a number which is appreciably different from the atomic weight of mercury. Theoretically, it is possible for a mercury isotope of atomic weight 197 to absorb an electron and so produce ordinary gold; but none of the six isotopes of mercury identified by Aston possesses this atomic weight. The alternative hypothesis, that the mercury nucleus may be disrupted with the ejection of a proton, is held by

Aston to be quite untenable, because the forces employed are "ludicrously inadequate" for the purpose. The components of a nucleus are bound together by forces of the order of millions of volts, and these are not yet available to the laboratory worker, except in the form of swiftly moving α-particles from radium-C, as employed by Rutherford.

Possible explanations of the production of mercury and of thallium from lead have been considered recently in these columns by A. C. Davies and F. Horton (NATURE, January 30, 1926, p. 152), who think that investigators should attempt to determine if hydrogen or helium is evolved during the changes: their production would indicate a disruption of the nucleus, their absence would favour the hypothesis of electron absorption. Up to the present no one has observed the liberation of these gases during the reported transmutations.

Criticisms of the experimental findings of Miethe and Stammreich, and of Nagaoka, centre around the question of the purity of the mercury used by them; Was it really free from gold? The answer to this question must depend upon the analytical method employed and upon the 'personal equation' of the observers. The method used by Miethe and Stammreich was to dissolve the mercury in nitric acid (1 : 4), fuse the undissolved residue with borax (0·1 gm.), and to measure the resulting sphere of gold, if any, under the microscope. They state that the limiting concentration of the detectable gold in an amalgam is 1 : 10^7 to 1 : 10^{12}, and that the amounts of gold obtained by transmutation were within 10^3–10^4 of these limits. In one of their experiments they distilled *in vacuo* 1 kilogram of purified mercury, which showed no trace of gold, with 0·5 mgm. of silver and 0·5 mgm. of gold, until only 1 gram of the mixture was left; in this residue they found *all* the silver and gold that had been put in (*Zeitschrift f. technische Physik*, 1925, 6, 74, 76).

In spite of such evidence, it is freely contended that distillation is not a trustworthy method of separating metals of high boiling-point from mercury, and that all the mercury that has been used in transmutation experiments was auriferous. Stammreich has discussed (*loc. cit.*) the possible ways in which gold might be carried over during the distillation of a gold amalgam. (*a*) It might distil over in virtue of its own vapour pressure. The vapour above the amalgam would contain gold, if only in an infinitesimal amount, and this amount would not sensibly increase when the amalgam was boiled. In the above experiment the vapour pressure of the gold must have been very nearly zero, and any error due to gold distilling over in the vapour phase would be well within the limits of accuracy of the method employed for determining the gold. (*b*) The vapour pressure of a gold amalgam might be higher than that of pure mercury. Such a phenomenon would be against all experience. (*c*) Vapour or minute drops of the (auriferous) mercury used for the mercury-pump might be carried over into the distillate. Miethe and Stammreich state that the distilling apparatus used by them precluded the possibility of such an occurrence.

In support of possibility (*a*), the critics quote the work of G. A. Hulett (*Physical Review*, 1911, 33, 307). This investigator submitted a mixture of 6·75 kgm. of thrice-distilled mercury and 45·5 gm. of electrolytically refined gold to two distillations *in vacuo*, and the second distillate was found by a colorimetric method due to T. K. Rose (*Chem. News*, 1892, 66, 271) to contain nearly 2 mgm. of the noble metal. It will be noted that the concentration of gold in the initial mixture was more than 1300 times greater than that in the mixture used by Miethe and Stammreich (*v.s.*). These authors attribute Hulett's result to spirting or irregular ebullition of the amalgam during distillation.

More recently Riesefeld and Haase have distilled an amalgam containing about 1 part of gold in 10 million of mercury under very carefully controlled conditions, using distilling apparatus specially designed to prevent mercury vapour diffusing back from the mercury-pump, and to prevent gold being carried over mechanically (*Berichte*, 1925, 58, 2828). The distillate was found to contain gold in determinable amount.

In their reply, Miethe and Stammreich adhere to their contention that gold enters the distillate, either from the pump or as the result of irregular ebullition. They point out that the microbalance which Riesefeld and Haase used for weighing their gold had an error of 0·003 mgm. and that this was exactly the weight of the gold they extracted from the third distillate. They note that the isolated gold was not pure, and they reaffirm that the mercury used in their own transmutation experiments was always previously purified from gold, to which end only two or three distillations were required as a rule, although so many as fifteen distillations had on occasion to be performed (*Berichte*, 1926, 59, 359).

In a discussion of this subject held at the third assembly of the Deutscher Physikertag in Danzig (September 1925), it was suggested that gold and mercury might distil over together as a constant-boiling mixture. Prof. Miethe replied that in all constant-boiling mixtures the boiling-points of the components are of the same order (mercury boils at 357° C. under atm. press., gold at above 2600° C.), and that the components are present in commensurable proportions; he had investigated the possibility and had concluded that such amalgams do not exist.

Another suggestion made was that the mercury used for the transmutations may have contained gold in a state unrecognisable by the chemical tests employed, *e.g.* in colloidal solution or as a chemical compound, and that these were afterwards broken down by the electric discharge. There is, however, no experimental basis for this explanation. Finally, it was suggested that a decisive answer could be obtained by collecting the mercury dispersed in the dielectric by the discharge (*v.s.*), purifying it from gold, and then resubmitting it to the discharge: if it was found that more gold was produced, transmutation would be established. The experimental difficulties of such a test would be very great; the highest gold-concentration hitherto obtained in the mercury-mud of the dielectric is 1 : 10,000.

This short sketch of the main issues of the controversy will leave the impression that the question is still *sub judice*. On one hand, we have the perfectly definite statements of Prof. Miethe, who is an experimenter of acknowledged ability, and has shown much skill in parrying the attacks of his critics. On the other hand, the accounts of some of his experiments, notably in regard to the distillation apparatus he employs, are somewhat lacking in precise detail; several investigators have entirely failed to reproduce his results (*e.g.* Tiede, Schleede, and Goldschmidt; Sheldon and Estey, Nature, November 28, 1925, 792; Piutti and Boggio-Lera, Nature, April 24, 1926, p. 604); and the considerations put forward by Dr. Aston still await a reply. Claims to have effected 'the great work' of transmutation have been made at frequent intervals since alchemy fell into disrepute, and their ignoble fate must make us sceptical of more recent contentions; but if these are proved to be baseless, it will be admitted that modern research into the constitution of the atom gave them a rational basis of possibility such as was never dreamed of by the mediæval alchemist, even in his most fantastic flights of imagination.

Since the above account was written, a lecture given by Prof. F. Haber to the Kaiser Wilhelm-Gesellschaft, in Berlin, has been published in the issue of *Die Naturwissenschaften* for May 7, in which he communicated the results of prolonged investigations on the alleged transformations of mercury into gold. These results, which appear quite convincing, show that the gold obtained by Nagaoka and by Miethe and Stammreich did not in all probability pre-exist in the mercury, but was derived from auriferous metal constituting the electrodes or other metallic parts of the apparatus employed.

Prof. Haber has worked out two chemical processes for separating and determining gold in the presence of a large excess of mercury, but in the experiments now recorded he used mercury which had been purified by extremely slow, repeated distillation. Nagaoka's experiment was repeated several times, using a less powerful discharge, which, however, was continued for fifty hours, and gold up to 1×10^{-7} gram was obtained; but Miethe's experiment of passing a discharge through paraffin between mercury poles gave no gold whatever. The mercury-lamp method, when modified to give electrons with much greater velocity, gave small amounts of gold, which, however, did not increase when the period of the discharge was prolonged from four to fifty-six hours.

Using a kind of X-ray tube with a cathode of tungsten wire, an anticathode of strongly cooled mercury, and 30,000 volts, Prof. Haber also obtained gold; in one experiment so much as $1{\cdot}6 \times 10^{-6}$ gram. This led him to examine the metallic connexions of the tube, and he found that whereas the parts of these within the apparatus contained 2×10^{-6} gram of gold before the experiment, only one-fortieth of this amount was present at the end, the difference corresponding approximately with the weight of gold found in the mercury. But the most important evidence he obtained was that gold was never found when he used electrodes completely free from that metal. He analysed electrolytic copper wire, nickel wire, steel screws and Swedish iron, and found them all to be auriferous; only thin tungsten wire contained no trace of gold. The silver obtained in transmutation experiments is believed to have a similar origin.

Prof. Haber does not propose to repeat Nagaoka's experiment with higher voltages, because he foresees little chance of success; voltages of the order of two million might lead to results, but at present one million volts is about the limit for laboratory work.

An interesting feature of the recent work on transmutation is the extraordinary delicacy of the tests now used for detecting gold. Prof. Haber relates that one of his young collaborators suddenly found traces of gold in a material he was analysing, but no one else could confirm the observation on other samples of the material. It turned out that the chemist was in the habit of removing his gold spectacles before he made an observation, and that on the occasion in question he had removed them and then grasped a strip of the purest lead to put into the crucible he was using in the analysis. On another occasion, some one in the laboratory was heating gold to a high temperature, and shortly afterwards a worker *in the next room* detected this metal in a substance which was known to have been previously quite free from it.

High-Frequency or 'Ironless' Induction Furnaces.

The emergence of the high-frequency induction furnace from the scientific worker's laboratory into the world of industrial production has aroused widespread interest. True, induction furnaces have long found successful application in the commercial world, but these have all been characterised by some form of iron core and have operated at relatively low frequencies. Although the possibilities of high-frequency inductive heating were demonstrated so far back as 1905 by Schneider, not much advance was made until 1919, when Northrup published an authoritative paper which renewed interest in the subject. How rapid has been the progress from that date may be judged from the fact that in 1925 high-frequency furnaces capable of handling 600-lb. charges of nickel alloys were in operation.

A high-frequency induction furnace, whether large or small, usually consists of a helix of copper tubing the turns of which are somewhat flattened and are separated from one another by a suitable electrical insulator. Electric currents (or oscillations) of the desired frequency are then passed through the furnace helix or inductor, which would speedily become hot were it not for a stream of cooling water passing through the interior of the copper tubing. Powerful eddy currents are induced in any conducting mass placed inside the helix, and a rapid rise of temperature of the material ensues provided conditions are suitable.

In practice, the charge (or metal to be heated) is contained in a crucible which is separated from the inductor coil by some refractory substance which acts both as a thermal and electrical insulator. The reader will in all probability have already surmised that the simple type of furnace (shown diagrammatically in Fig. 1) required for high-frequency inductive heating is not the most complicated part of the plant. Indeed the design of apparatus for the generation of oscillations of the desired frequency has made the greatest demands on the ingenuity of those responsible for the development of methods of high-frequency inductive heating.

ACCESSORY APPARATUS.

Northrup has produced a 'converter' or oscillation generator which consists essentially of two suitably insulated water-cooled electrodes projecting inside a closed vessel containing some mercury. Arrangements are provided for regulating the height of the electrodes in respect to the mercury level and for filling the upper part of the vessel with either hydrogen or alcohol vapour. Energy is delivered to the electrodes at, say, 50 cycles, and at a pressure of 6600 volts R.M.S. When this 'spark gap' is shunted with an oscillatory circuit comprising the furnace inductor coil and a bank of condensers, high-frequency currents are generated in the furnace circuit. The frequency of the oscillations is determined chiefly by the inductance of the furnace coil and leads and the capacity of the condenser system. This form of 'converter' or oscillation generator seems particularly suitable for units of about 35-40 K.V.A. input, and units of this capacity are finding extensive industrial application at the present time.

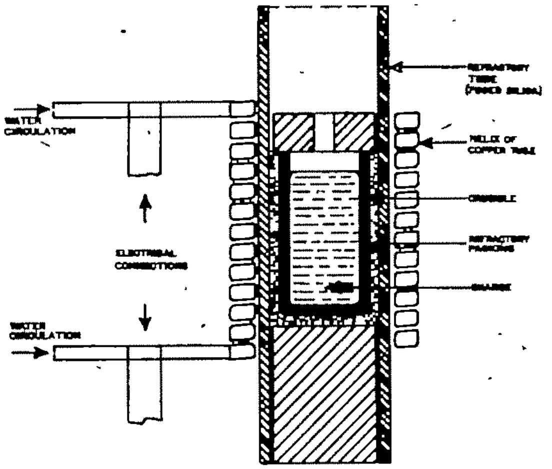

FIG. 1.—Diagrammatic representation of a high-frequency or 'ironless' induction furnace.

The fact that the larger so-called high-frequency furnaces could be operated successfully at moderate frequencies has permitted the use of special alternators for supplying energy direct to the furnace coil. Brace has recently described an alternator which delivered 400 amperes at 250-300 volts at 5000 cycles, and gave an excellent mechanical and electrical performance when used in conjunction with a 225-lb. ferrous furnace. Even lower frequencies have been employed, for Campbell mentions 400 cycles and capacities of 600 lb.

While the mercury gap converter and the alternator as sources of high-frequency currents have been developed in America, France has not been idle, for the Compagnie Électro-Thermique, following the practice of Prof. Ribaud, has produced single-phase equipments involving open spark gaps. These interrupters, fitted with rapidly revolving studded armatures, are reminiscent of the early high-power wireless transmitters, and are probably very robust (a consideration for foundry use).

Both the Northrup converter and the Ribaud rotary gap equipment can, if desired, be modified for use with three-phase supply, thus approximately trebling the capacity of the furnace. Thermionic valves or vacuum tubes can be utilised as oscillation generators for small furnaces, but it will be realised that large valves and the accompanying electrical gear are scarcely proper inhabitants of the foundry. Poulsen arcs and Lepel discharge gaps can also be used as sources of high-frequency energy, but do not appear to have been developed commercially in connexion with high-frequency induction heating.

Although the expression 'high-frequency' inductive heating has often been applied to all induction methods which dispense with the iron linkage circuit, yet the large so-called high-frequency furnaces now operate at frequencies of 400-500 cycles per sec., frequencies which are no longer high, at least from the 'radio' point of view. Perhaps Northrup's expression 'ironless' induction would, if generally adopted, avoid all risk of confusion.

Birch and Ryland, who have attacked the subject from the mathematical aspect, rather suggest a distinction should be made according to whether the electric currents induced in the melt are substantially confined to the skin or flow through the whole volume of the material.

APPLICATIONS IN LABORATORY AND WORKS.

High temperature research already owes a great deal to ironless inductive heating, for it is now possible to adopt refinements which are practically impossible with other types of furnaces. Except in special cases the heat is generated where required—namely, in the charge. Consequently induction furnaces are unique in that the charge is the hottest part of the whole furnace. This fact is all-important in considering the behaviour of refractories surrounding the melt. The inner lining of the crucible must, of course, be capable of resisting the action of the molten metal, but owing to the steep temperature gradient around the charge, a much less refractory material may be used to support the crucible if desired. Frequently the crucible and charge are contained in a tube of fused silica dimensioned so as to pass through the furnace coil (Fig. 1). The close proximity of the water-cooled furnace coil to the central portion of the fused silica tube prevents undue temperature rise, and by making suitable connexions at the ends of the tube, metal melting can be conducted at temperatures well over 2000° C. in a controlled atmosphere or *in vacuo*. As many metals react at high temperatures with air or ordinary furnace gases, the preparation of many high melting-point alloys of great purity has been made possible by the advent of the ironless induction furnace.

High temperatures can be attained so readily in small furnaces working at moderate powers that the chief difficulty of the research worker is to discover refractory material capable of withstanding the action of liquid or gaseous metals in these circumstances. Where exceedingly high temperatures are required, the crucible containing the material to be heated is placed inside a thin cylinder of graphite which is suitably lagged on the outside to prevent undue loss of heat.

Graphite becomes hot much more quickly than metals in the high-frequency or ironless induction furnace owing to its higher and more suitable electrical resistivity. There does not seem great difficulty in actually attaining temperatures in the neighbourhood of 3000° C., but certain inconveniences are apt to arise; vapours and sublimed material obstruct the sight hole, the graphite is apt to react with refractories and even the material in the crucible, and the quantity of gas evolved continuously from the furnace is enormous. Electrical non-conductors (such as glass) can sometimes be melted in ironless induction furnaces by surrounding the crucible with a graphite or metallic sleeve.

Perhaps the best-known application of ironless inductive heating in Great Britain is in the manufacture of the nickel-iron alloys (Mumetal), which possesses exceedingly high permeabilities at low magnetising forces. This alloy is used for 'loading' submarine telegraphic cables, which are thereby enabled to handle traffic at a much greater rate. No fewer than forty-two Ajax Northrup converter units (mercury gap) have been installed for one firm dealing with this alloy. The desirable magnetic properties of the nickel iron alloys diminish rapidly in the presence of impurities, especially carbon, consequently it is not difficult to understand why ironless inductive methods have found favour. Although the weight of melt per furnace (20 lb.) may appear small for some purposes, yet the exceedingly rapid rate of melting enables a considerable output to be maintained.

The cleanliness, ease of control and rapidity of melting have no doubt appealed to those concerned with precious metals, particularly metals with high melting points such as platinum. Further, the violent electrical stirring which is always present in the liquid metal so long as the furnace is in operation, assists in the preparation of the alloys, particularly when the alloying metals possess very different densities. Quite at the other end of the scale of dimensions are the 600 lb. brass, copper, or nickel silver melting furnaces, which may operate at frequencies so low as 400-500 cycles per second.

These ironless, medium-frequency induction furnaces, unlike the true iron-cored low-frequency furnaces, can be operated economically for short periods for alloys of varying compositions, and do not require rings of metal to be left in the furnaces at the conclusion of melting operations, so as to permit the starting up of the furnaces on a future occasion.

While ironless inductive heating finds its chief application in the melting operations, it has also been applied to the heat treatment and hot working of metals. A cold iron or steel bar inserted in a small furnace becomes red hot in a few seconds after the furnace has been put in operation, owing to the hysteresis losses in the magnetic material.

THEORETICAL CONSIDERATIONS.

Those concerned with the practical applications of ironless inductive heating, and with no taste for mathematics, will find articles by Campbell and Gifford of interest. Prof. Ribaud has also given an excellent review of the subject, and he is perhaps unique in bringing together the practical and theoretical aspects of the subject by means of his simple but valuable experiments and conclusions. The accurate measurement of high-frequency resistances, or inductances of furnace and charge, is difficult, and this no doubt partly accounts for the fact that accumulated experience still plays the chief part in the design of new furnaces and plant. There is some ground for believing that the mathematical theories of ironless induction furnaces which have been propounded in the past are a little out of touch with reality.

The two outstanding mathematical accounts of ironless inductive heating are by Northrup and later by the joint authors Birch and Davis, and it is noteworthy that the latter take an exception to a rather fundamental statement of Northrup, namely—"That the effective ohmic resistance of the charge is equal to its reactance."

Again, the reader is apt to be misled by the conclusion of Birch and Davis, who, as a result of their mathematical argument, state as follows: It will be of interest to consider the frequency which gives maximum heating in several cases. For a charge of copper 3 cm. radius

$$p > 1{\cdot}5 \times 10^2 \text{ per sec. (where } p \text{ is the pulsatance).}$$

This corresponds to a frequency of, say, 25 cycles per sec. (approx.). The present writer was able to test this conclusion by experiment. A current of 200 amperes at 50 cycles was passed through an ordinary 4-in. diameter furnace coil, inside of which was placed a cylinder of copper 2 in. in diameter. After five minutes had elapsed the temperature rise of the charge was imperceptible as judged by hand. The same furnace and charge were then attached to an Ajax Northrup converter working on low power, and in the short period of eight minutes the cylinder was found to be red hot. Under the latter conditions, the frequency was in the neighbourhood of 25,000 cycles per second, and the value of current flowing in the furnace coil was known to be much less than 200 amperes.

These experiments would appear to indicate that this statement of Birch and Davis as to frequency requires modification. Generally speaking, exact mathematical prediction as to the behaviour of high-frequency or ironless induction furnaces has not been very successful, possibly owing to lack of complete knowledge concerning them. On the other hand, those engaged in the commercial exploitation of these furnaces in Great Britain have acquired extensive experience as to their various applications, and potential users can anticipate with confidence the performance of a high-frequency or ironless induction plant under definite conditions.

News and Views.

IN modern chemical literature, specially that which deals with the binding of atoms together to form molecules, the nomenclature has become very complex and is altogether bewildering for the student who has not the time for a detailed study of the question. He is left wondering what the difference is between valency, co-valency and electro-valency, and wherein the distinction lies between bonds which are polar, non-polar and semi-polar. In a discourse entitled "Electrons, Atoms and Molecules," published as a special supplement in this number of NATURE, Prof. T. M. Lowry presents some aspects of modern theoretical chemistry. He has succeeded in a few pages in giving a clear account of a few at least of the large number of theories which are at present on the chemical market. In the early paragraphs the author emphasises the debt which the chemist owes to modern physics for the methods which lead to the measurement of molecular dimensions. Due credit is given to X-ray analysis for the recent development of the stereochemistry of solids, while further sections are devoted to the application of electronic theories to specific problems, such as affinity and valency. In assuming that the modern 'child of five' will not hesitate to build up the correct lattice of the diamond when playing with his tetrahedral toy, Prof. Lowry shows the optimism of the true man of science.

THE twelfth annual report of the Carnegie United Kingdom Trust, dated March 12, 1926, contains, in addition to its report, a survey of the activities of the Trust during the past five years. Prof. Adams's report on the Borough Library service led, it is stated, to the Trust's County Library policy which has met with general acceptance throughout England, Scotland and Wales. New opportunities are now being provided thereby in the rural and semi-urban districts for intellectual development and recreative reading at a nominal cost. The County Library system, however, is linked up with the policy of the Central Loan Collections established in London, Dunfermline and Dublin. The future financial positions of these institutions are now under the consideration of the Committee on Public Libraries set up by the Board of Education. The cost of administering these Collections is not shown in the report, but it is known that the income of the Central Library for Students in London depends in part upon grants made by the Carnegie United Kingdom Trust and upon private generosity—sources which cannot be regarded as permanent. The subscriptions received by the Central Library from the borrowing libraries amounted in 1925 to 580*l.* only—in return for the issue of some 25,000 volumes.

THE financial position of the Central Loan Collections is therefore far from satisfactory. We suggest that State assistance might be limited to the free postal carriage of books, coupled with conditional access to the contents of the State libraries. This relief would justify a correspondingly larger contribution from the borrowing libraries, which at present pay the cost of carriage each way. This arrangement would involve a minimum of State interference with, or responsibility for, the administration of the Loan Collections. The taking over by the State of the Central Library for Students would not conduce to a healthy development of the County Library service. The County unit is being applied with good augury of success to other branches of the Trust's policy. Community Councils are linking up the voluntary associations for the promotion of adult education, music and the drama and social services, with the statutory authorities in the counties. Two new departures in the Trust's future activities are adumbrated: (1) a much-needed inquiry into the work of the local museums, and (2) an experimental erection at Sawston in Cambridgeshire of a building to be known as the "Village College," for which the County Authority is to provide the cost of the school while the Trust contributes the rooms for adult education. The experiment is a bold one, and the results obtained thereunder will be followed with interest.

THE problem of finding a permanent protective coating for iron is one of the most important in the whole field of applied science, but one which unceasing effort has so far been unable to solve. In a preliminary communication to the *Zeitschrift für angewandte Chemie* (May 6), Dr. A. V. Blom, of Berne, Switzerland, announces that he has discovered a lead pigment which when applied to iron produces a surface that will not rust. The pigment is made by melting lead in an electric furnace and starting the reaction by passing air and reducing gases through a thin layer of the molten metal. The resulting dross or scale is essentially a pyrosol of lead in yellow lead oxide, and, according to the operating conditions, it is either dense or voluminous; but it must have a particular structure if, after pulverising and mixing with specially prepared linseed oil, it is to be effective as a protective coating for iron.

DR. BLOM has not yet worked out a complete theory of the action of his pigment, but his present view is that the highly dispersed basic lead pigment saponifies the linseed oil, that the fatty acids liberated in this way, and also on drying, react with the lead oxide to produce very finely-divided particles of lead, which, in virtue of their special form and Brownian motion, penetrate the surface of the iron and thus cause a kind of cementation. In experimental tests with sheet iron that had been painted or sprayed with the new pigment, lead was found in the surface of the iron in every case; in one experiment the amount was 1·36 mgm. per 100 sq. cm. of surface four weeks after application. Tests on different kinds of iron ware, extending over several months, gave uniformly good results, and short, drastic tests with steam were most successful. The pigment is extraordinarily adhesive, and although its efficiency is mainly due to the lead particles which diffuse into the iron, the coating itself plays a part in the protection. To realise the potential importance of Dr. Blom's discovery, it may be recalled that in 1922 Sir Robert Hadfield estimated that the world loss due to corrosion in 1920 was 29 million tons of iron, valued at 700 millions sterling.

THE demand for electrical energy has led to the construction of large generating stations and to the laying out of great networks of distributing lines. It is highly probable that these networks will be greatly increased in the immediate future This will necessitate the adoption of very high pressures in order to keep the losses within economic limits. It will also make it necessary to have circuit breakers capable of dealing with enormous currents. The switch houses necessary to control the system will be much larger than the generating stations. This will make the direct control of the system very difficult. It is customary to control the switches from a separate room, in which a switchboard and the necessary instruments are provided. So far as the normal operation of the system is concerned this greatly simplifies the routine work of the attendants; but when anything abnormal has to be done, as, for example, when a generating set has to be switched from one section of the mains to another, there is a serious risk of damage being done to the machines or the network. To obviate this difficulty the Oerlikon Co. of Switzerland describes in its bulletin for January a device which makes errors in operation almost impossible. They provide a miniature "busbar" system where signalling devices indicate automatically which of the different switches and circuit-breakers are closed or open Changes in connexions are first made and considered on the miniature board. When they are seen to be correct, the gear itself is operated in the switch house. The necessary switches are indicated by lighted lamps, so that there is practically no risk of a switching error. This system has been installed in the great Gennevilliers power station near Paris, which operates part of its network at 60,000 volts.

MR. J. E. SEARS, Jun., delivered the Friday evening discourse at the Royal Institution on May 21, taking as his subject "Some Recent Developments in the Art of Fine Measurement," and dealing particularly with the measurement of length. Modern end standards offer superior accuracy of definition to the actual reference standards at present current. Machines are available which are capable of measuring such standards to an accuracy of 0·000001 in. Gauges of this very accurate finish will 'wring' together. This action is due to the presence of minute traces of grease or moisture on their surfaces. The thickness of the wringing film is of the order of 0·0000005 in., the known minimum thickness of a free liquid film. The wave-length of light affords the possibility of a 'natural' standard of extremely high precision, whereas previously natural standards have proved unreliable. Interference methods are used. The direct determination is limited to a distance of about 4 in., but by the use of multiple reflections in white light greater lengths in simple integral numerical relations can be determined. Reference was also made to improved methods of measuring internal diameters, and a description given of a machine designed by the author for this purpose. The nature of the fit of plug and ring gauges under different conditions was shown; when well greased a plug will pass through a ring definitely smaller than itself, the ring expanding elastically by an amount which can be shown experimentally by measurement of its outside diameter. The method of optical projection is very useful for the accurate measurement of profiles.

AT the annual meeting of Messrs. Brunner. Mond and Co, Ltd., held on May 13, Sir Alfred Mond, who has succeeded Mr. Roscoe Brunner as chairman of the Company, announced an important development in the activities of the subsidiary undertaking, Synthetic Nitrates, Ltd., which is the only producer of synthetic ammonia in Great Britain. The plant of this Company is being greatly extended, and before the end of the year 1927 it is anticipated that the present output will be trebled. Among the projected new manufactures are ammonium nitrate, sodium nitrate, nitric acid, anhydrous ammonia, ammonium carbonate and bicarbonate. During the past year Synthetic Nitrates made a profit of 103,647*l.* after allowing for substantial depreciation, and much larger profits are expected in the future. In Sir Alfred Mond's opinion, recent developments in chemical engineering have opened up possibilities of progress the limits of which cannot be foreseen.

THE Prime Minister of the Commonwealth of Australia has announced the personnel of an executive committee the formation of which was recently recommended by Sir Frank Heath as the first step in the reorganisation of the Institute of Science and Industry. The chairman is Mr. G. A. Julius, a prominent engineer of Sydney and president of the Engineering Standards Association. The other two members are Mr. W. J. Newbigin, who is intimately associated with the commercial life of Australia, and Prof. A. C. D. Rivett, who recently succeeded Sir David Orme Masson in the chair of chemistry in the University of Melbourne. It is understood that the new body will possess extensive powers and, together with an advisory council and State advisory committees, will be charged with the organisation and development of national effort in scientific and industrial research.

THE Adelaide Correspondent of the *Times* in the issue of May 20 announces the departure for Oodnadatta of an expedition, financed by Mr. Donald Mackay of Sydney, to explore unknown country in the Northern Territory. The object of the expedition is to carry on research in geography, geology and anthropology. It is also intended to search for precious metals, of which the country west of Charlotte Waters, north of the boundary of Southern Australia and the Northern Territory, is said to contain an enormous wealth. The leader of the expedition is Mr. Herbert Basedow, Protector of the Aborigines, and the author of a recently published book on the Australian aboriginal—a subject on which he is an acknowledged authority. Kinematograph and phonograph apparatus are to be carried, with the view of recording the ceremonies and songs of the almost unknown natives of these parts.

THE third edition of the Kew Hand List of Coniferæ, which includes in this case the Gnetaceæ as well as the Cycadaceæ, has recently been issued by the Royal Botanic Gardens (price 1*s* 6*d*). From the preface to this edition by the Director, Dr. A W. Hill, it appears that a list of the Cycads in cultivation at Kew has not been published before, though it is believed that one or two of the fine specimens growing in the Palm House were brought from South Africa in the days of Sir Joseph Banks. The transference of the Gymnosperms from Museum I to Museum III at Kew has also necessitated the addition of a section to the hand list which deals with the economic properties of the Gymnosperms and serves as a guide to this museum collection The heavy greasy deposit from the London smoke is very deleterious to the conifers, as to all evergreens. Recently the Forestry Commissioners have recognised this fact and a special collection under conditions more favourable to the growth of these trees is being built up at Bedgebury, near Tunbridge Wells, under the control of Kew in co-operation with the Forestry Commission. The Director repeats the statement that the deposits from the smoke block the stomata of the leaves and thus impair their vitality. If, however, recent American work is correct (J. B. Rhine, *Botanical Gazette*, vol. 78, pp. 226-232, 1924) the stomata of the leaves of such plants when grown in places quite free from atmospheric contamination are still found to be blocked by a waxy substance which is readily soluble in alcohol, so that this black deposit is a natural product of the leaf and has no connexion with smoke injury.

THE Field Museum, Chicago, is to be complimented on its decision to publish the results of its curatorial experience in a series of small publications under the heading "Museum Technique." It is fitting that the author of the first number, entitled "Herbarium Organisation," should be Dr. Millspaugh, to whose efforts and organising ability is due the high position of the fine herbarium The various blanks, cards, tickets, index slips, loan forms, and catalogue pages reproduced in the pamphlet may provide useful suggestions to any commencing a large herbarium Such forms look formidable, but when carefully drawn up, as here, save time in the end. The best cases are said to be those of steel, since they are the most dust-proof, do not warp, are more fire-proof, and take up less space. Each pigeon-hole is converted into a drawer by placing beneath its contents a straw-board slide, to the front of which is hinged a one-inch drop that serves as both drawer-pull and label-holder.

WE have recently received a copy of Heft 3 and 4 of a new genetical journal published in Zürich, the *Archiv der Julius Klaus-Stiftung*. It is to appear in four parts per year at a subscription price of 40 Swiss francs The journal is devoted to contributions on heredity, social anthropology and race hygiene, and the publishers are Art Institute Orell Füssli, Zurich The present number contains a short paper on the inheritance of myopia and hemeralopia in man by Dr Gassler, and an extended account of genetical and cytological studies on certain Primula hybrids, by Drs Ernst and Moser Both *P. Auricula* and *P. hirsuta* and their hybrids are found to have 72 chromosomes (octoploid). These interesting hybrids have long been known as *P pubescens* Jacq, and are the origin of garden Auriculas The hybrids produce nearly as much pollen as the parent species, and some of the F_1 types resemble either parent. A coloured plate shows very well the nuances of colour in the flowers and leaves of various types. This journal will form a valuable addition to the numerous genetical publications already in existence.

THE seventh annual meeting of the American Geophysical Union was held in Washington, D C., on April 29 and 30. The six sections met separately before the general meeting of the Union. At the latter there was a symposium on the constitution of the earth, introduced by brief summaries of various aspects of the subject The sections relate to geodesy, seismology, meteorology, terrestrial magnetism, and electricity, oceanography, and volcanology. The section on meteorology held a discussion on questions involving international co-operation, including the co-operative measurement of the sun's general and ultra-violet radiation (and the estimation of the ozone content of the atmosphere), and on the best method of establishing a chain of meteorological stations along the border of the polar basin

SIR J. C BOSE delivered a lecture on May 20 before the Fondation Universitaire, Brussels, on his recent work on sensitivity in plants. His Majesty the King of Belgium and his Ministers were present at the lecture. In recognition of his work in advancing science, the decoration of commandeur, Ordre de Léopold, has been conferred on Sir J C. Bose.

DR. ALDO CASTELLANI has just returned from America, where, at the invitation of the authorities of the Tulane University, New Orleans, he has established and organised a tropical medicine division in the Medical School. During his visit he had the honour of being invited to deliver the Gehrman Memorial Lecture series at the University of Illinois, and later at the annual convention of the American Medical Association and its Medical Exhibition on scientific subjects he was awarded the gold medal, the highest recognition which can be given by the Association. The award "was based on the excellent investigation in comparatively unexplored fields of Medicine and for the perfection of the display" of specimens

THE one hundred and seventh annual meeting of the Swiss Society of Natural Sciences will be held at Fribourg on August 29-September 1 This will be the fifth occasion on which the Society has visited the little town with its comparatively young and vigorous university. Seventeen sections are being organised, covering most branches of pure and applied science; and excursions in the neighbourhood of Fribourg are a feature of the programme Lectures will be delivered by Prof. J. Reinke, of Kiel, on natural forces; by Prof. J. B. Senderens, of Toulouse, on catalysis in chemistry and biology; and by Prof. P. Debye, of Zurich, on molecular forces. All communications should be addressed to the president of the Society, Prof. Dr. S. Bays, Le Châtelet, Fribourg.

REFERRING to his article "Tests of Relativity Theory," NATURE, April 10, Prof. A. S. Eve now writes that a mistake occurs on p. 521, col. 2, line 29. In the sentence "The compromise of Silberstein that in *rotation* there is full drag, and that in *translation* there is a partial drag, will suit the experimental evidence in hand, but no one seriously supposes that such will be the ultimate result of further experiments," the words now italicised should be exchanged. On p. 383 in Silberstein's "Theory of Relativity" it is clearly pointed out that in the theory of the famous Chicago experiment "If there is a full drag, there should be no fringe shift at all," and this is otherwise obvious. Dr. Silberstein pointed out the error to Prof. Eve, and added the following interesting comment: "Nor is there actually a 'compromise'; absence of *spinning* (rotational) drag is well compatible with the presence of a partial (and even almost complete) *translational* drag."

MR. F. EDWARDS, 83a High Street, Marylebone, W.1, has issued a catalogue (No. 481) of upwards of 300 second-hand works on botany, general natural history and zoology, some rare. A number of herbals are included. The catalogue can be obtained free upon application.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A junior lecturer in botany at the Royal Technical College, Glasgow—The Director (June 7). A junior engineer at the Forest Products Research Laboratory of the Department of Scientific and Industrial Research, South Farnborough—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (June 12). An assistant lecturer in zoology at the University College of North Wales, Bangor—The Secretary and Registrar (June 14). One or two assistant superintendents in the Geological Survey of India—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (June 26). A works chemist at a large firm of woollen manufacturers in the West Riding of Yorkshire—The Secretary, British Research Association, Torridon, Headingley, Leeds.

Our Astronomical Column.

THE NOVA IN MESSIER 61.—Several additional observations have come to hand of this nova, the detection of which by Prof. M. Wolf and Dr. K. Reinmuth was announced in the issue of NATURE of May 15.

The discoverers note (*Beobach. Zirk.*, Nr. 20) that a plate taken on April 15 shows no trace of the nova, while on May 9 it was between mag. 13 and mag. 14, being slightly fainter than the 13th mag. star south preceding the nucleus at a distance of 2′·6. Lorenz gives the position of the nucleus of the nebula as R.A. $12^{h}\ 16^{m}\ 48^{s}{\cdot}58$, N. Decl. 5° 1′ 43″·5, equinox 1900·0.

The nova was observed at Greenwich both visually and photographically on May 15 and 16 by Messrs. Melotte, Merton, and Steavenson The *Times* of May 21 also reports that it was observed at Harvard University Observatory. On the very doubtful assumption that the distance of the nebula is 10 million light years it is deduced that the nova is 10 million times brighter than the sun, which would make it the brightest nova on record except that in the Andromede nebula in 1885. But these estimates should not be quoted in the public press without a warning of their extreme uncertainty.

FIREBALL ON MAY 2.—Mr. W. F. Denning writes that "A magnificent fireball was observed on May 2 at $23^{h}\ 30^{m}$ G.M.T. from various places in the N.W. of Ireland. Reports have come from Co. Tyrone, Donegal, Londonderry, and other parts, but unfortunately they are not of the required character and give few details of utility for computing the real path of the object. The light it exhibited was astonishing, and some people describe it as of dazzling intensity. An observer at Ballybofey says his attention was attracted by a flash; then a more prolonged light illuminated the whole countryside, and on looking up he saw a large ball of fire which broke up into three or four pieces as it fell to near the N.W. horizon. Another spectator at Dunnamore describes the illumination as quite dimming the 12-volt lamps of the motor in which he was riding. He observed the meteor explode into four fragments. The observations of position are fairly consistent, and prove that the fireball was probably directed from a radiant near β Libræ and that it pursued a path of about 92 miles at a velocity of about 15 miles per second. The height was from 64 to 47 miles, but it seems highly probable that the path was longer than this and that the height at disappearance was less than that given. Possibly the meteor may have descended to within about 30 miles at the termination of its luminous flight, but data of greater accuracy and consistency are needed

COMETS.—*Astr. Nachr.* No. 5440 contains two reproductions of photographs of Ensor's Comet obtained at Bergedorf Observatory. That on March 16, by A. Schwassmann and J. Stobbe, has been already described in this column The other was taken by the Director, R. Schorr, with the reflecting telescope on April 3, the exposure time being 30 minutes. The comet appears as a straight streak 35′ long in Position Angle 310°. There is no nucleus; the head has a diameter of 2′; the tail gradually widens, being 6′ broad at its extremity. The position angle increased by 60° between March 16 and April 3. Another exposure (not reproduced) was made on April 13, lasting 1 hour. The comet appeared as a very faint glimmer, magnitude 17, the tail being 30′ long and 5′ broad, position angle 0°.

Orkisz's Comet was photographed at Bergedorf on May 2, its magnitude being 16. It was under observation for an interval of 13 months, which will enable the orbit to be deduced with great precision.

Research Items.

CALIFORNIAN ANTHROPOMETRY.—A valuable contribution to the physical anthropology of the American-Indian people is made in a comprehensive study of the available measurements on the living and on crania which is published by Mr. Edward Winslow Gifford as Part 2 of vol 22 of the *University of California Publication in American Archæology and Ethnology*. The aborigines of California fall into two main groups, one low-faced, the other high-faced. The low-faced group constitutes the Yuki type, with high nasal index, relatively low cephalic index, and short stature The high-faced group is variable in nasal and cephalic index and medium to tall in stature. This group is divided into a broad-headed sub-group of wide distribution—the Californian type, divisible into narrow-nosed, broad-nosed, and tall; and secondly, a narrow-headed, narrow-nosed sub-group, the Western Mono type. The cranial material is not so representative in distribution as the measurements from the living; but it affords seven types, of which three may be local specialisations of a fundamental type with medium facial, medium to high cephalic, and medium nasal indices. This fundamental type appears to have as its nearest living representative the Californian type. Unfortunately a comparison between living and cranial measurements is impossible, as the two classes of material do not coincide in distribution In the case of the Yuki, where there is adequate material, there is practically no difference between living and dead. Nowhere is there any indication of stratification of types. In the matter of extra-Californian relations, Boas reports a type from the coast of British Columbia with cephalic index 77-81, which resembles the Yuki, while the Californian type suggests Boas's brachycephalic type, the Tinneh. His Kwakiutl and Shuswap suggest the narrow-nosed sub-type of the Californian. The Athabascans of California do not correspond to this type, such of them as the Wailaki and the Kato being of the Yuki type

MANIFESTATIONS OF LIFE—The editor of *Scientia*, Prof. E. Rignano, has written in the February issue and the four preceding issues of his journal a series of articles on "Les Manifestations finalistes de la Vie," in which he challenges the mechanistic position. He discusses among other subjects development and regeneration, adaptation, the behaviour of the lower organisms, reflexes and instincts At the end of the article on the lower organisms he summarises the facts and considerations on their movements, and points out that no physico-chemical process in the inorganic world in the least resembles the avoiding reactions of these organisms, and that no non-living substance exhibits a behaviour influenced by past experiences. In the presence of these facts he writes: Should we not ask if we are not shutting our eyes to the most patent reality if we continue to say that the properties of matter suffice to explain the phenomena of life?

HERRINGS ON THE WELSH COAST.—Volume 1 of a new series of reports on work done in the Zoological Department, University College of Wales, Aberystwyth, issued in December last, has recently been received. The editor, Prof. R. Douglas Laurie, in an introduction gives a list of the researches at present in progress, and expresses a hope that reports will be issued annually The current volume is largely devoted to an account by Mr. E Emrys Watkin of some preliminary investigations upon the herring shoals visiting local waters in 1921 and 1922. During the autumn of 1922, thirteen samples comprising a total of 1989 fishes taken from commercial catches at Borth, Aberystwyth, and Newquay were examined, and data collected on length, sex, degree of maturity, number of rings to scale, and growth observations on the scale. Mr. Watkin concludes that fishes with 3 and 4 rings to the scale formed 68 per cent. of the fishery. A number of distinct schools of herrings visited the fishing-grounds, of which some came to spawn, but others to feed It is to be noted that measurements of growth increments of the actual scale were directly compared, whereas it is usual first to calculate the length of *fish* which by theory corresponds to each of the winter rings on the scale, and then compare these lengths. It is to be hoped that in his future reports Mr. Watkin will adopt the customary practice.

A NEW NEMATODE FROM THE RAT.—Eloise B Cram describes (*Proc U.S Nat Mus*, vol. 68, Art 15, 1926) a new nematode, *Protospirura columbiana*, present in large numbers in the stomach and small intestine of wild rats (*Rattus norvegicus*) captured in the National Zoological Park, Washington. Details are given of the characters of both sexes (the males are 23-43 mm. long and the females 45-100 mm), and a table is given of the known species of Protospirura. Embryonated eggs from the uteri of the female worms were fed, with bread, to cockroaches in which the larvæ were afterwards found encysted, chiefly in the loose tissue in the abdomen and in the thorax. Though encysted larvæ are to be found in the cockroach about one month after feeding the latter with the eggs of the worm, the larvæ do not appear to be infective until about the fortieth day. Such larvæ when fed to rats developed into adult examples; after 53 days they were mature but not fully grown, but after 115 days they had attained the size of the majority of examples found in the naturally infected rats The finding of this nematode in wild rats in the Zoological Park, but not in those from other parts of the city, suggests the possibility that the normal host may be a rodent other than the rat living in the Park. "That rats and cockroaches, pests commonly present around such places, may play a part in the dissemination of parasites formerly absent in a country but brought in by the animals in the Zoological Park is a possibility the recognition of which may have a practical significance"

THE CHLOROSIS OF FRUIT TREES—Messrs. T. Wallace and C. E. T. Mann present some very interesting if puzzling data as the result of the chemical investigation of the foliage of chlorotic apple trees in the *Journal of Pomology and Horticultural Science* (Vol. 5, No 2, March 1926) They have been studying examples of chlorotic foliage, occurring in soil rich in calcium carbonate, in which there is every reason to associate chlorosis with the calcium carbonate; in some cases comparison was possible with normal foliage, in other cases with green foliage obtained as the result of spraying the trees with sulphate of iron. In either case the same general types of difference between green and chlorotic foliage were noticed and may be summarised as follows: (1) The percentage of dry matter is higher in the green leaves; (2) ash content is usually higher in the chlorotic leaves, (3) the percentage of calcium is markedly lower in the ash of the chlorotic leaves, (4) the percentages of sodium and especially of potassium are always much higher in the ash of the chlorotic leaves These conclusions are amply justified by the experimental data quoted and appear very intriguing. Why, for example, should spraying with sulphate of iron produce this marked reversal in the relative proportions of calcium and potassium in the ash of the foliage leaves?

THE 'FLOWERING' OF LAKES.—The phenomenon termed by the ancients *flos-aquæ* and described by Pliny, who observed it on Lake Bolsena, is not of frequent occurrence on the large sub-alpine lakes, but it appeared during last August on Lake Como. The results of its investigation have now been presented to the Reale Istituto Lombardo di Scienze e Lettere. The 'flowering' was manifested over almost the whole surface of the lake simultaneously and persisted for several days, during which perfect calm prevailed, gradually disappearing when the wind rose. By means of a small net several decilitres of a pea-green gelatinous mass was obtainable in a few minutes, and this proved to be *Microcystis æruginosa* (Henfrey) Lemm The asphyxiation of fish sometimes occurring when this 'flowering' takes place on small lakes, is usually the cause, and not an effect, of the phenomenon. In sheltered pools subject to frequent and abundant flowering, the algal mass may, however, favour the growth of bacteria and thus lead to such consumption of oxygen and production of non-respirable gases as to render fish life untenable.

VEGETIN.—In the *Rendiconti* of the Reale Istituto Lombardo di Scienze e Lettere, Prof. Montemartini gives the results of experiments made with a fungicide known as vegetin, which is an impalpable, black powder and has carbon as its fundamental ingredient. The experiments were made with leaves of potato, tomato, mulberry, Broussonetia, fig, Ricinus, horse chestnut, and *Tropæolum majus*. Although the efficacy of this preparation as a fungicide is left in doubt, in most instances leaves over which it was dusted performed their metabolic functions appreciably more actively than similar leaves not so treated. A further series of experiments is projected with the view of ascertaining the mechanism of this effect.

THE MINERALS OF BENTONITE.—The first fruits of an important investigation of the mineral composition of clays are presented by C. S Ross and E V. Shannon in a paper dealing with bentonites and related clays, and published in the *Journ. Amer. Ceramic Soc.* for February 1926. Bentonite is a widely distributed clay-rock that has resulted from the devitrification and alteration of glassy volcanic ash. Its characteristic minerals are completely crystalline and have a micaceous habit, high birefringence, and easy cleavage The high absorptive power of bentonite is not due, as has been thought, to the presence of gel colloids, for few of the crystal films are so small as to reach colloidal size The peculiar properties are held to be a consequence of the easy cleavage of the minerals, giving a very great surface area, and of the felt-like texture which facilitates permeability. A large number of analyses of the clay-minerals from bentonite indicates that, like the type montmorillonite from France, the composition of the most abundant mineral is $(Mg, Ca)O\,.\,Al_2O_3\,.\,5SiO_2\,.\,nH_2O$. This mineral has also been recognised in fuller's earth. Beidellite also occurs in bentonites, and has the formula $Al_2O_3\,.\,3SiO_2\,.\,nH_2O$. A third micaceous mineral has the composition of halloysite, $Al_2O_3\,.\,2SiO_2\,.\,nH_2O$, but is visibly crystalline and has a high birefringence.

TROPICAL CYCLONES OF THE PACIFIC.—A description of the storms is given by Dr. S. S Visher and is published as *Bulletin 20 of the Bernice P. Bishop Museum*, Honolulu, 1925 The general characteristic of the cyclones is described, with their distribution and frequency The information has been collated from various sources, and in this way the publication is more complete and of greater value Most of the storms appear to start between 10° and 20° north and south. On an average more than fifty tropical cyclones are said to develop each year in the Pacific Lists are given of the number of storms experienced in each year, and their occurrence is also listed for the several months. A majority of the tropical cyclones of the Pacific move westward and poleward until they arrive in about lat. 20°-30°, and then they recurve and move eastward. Frequently cyclones move more abnormally. Cyclones differ considerably in their speed of travel, the movement of the storm ranging from 1 mile to more than 50 miles an hour: at their initiation they generally move slowly. Tropical cyclones are classified in three types with respect to duration, the short-lived storm lasting a day or two, the common storm lasting three to six days, and the long-lived storm lasting more than a week, some of the long-lived storms are followed for more than three weeks. The storms are classified for intensity. With reference to predicting storms it is stated that the advantage of prediction would be so great that many attempts have been made at forecasting, but it seems likely that it will always be impossible to do more than state the probability of a hurricane occurring somewhere in a rather large region. Much useful information is given on numerous points of interest with regard to cyclones in the Pacific.

EXTINCT AMERICAN CARNIVORES —A number of the *Bulletin of the American Museum of Natural History* has appeared giving a very full account by Childs Frick of certain Tertiary carnivores (vol. 66, art. 1, 1926: "The Hemicyoninæ and an American Tertiary Bear"). The author collects together certain genera, namely, Hemicyon, Dinocyon, Hyænarctos, and Ursavus, into what he terms a 'morphological group,' the Hemicyoninæ A 'morphological group' is explained as a collective term for an assemblage of animals which are united by certain characters but more or less widely separated by others, and is used to avoid the terms 'family or sub-family' with their implication of close relationship. The paper describes in considerable detail the members which form this group, and, as an addendum, a new genus, Plionarctos, of true bears.

A RICH LINE SPECTRUM —In the March issue of the *Journal of the Franklin Institute*, Dr. Marion Eppley describes a simple means of obtaining a series of closely spaced lines of nearly equal intensities between wave-lengths 6678 and 3990 Å.U. for reference and other purposes. The end of a carbon rod of about 0·6 cm. diameter is heated to redness in a bunsen flame and dipped into a dry powder of vanadic acid, molybdic acid, and anhydrous titanic oxide in the proportions 8 : 5 : 2 by weight. The end of the rod is again heated to fuse the adhering powder and the process repeated until a thick crust of the mixture has been formed on the end of the rod Two rods with their ends about 1 cm. apart are used as the electrodes of an ordinary spark arrangement. To identify the lines of this spectrum the spark spectrum of an alloy of cadmium, zinc, lead, and tin in the proportions 35 : 35 : 73 : 30 is photographed upon it. This alloy has several advantages over that used by Hartley.

SOLUBILITY OF CALCIUM SULPHATE.—The solubility of those phases of calcium sulphate existent at the temperature of boiler water has been determined by R. E. Hall, J. A. Robb, and C. E. Colman, and the results published in the *Journal of the American Chemical Society* for April 1926. The solutions were prepared in an iron autoclave with an internal filter consisting of layers of woven cloth supported on a perforated steel frame. Their results and those of previous workers are in good agreement at higher temperatures, but the difficulty in controlling the lower temperatures renders measurements under the latter conditions less trustworthy.

The Atomic Weight of Meteoric Chlorine.—The constancy of the atomic weight of chlorine of marine origin has suggested an investigation of the constancy of the atomic weight of the element from minerals of non-marine origin and of that from meteorites. The determinations were carried out by W. D. Harkins and S. B. Stone, who found the ratio of silver to silver chloride by dissolving pure silver in nitric acid in a long-necked quartz flask and treating it with the different specimens of hydrochloric acid. The constancy of the isotopic composition is shown by the values for meteoric and terrestrial chlorine, given in the *Journal of the American Chemical Society* for April 1926, which are identical within the limits of the very small experimental error.

Benzole Research.—We have received a copy of the Report of the Joint Benzole Research Committee for 1926, giving a detailed account of the work carried out by the Association's chief research chemist, Mr. W. H. Hoffert. The report discusses the relative values of the absorption powers of active carbon, silica gel and ferric oxide gel, in the recovery of benzole, and examines the possibilities of cresol and tetralin as wash oils in place of creosote and gas oil. Most important is the investigation of the tendency of poorly refined benzoles to form resins on storage or when used in internal-combustion engines, with several photographs illustrating the effects of different samples on the production of carbon in a motor-car engine after 100 hours running on a test bench. The results of the tests indicate that the deposits are due to the presence of unsaturated constituents. The report is completed by the addition of a classified bibliography.

Heats of Fusion of Low Melting-Point Organic Solvents.—The heat of fusion of a solvent can be calculated from the freezing-points of two solutions at two different concentrations. The apparatus, described in the February issue of the *Bulletin of the Chemical Society of Japan*, consists of a small vessel immersed in an ether or pentane bath cooled in liquid air, the temperature being controlled by an electric heater. The heats of fusion were calculated from the values of two points falling on the straight line obtained by plotting against the logarithms of the molar fractions.

Accurate Heats of Vaporisation of Liquids.—A paper by J. H. Mathews appearing in the *Journal of the American Chemical Society* for March 1926 describes the accurate determination of the latent heats of evaporation of fifty-nine liquids. The liquid, contained in a glass vessel surrounded by vapour and suspended from the arm of a balance, is heated electrically by a platinum spiral immersed in it. The method gives values which are more trustworthy than those obtained from vapour pressure measurements, since small errors in the determination of the vapour pressures lead to relatively large errors in the value of the latent heat.

Inflammability of Firedamp in the Presence of Blackdamp.—The limits of inflammability of firedamp in atmospheres which contain blackdamp is the subject of a report by H. F. Coward and F. J. Hartwell of the Safety in Mines Research Board (Mines Department. Safety in Mines Research Board. Paper No. 19: The Limits of Inflammability of Firedamp in Atmospheres which contain Blackdamp. H.M.S.O. Price 6*d*. net). It was found impossible to explode air-firedamp mixtures containing more than 25 per cent. of carbon dioxide or more than 38·5 per cent. of nitrogen. The minimum amount of blackdamp necessary to prevent explosion in air-firedamp mixtures lies between these limits and depends on the ratio of carbon dioxide to nitrogen in the blackdamp.

Changes in the Gastric Secretion of Birds.—In his investigations on the stomach of the pigeon, Claude Bernard found that, while the young are being reared, the glands of the first of the three stomachs of the parent birds furnish a lacteal secretion which, while it softens the grains they eat, also modifies this grain so as to render it suitable for the young birds. After a time, however, the stomachs of the parents resume their normal condition and begin again to secrete ordinary gastric juice, which contains from 2·5 to 5 per cent. of gastric acid. Since this acid would be highly injurious to the young, the latter are driven from the nest by their parents and, if incapable of fending for themselves, soon perish of starvation. That this instinctive knowledge of the poisonous character of the normal gastric juice is not shared by all birds is shown by observations by P. J. Kaas, described in the *Atti della Pontificia Accademia delle Scienze* (*Nuovi Lincei*). A nest of five goldfinches, transferred to a cage, were fed morning and evening, through the wires, by the parent birds, until one day, two hours after their morning meal, they were all found dead. Evidently, if the young birds are unable to fly and feed themselves before the time when the gastric juices of the parents revert to their normal composition, they perish, not by inanition, as is the case with pigeons, but by poisoning. It is a singular phenomenon, which has been repeatedly confirmed, that this reversion occurs simultaneously with both parents. The elimination by these means of the individual birds incapable of supporting themselves is regarded as one of the processes by which the preservation of specific characters is effected.

Manufacture of Smokeless Fuel.—In a paper recently read before the South Wales Institute of Engineers at Cardiff, Mr. David Brownlie discussed the production of free-burning smokeless fuel by low-temperature carbonisation by processes involving the compression or briquetting of the charge. Such processes may involve mechanical compression of the viscous charge during carbonisation, preliminary briquetting by means of pitch or other binder, or preliminary briquetting without the use of an externally produced binder. Processes of the last class usually necessitate the use of very high pressures, but a new process (*Delkescamp*) of German origin was described in which a portion of the coal ground to a colloidal condition with water is admixed with the use of quite moderate pressures, and the mixture can be briquetted and then carbonised at low or high temperatures. Mr. Brownlie put forward a strong plea for the further study of low-temperature carbonisation. That it is difficult to establish on an industrial scale is clear from Mr. Brownlie's statement that the relevant processes and patents are numbered by hundreds, yet none of these is known to have established itself permanently.

Vocational Guidance.[1]

THE report under notice is the account of a research in vocational guidance undertaken jointly by the Industrial Fatigue Research Board and the National Institute of Industrial Psychology. Up to the present, most of the work on vocational psychology has been concerned with vocational selection, which is an attempt to choose by scientific means those from a group of applicants who are most likely to be suitable for some specific occupation. In vocational selection, no attempt is made to determine the best careers for those who are unsuccessful in the particular tests given. Vocational guidance, on the other hand, seeks to determine the special qualifications of a child with the view of guiding him into the career best fitted for his abilities. It has a wider outlook than vocational selection, and is of greater social importance; it is, however, a far more difficult study on account of the multitudinous occupations which children can enter and their varying psychological requirements.

Only a hundred children were examined during the inquiry, the main object being to test the possibility of the method rather than the reliability of the results. The first step taken was to select a representative London borough, and then to find out the occupations taken up by 1000 children who had recently left the schools where it was proposed to give the tests. This gave an indication of the labour demand in the district and the relative proportions of the various occupations offering employment. One hundred children—half girls and half boys—who were leaving school within a year were then examined. Their intelligence was tested by oral tests, by non-verbal tests, and by performance tests. These various means of testing intelligence served to discover the special medium through which native intelligence expressed itself, and avoided the error of assuming that intelligence can only be expressed by means of words. Scholastic tests and tests of special abilities were also given, and an attempt was made to estimate the character, qualities, and the home conditions of the children examined.

When all possible information in regard to the children had been gathered, a consultation took place between the psychologists concerned in the research, the teachers, and the members of the care committee. Each child was personally discussed, and no hard and fast rules were laid down as to what particular test scores were required in order to recommend an occupation to a child. Each child was considered specially, and all the factors bearing on his case taken into consideration. Thus it might happen that although a particular child had sufficient intelligence for a certain occupation, yet he was lacking in the special abilities or the character qualities it demanded; when this was the case he would be advised to take up an occupation where the lack of such qualities would be no hindrance. Or a child might have the special qualities demanded by an occupation in a marked degree and yet lack sufficient intelligence to make advancement in the occupation possible, so that to send him into that employment would mean that he would ultimately fail.

After two years, the homes of all the children were revisited and information as to their present employment gathered. Among those children who had been able to enter the employment recommended or one similar to it, 83 per cent. were satisfied and only 2 per cent. were dissatisfied; of those who had not entered the employment advised, 39 per cent. were satisfied and 42 per cent. were dissatisfied. Moreover, fewer changes of place had occurred among those who had taken the advice given than among those who had not.

Although the fewness of the numbers of children dealt with and the shortness of the period which has elapsed since the original advice was given make definite conclusions impossible, yet those already obtained are most encouraging and certainly warrant further research along the same lines. Fortunately this is being undertaken on an extended scale by the National Institute of Industrial Psychology through the generosity of the Carnegie United Kingdom Trust.

Diffuse Matter in Interstellar Space.[1]

AN attempt is first made to estimate the density, temperature and state of ionisation of gaseous matter diffused through the stellar system. It is concluded that the density is about 10^{-24} gm./cm.^{3}, temperature 10,000°–20,000°, and that atoms are ionised down to 15-20 volts.

The black-body temperature of space is about 3°, but analysis of the processes of interchange between radiant energy and atomic kinetic energy in diffuse gas indicates that ionisation and capture form the main process; and this tends to raise the temperature to the level of effective temperatures of stars independently of dilution of radiation. (Hottest stars must be given the greatest weight.) Against this, temperature is lowered appreciably, but not excessively, by radiation of electrons at encounters without capture (orbit switches). The temperature of diffuse nebulæ will be same as that of general interstellar gas. This temperature cannot be found accurately, because it depends on the distribution of stellar radiation far in the ultra-violet, where it is rash to apply the black-body law; but it is as likely to exceed as to fall short of estimate.

An upper limit to density (about 10[illegible]) is obtained from the dynamics of stellar motions; the gravitational effect of greater mass would make the speeds of stars greater than those which are observed. The more definite estimate (10^{-24}) is based on the extension and distribution of condensations of the medium (diffuse nebulæ) by the application of the theory of equilibrium of an isothermal gas. It is concluded that the central density of a diffuse nebula of typical size is about 10[illegible].

The usual equilibrium formula for the amount of ionisation is modified to apply to matter in a field of 'evenly diluted' radiation. Calcium is mainly doubly ionised, but there is sufficient singly ionised calcium to give *H* and *K* absorption in distant stars. Assuming that the abundance of calcium is the same as on the earth, and using Milne's determination of the monochromatic absorption coefficient, the first calculation gives an *H* and *K* absorption of 1 mag. per 100 parsecs. Neutral calcium is nearly a million times weaker. Sodium is mainly singly ionised, and the first calculation gives *D* lines of neutral sodium about [illegible] strength of *H* and *K* lines. Corrections are indicated which would make calcium absorption weaker and sodium absorption stronger, and it appears that the results are consistent with the appearance of H and K and slightly weaker D lines in stars distant 500-1000 parsecs. If the light passes through a nebulous condensation, the required distance is reduced.

---

[1] Summary of the Bakerian Lecture delivered by Prof. A. S. Eddington, F.R.S., before the Royal Society on May 6.

These results are compared with the phenomenon of ‘fixed’ sodium and calcium lines which, according to Plaskett's investigation, must be ascribed to an interstellar cloud. Arguments associating the phenomenon with the stimulation or emission of matter from the star showing the lines appear to be untenable It is considered that absorption occurs evenly along light-tracks; but it is recognised that limitation to stars of type earlier than B3 is not very satisfactorily explained. In most stars of later type (where fixed lines are not marked by stellar lines) the absence may be ascribed to insufficient distance

The dimming of distant stars by interstellar gas would be caused chiefly by electron scattering, but this is insufficient to produce observable effects It is considered that the absence of any reddening of distant stars is no evidence of the transparency of space. It is impossible on the present theory to explain obscuration of stars by dark nebulæ, and the question arises whether we must not admit that these contain non-gaseous (meteoric) matter, in order to account for their opacity.

The accretion of mass by stars moving through the interstellar medium must in general be very much less than loss of mass by radiation, so that there is no appreciable effect on the rate of stellar evolution. It is suggested, however, that there will be sharp differentiation of those stars which have velocities less than the velocity of sound (about 4 km. per sec.) Possibly these may reach a steady mass—a speculation bearing on the association of the B type of spectrum with unusually low velocity and with condensations of interstellar gas.

Research on the Fauna of Malaysia.

THE periodical *Treubia*, the organ of the scientific institutes centred at Buitenzorg, Java, is now in its eighth volume, and it functions as the chief medium for the publication of researches specially concerned with the Malayan fauna It is issued at no fixed dates and each completed volume comprises four parts. In the recent numbers of that journal are various papers of interest to students of zoogeography, and to specialists in taxonomy

Dr. H. C. Delsman, in collaboration with Dr. J. E. de Man (in vol 6, liv 3-4), provides a well-illustrated account of certain edible crabs obtainable in the Batavia fish-market under the Malayan name of *radjungans* The commonest species is *Neptunus pelagicus* (L.), which meets with a ready demand among native consumers. It is identical with the "blue swimming crab" of Australia, which is the chief edible crab in the Sydney markets The species is very widely distributed, occurring continuously from the Red Sea, through the Indian and Pacific Oceans, to Japan. Its presence at Port Said is remarkable and is probably due to the cutting of the Suez Canal. Although this crab is the dominant saleable species in Batavia, there are a number of other species that are sold in smaller numbers. These have been submitted to Dr. de Man in Holland for examination. Among them, *Neptunus sanguinolentus* (Herbst) also occurs around the Hawaiian Islands in abundance; *Charybdis cruciata* (Herbst), with the cruciform mark on its carapace, has been suggested as the crab mentioned in the story, by old writers, connected with the legend of St Xavier and the crucifix, *Podopthalmus vigil* (Fabr.) differs from all other Indo-Pacific swimming crabs by its enormously elongated eye-stalks, which together occupy the whole width of the carapace.

Other papers in the same volume are chiefly concerned with insects, and of these, one of the most interesting is by Mr. Oscar John on termites. This contribution is wider in its scope than the others, since it deals with species from Ceylon, the Malaya Peninsula, and the islands of Java, Sumatra, etc Included in this article is a discussion of post-embryonic development and caste differentiation among such insects. Most of the species belong to the family Termitidæ, and, of these, the economy of *Macrotermes carbonarius* Hag. is very fully illustrated. Of special interest are photographs of the queen surrounded by her attendant workers in the royal cell, which strongly recalls Escherich's well-known figure of the same feature in *Termes bellicosus*.

Vol 7, liv. 2 is devoted to reports on various orders of animals, mainly insects, found in the island of Buru. Mr. J K. de Jong of Amsterdam deals with the reptiles. Twenty-seven species are mentioned, two of which are believed to be new. The papers on insects deal with a number of families of Coleoptera by various authorities. Diptera Nematocera are described by Mr F. W Edwards of the British Museum, and Dr. H. H. Karny of the Buitenzorg Museum has an extensive paper on the long-horned grasshoppers (Tettigoniidæ) found in the island Vol 8, liv. 1-2, is given up to a long memoir by Graf. Hermann Vitzthum of Munich on Malayan Acari, illustrated by more than 100 figures. About one-half the species enumerated are new, and both parasitic and free-living forms are dealt with.

The Scott Polar Research Institute, Cambridge.

THE inauguration of the Polar Research Institute, founded at Cambridge in memory of the late Captain Robert Falcon Scott, took place on Saturday, May 22. The proceedings were somewhat modified by the recent industrial upset, which prevented Dr Nansen and a group of other eminent foreign explorers from attending, so that a lecture on the "Aims of Polar Exploration", by Dr. Nansen, had to be abandoned. However, on the invitation of the Vice-Chancellor, Dr. A C. Seward, a party of some thirty non-residents, of whom more than twenty had crossed one of the polar circles, joined a number of residents at a dinner given by him, and most of the guests were able to visit the Institute in its temporary quarters during the afternoon. Amongst those present at the dinner were Mrs. Hilton Young (Lady Scott), Admiral Sir George Egerton, Rear-Admiral Skelton, Sir J J Thomson, Sir Charles Walston, Sir William Hardy, Sir Geoffrey Butler, and representatives of all the important British Antarctic Expeditions.

At the dinner the Vice-Chancellor, in welcoming the guests, spoke of the honour done to the University of Cambridge by the trustees of the Scott Memorial Fund in handing over to it the care of the Institute and an endowment of nearly 12,000*l.*

Sir T. W. Edgeworth David, in returning thanks on behalf of the guests, spoke of the scarcely touched resources of the polar regions, and of the scientific problems the clues of which are to be found there and nowhere else. He referred also in glowing terms to the man whose name the Institute commemorated, and to his companions. The wonderful sketches of Dr. E. A. Wilson were especially remarked upon, of which some were on view in the Institute in the afternoon.

The toast of the Institute was proposed by Commander Hilton Young and responded to by the Director (Mr. Frank Debenham). Commander Hilton Young pointed out that the Institute now inaugurated should be not only a worthy memorial of the great deeds of the past but also a source of inspiration for the future. The generosity of the Scott Memorial Fund trustees enabled the University to begin the work of the Institute, but in order to erect a building for its accommodation a further 10,000*l.* is required. There must be many who would wish to do honour to the name of Captain Scott and assist in further research in the polar regions.

The Director outlined the means by which the committee of management, consisting of the Vice-Chancellor, Dr. H. R. Mill, Mr. R. E. Priestley, Mr. J. M. Wordie, and himself, hoped to realise the aim of the Institute in assisting polar research. They had seen during the afternoon the nucleus of the collections of books, maps, and polar travelling gear which would gradually become a comprehensive library and museum—a source of information for those who were undertaking research in polar matters, whether by exploration itself or by more academic means. The past discontinuity in polar research was largely due to the fact that the results and experience of one expedition were sometimes not published and were dispersed, so that later expeditions were unable to profit thereby. The Director invited the deposit of original records and technical gear so that such gaps might be bridged. The pictorial side of polar research was not neglected, especially in the pictures of the Franklin Search Expedition, presented by Dr F. H H. Guillemard, those of the 1895 expedition, presented by Mrs. Kriel (Lady Markham), and the fine collection of enlargements of the *Terra Nova* Expedition, the gift of the photographic artist, Mr. H. G. Ponting. The building the committee had in mind to construct when funds permitted would contain provision for the rapidly increasing library, the practical museum, and research rooms, to be used by any one discussing the polar regions, whether working up field observations or preparing to go to make them. In expressing his regret at the absence of many eminent foreign explorers from the gathering, the Director emphasised the international character of polar research, and expressed the hope that there would always be close co-operation between those in charge of the Institute and its well-wishers in other countries.

University and Educational Intelligence.

CAMBRIDGE.—The University has returned to work and with the postponed examinations looming large upon the horizon, the majority of people are looking anxious. This anxiety is in many cases intensified by the fact that some of the tests will now take place within the period allotted to social functions.

The Committee which is engaged in making offers of lectureships and demonstratorships to those entitled to them under the new statutes has presented an interim report dealing with the principles on which it is working. In general, lecturers are being offered a basic salary (for a basic amount of work) of 200*l.* rising to 250*l* and 300*l.* after three and ten years' service respectively. Demonstrators are being offered 150*l.*; in each case a fellowship allowance is to be made to such persons holding these appointments as are not fellows of colleges. A list of those to whom offers have already been made is published, from which it appears that almost all those who have been called demonstrators in the past will now be termed lecturers In point of fact they have, in the vast majority of cases, been carrying out the duties of lecturers for a long time; they will now have an official title corresponding to their actual work, but it is doubtful whether they will receive the seniority to which they are entitled.

Mr. J. Gray, fellow of King's College, has been appointed University lecturer in experimental zoology. Mr. Gray has been engaged on cytological research since the War.

EDINBURGH.—The Curators of the University of Edinburgh have appointed Prof. A J. Clark, at present professor of pharmacology and dean of the Faculty of Medicine, University College, London, to be professor of materia medica in succession to the late Prof. A. R. Cushny, who died on February 25.

LONDON.—The site of 11½ acres behind the British Museum, purchased by the Government for the University of London, has been re-sold to the vendor, the Duke of Bedford, under the terms of the conveyance, which provided that if the site could not be used for the proposed purpose in five years, the vendor should be given the option to re-purchase. The announcement has made a painful impression in the University and cannot fail to have an important bearing on future developments

Convocation on May 11 adopted three resolutions adverse to the recommendations of the Departmental Committee of the Board of Education. These declared that the creation of a Council to control the finance of the University would have "prejudicial effects" upon the University, that the reconstitution of the Senate would be "a grave error," and that necessary modifications of the constitution of the University should be formulated by the Senate and not by a Statutory Commission. It should be added that the meeting was sparsely attended owing to the general strike, and that the terms of the resolutions, though recommended by the standing committee, were not previously circulated. The suggestion that the question should be considered at an adjourned meeting, or that an extraordinary meeting of Convocation should be convened, was not, however, supported. The opposition which the Senate is offering to the report of the Departmental Committee is centred mainly on the status of the proposed Council. A large majority of the members of the Senate would prefer that the Council should be a statutory finance committee of the Senate with a prescribed constitution. A Committee has been appointed by the Senate to draw up suggestions for an agreed reconstitution.

A LIMITED number of seed analysts will be admitted to the fifth course of training to be held this summer at the Official Seed Testing Station, Cambridge, on June 21-July 20, on the following conditions. Applicants must be (*a*) nominated by seed firms; (*b*) recommended by universities, agricultural colleges, and institutions; or (*c*) approved by the Council of the Institute. The examination following the course is also open to approved practical seed analysts Applications must reach the Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge, not later than June 7

Applications are invited by the Empire Cotton Growing Corporation for a number of research studentships—senior and junior—each of the annual value of 250*l* plus certain allowances for travelling expenses, lecture fees, and books Candidates for senior studentships must be graduates who, since taking their degree, have had at least a year's training in research methods, or have done a year's post-graduate work in agriculture, or taken other advanced post-graduate courses. Junior studentships are intended to assist men who, as a rule, have passed all examinations for, and are otherwise qualified to take, a degree qualifying for the senior studentships. Particulars of the studentships and forms of application can be obtained from the Secretary, Empire Cotton Growing Corporation, Millbank House, Millbank, S.W.1. Completed forms must reach the Secretary by, at latest, June 22.

In an article by Prof Grossmann in the *Chemiker-Zeitung* for April 17, attention is directed to the fact that interest in the study by technologists of foreign languages and especially of English, which is of vital importance for the rebuilding of the German export trade, has lately begun to recover from the setback caused by the War. At Charlottenburg a lectureship in "Technical English" has been established, and the English lectures have been very popular. Reference is made in the article to the recent publication, under the name of "Technische Sprachblatter," of a cheap series of instructive diagrams, representing a great variety of mechanical and other appliances, reference to the numbers on which greatly facilitates the memorising of technical terms in the foreign language. An illustration is reproduced showing a cross-section through a street, with no fewer than sixty different objects numbered and indexed below in English and in German. Thus the study of technical terms, which often presents considerable difficulty when reliance is placed upon dictionaries, is very greatly facilitated. A parallel series might be very useful to students in Great Britain.

The fourth biennial conference of the International Federation of University Women is to be held on July 27–August 2 at Amsterdam. A preliminary programme, published in the Federation's *Occasional Paper*, No. 5, specifies the following among other subjects for discussion: the question of an international language, international fellowships for research, recent developments in pre-school education, some results of the inquiry into methods of secondary education. The same Paper contains reports from holders of international fellowships, namely, from Dr. Hanna Rydh, who was awarded 300*l.* by the British Federation of University Women, on "The Age and Art of the Cave Men," and from Dr. Leonore Brecher of Austria, who was awarded 1000 dollars by the American Federation, on "Colour Adaptation of Pupæ," and a summary of publications by the holder of the Swedish Federation prize fellowship for research in science and holders of the Rose Sidgwick Memorial fellowships. A list is given of club-houses in the United States, Belgium, Canada, France, Great Britain, and Italy which offer special privileges to all travelling members of the International Federation. Associations of university women in Bulgaria, Luxembourg, and Roumania were admitted to the Federation in 1925. Egypt, Esthonia, Germany, and Poland have associations which will, it is hoped, be affiliated before long.

Contemporary Birthdays.

May 29, 1855.	Sir David Bruce, K.C.B., F.R.S.
May 29, 1843.	Major Patrick George Craigie, C.B.
May 31, 1845.	Col. Rookes Evelyn Crompton, C.B
May 31, 1863.	Sir Francis E. Younghusband, K.C.S.I.
June 1, 1866.	Dr Charles B Davenport, Ph.D (Harvard).
June 2, 1850.	Sir Edward A. Sharpey-Schafer, F.R.S.
June 2, 1866.	Dr Leonard Erskine Hill, F.R.S
June 3, 1853.	Sir W. M. Flinders Petrie, F.R.S.

Sir David Bruce, though by birth an Australian, was educated at Stirling High School and the University of Edinburgh. He entered the Royal Army Medical Corps in 1883. Assistant professor of pathology at the Army Medical School, Netley, from 1889 until 1894, he afterwards engaged in a series of investigations (constituting in reality his life's work) on the causation of certain diseases affecting man and animals, namely, Mediterranean or Malta fever, cholera, sleeping sickness, tetanus, and trench fever The importance of his discoveries and conclusions in these fields of inquiry are well known The Royal Society awarded him one of its Royal Medals in 1905, and the Buchanan medal in 1922. Sir David was also the recipient of the Albert Medal of the Royal Society of Arts in 1923. He is a corresponding member of the Paris Academy of Sciences.

Major Craigie, who was born at Perth, was educated there at the Academy, and at the Universities of Edinburgh and Cambridge. He has carried out much official work in agricultural matters and in statistical inquiries for successive Governments and for public authorities In 1900 he was president of Section F (Economics) of the British Association, and in 1902 president of the Royal Statistical Society. He was, from 1897 until 1906, assistant secretary of the Board of Agriculture and Fisheries. He has been Gilbey lecturer in the history and economics of agriculture in the University of Cambridge

Col. Crompton was educated at Elstree and Harrow. Entering the army after school life, he was, down to the year 1875, in India with the Rifle Brigade. Afterwards he engaged in electrical engineering, founded the firm which bears his name, and continued as managing director for nearly thirty years. During the early period of electric supply, Col Crompton shared with Mr. Ferranti most of the work of designing the power stations of Great Britain, and abroad in the same field he has developed undertakings. He has been twice president of the Institution of Electrical Engineers Early this year the Faraday Society awarded him its gold medal. Elected by the Institution of Civil Engineers (1910) as engineer to the Road Board, he was responsible for the major portion of the experimental work which led to modern developments. Col. Crompton, after the War, was the recipient of an award from the Awards to Inventors Commission for work on the 'tanks.'

Sir Francis Younghusband, soldier, traveller, and geographer, was born at Murree, and educated at Clifton College and Sandhurst. After attaining his army captaincy in 1889, he was transferred to the Indian Political Department. He has travelled in Manchuria, Chinese Turkestan, the Transvaal, Rhodesia, and in many other parts of the world. Sir Francis was awarded the Founder's medal of the Royal Geographical Society in 1891. His publications include "Wonders of the Himalaya" (1924).

Societies and Academies.

London.

Geological Society, May 5.—**K. A. Davies**: The geology of the country between Drygarn and Abergwesyn (Breconshire). The area, 20 square miles of country, is situated 5 miles north of Llanwrtyd Wells, and 3 or 4 miles south-west of the Rhayader district. The rocks belong to the Bala and to the Valentian series, but the latter only is described in detail. The Valentian rocks rest conformably upon the Bala. The sediments are generally of the mudstone-and-shale type, with subsidiary bands of grit and conglomerate. A full graptolitic succession in the Valentian rocks has been proved. The area lies on the western flank of the Towy anticlinorium, but the strata are folded into a subsidiary syncline (the Gwesyn syncline) and anticline (the Rhiwnant anticline), with their axes parallel to that of the main structure, that is, from south-west to north-east. Faulting is practically restricted to the southern side of the Gwesyn syncline, where for some distance an important strike-fault separates the Birkhill from the Bala rocks. The rocks are highly cleaved, the strike of the cleavage-planes being approximately parallel to the strike of the strata. The total thickness of the Birkhill rocks is similar to that of the Rhayader country, but much greater than at Plynlimon. The Birkhill rocks are thicker on the north-western than on the south-eastern side of the area.—**R. M. Jehu**: The geology of the district around Towyn and Abergynolwyn (Merioneth). The area, about 35 square miles, lies south-west of the Corris district. The rocks belong to the Bala and Valentian series, and consist mainly of mudstones and shales with subordinate bands of grit. The district is on the south-eastern flank of the Harlech dome, so that, in general, the strata strike from south-west to north-east and dip south-eastwards; but the area is crossed transversely by large anticlinal and synclinal folds, the axes of which trend north-north-eastwards in the south and become north-and-south farther north. The Bala or Tal-y-llyn fault runs from south-west to north-east through the area and is marked by the straight, steep-sided Tal-y-llyn Valley. This is probably a tear-fault with comparatively little vertical displacement. The southern part of the area is much affected by faulting, and three main groups of faults may be recognised: namely, (1) an east-and-west group; (2) a north-east and south-west group; and (3) a north-west and south-east group. The rocks are highly cleaved, and the extraction of fossils is thereby rendered difficult. The strike of the cleavage-planes is approximately from south-west to north-east.

Linnean Society, May 6.—**A. W. Hill**: The genus Lilæopsis, a study in geographical distribution. There are some fourteen clearly-marked species. Three occur in N. America from Alaska to Florida and Arizona, one both in E.N. America and in E.S. America, and one in Mexico and in Ecuador. One is found in Brazil and one in the Andes of S. America, another in western S. America and Chiloe, and one in the Falkland Islands and in S. Georgia, while the remaining species are natives of Tasmania, Australia and New Zealand. The leaves are rather in the nature of phyllodes, since a specimen has been found with small leaflets attached to the septate rachis.—**R. D'O. Good**: The genus Empetrum. Empetrum has a very wide but discontinuous geographic range. In the nothern hemisphere it occurs almost everywhere above the latitude 40° N. In the southern hemisphere it was found in western South America below the latitude 35° S., throughout Fuegia and the Falklands, and in the Tristan d'Acunha island group. The abundance of the genus has resulted in the collection of an unusually large number of specimens, which differ considerably among themselves. This variation is due chiefly to the differential development of general habit, degree of hairiness, shape and size of leaf, arrangement of leaves, angle of leaf insertion, sex of flower, and colour of berry, showing three distinct types of variation, 'continuous,' 'compound-continuous,' and 'discontinuous.' Very few of the theoretically possible character-combinations occur, and any individual plant can be placed without hesitation into one of ten distinct units. This feature is due mainly to correlated variation (the association of a particular condition in one variable character with a definite condition in some other character), but also to marked geographical segregation. The generic constitution is best expressed taxonomically by recognising two distinct species, one with a subspecies, a variety and three forms, and the other with three forms.—**J. T. Cunningham**: On the nuptial pads of frogs and toads from the Lamarckian point of view. The nuptial pads of the common frog are thickenings of the horny epidermis on the inner sides of the fore-feet or hands. They are entirely absent in the female. They give the male a firmer hold of the female in the axillary amplexus which precedes spawning. In amplexus, although the male's hands and nuptial pads are partly in contact with the skin of the female, they are also in contact with each other, and the more the female struggles the more tightly are the pads pressed together. There are bones beneath the pads, while the skin of the female in contact with the hands covers the soft abdomen. Thus the nuptial pads are in harmony with other secondary sexual characters in male animals in being related to mechanical stimulation, which is confined to the males.—**B. M. Griffiths**: The phytoplankton of the Isle of Anglesey and of Llyn Ogden, North Wales.—**Miss Isobel Dean**: ***Ainigmaptilon haswelli***, n.g. et sp.; a new alcyonarian type.

Paris.

Academy of Sciences, April 19.—**Paul Appell**: The arithmetical nature of Euler's constant. A correction to the note on the same subject in the preceding issue of the *Comptes rendus*.—**Charles Moureu** and **Charles Dufraisse**. Autoxidation and antioxygen action. The catalytic actions of nitrogen compounds. General considerations. Numerous compounds of nitrogen exert an action on autoxidation.—— **Tzitzeica**: Certain congruences.—**A. Buhl**: Continued groups and the integration of Maurer's equations.—— **Cartan**: Certain differential systems the unknowns of which are forms of Pfaff.—**Georges J. Rémoundos**: Paths of determination and asymptotic values of algebroid functions.—— **Swyngedauw**: The change of velocity of a belt close to the points of contact with the pulley.—**F. Baldet**, **V. Burson** and **H. Grenat**: The magnetic storm and the aurora borealis of April 14, 1926. The magnetograph at Meudon Observatory showed two strong deviations on April 14, and several good photographs of the solar layers were obtained at the same time. In the evening a fairly intense aurora was observed, and simultaneously a strong deviation of the magnetic needle was recorded. It is interesting to note that the interval of time between this magnetic storm and the earlier one on March 9 was nearly exactly $8R/6$, in accordance with the rule discovered by M. Deslandres, that the time interval between magnetic storms is a simple multiple of $R/6$, R being the period of synodic rotation of the sunspots.—Raoul **Ferrier**: The transformation of pre-quantic equations.—Svend Aage **Schou**: The absorption of the ultra-violet rays by aldehydes. Absorption is stronger in hexane solution than in water, and this is interpreted as being due to the formation of the hydrate in water. The absorption of the extreme ultra-violet rays by well purified aldehydes is very small: if this is attributed to the presence of some of the enol form, then the proportion of this in neutral aqueous solution is certainly less than 1 in 15,000.—Michel O **Samsoen** and P. Mondain **Monval**: The specific heat anomalies of vitreous bodies. The case of boric anhydride and glycerine. The specific heats of these substances, plotted as a function of the temperature, show discontinuities similar to those found by the dilatometric method, but the temperatures of transformation do not exactly correspond.—V. **Auger** and J. N. **Longinescu**: Uranium oranges and reds.—A. **Travers**: The mechanism of the oxidation of manganese to permanganic acid by Proctor Smith's reagent (alkaline persulphate + silver nitrate). The mixture of solutions of alkaline persulphate and silver nitrate gives rise to silver peroxide which can be isolated in the form of $3Ag_2O_2 . AgNO_3$. The formation of this peroxide explains the catalytic action of silver nitrate in the oxidation of manganese salts to permanganate by persulphates —Jean Marc **Dumoulin**: The catalytic dehydration of the vinylalkylcarbinols. Trials of various catalysts for this reaction showed that the best yields were obtained by alumina precipitated from the sulphate according to the method of Senderens. Three alcohols have been dehydrated and the resulting hydrocarbons (pentadienes, hexadienes, and heptadienes) identified.—R **Lantz** and A. **Wahl**: Some new derivatives of the naphthoquinones —C. **Dauzère**: The inversions of temperature. A study of the effect of the nocturnal radiation of the soil on air temperature —Ph. **Joyet-Lavergne**: The differences of potentials of oxidation and reduction in the spores of *Equisetum arvense*.—E. **Chemin**: *Colaconema reticulatum*. This was found by A. L. Batters developing in the external membrane of *Desmarestia Dudresnayi*, and was considered by him as belonging to the genus Colaconema (?). The author gives further details and considers that the interrogation mark may be removed as the genus is undoubtedly Colaconema.—R. **Combes**: Study of the autumnal migration of the nitrogenous substances in the oak, by analysis of whole plants. By the analysis of seedling oaks it was shown that while changing their colour the leaves lose more than half their nitrogenous substances, and this accumulates in the living organs. During this migration the amount of nitrogen in the whole plant does not vary sensibly.—Marcel **Brandza**: Polychromy in Myxomycetes living in full sunlight.—E. **Aubel**, L. **Genevois**, and J. **Salabartan**: Remarks on the culture of a yeast in a synthetic medium.—Alphonse **Labbé**: A new halophil copepod, *Parametis sanguineus*.

COPENHAGEN.

Royal Danish Academy of Science and Letters, November 27, 1925.—H. A. **Kramers**: Some remarks on the theory of absorption and refraction of X-rays. The general connexion between the absorption and refraction of electromagnetic waves can also be traced in the X-ray region. It allows of a simple explanation of certain features of the experimental laws of X-ray absorption, and leads to definite predictions regarding the dependency of the refraction on the wave-length.

December 11, 1925.—C. **Juel**: Congruence of the second degree. The congruence of straight lines in space can be defined as a congruence contained in a linear complex which is of the second order and the second class and has 0, 2 or 4, or else an infinite number of straight lines in common with each hyperboloid in the complex. This congruence is algebraic, and is determined by purely descriptive results.

January 15.—Niels **Nielsen**: (1) Note on certain developments of a holomorph function. Applying the principle of *renversement* (*Journal de Crelle*, t. 132), two developments are indicated of a holomorphic function in the neighbourhood of the origin, developments of which the region of convergence is generally closed. (2) Research on cylindrical functions and on certain analogous functions. Research on derivatives of the function of Lommel, taken in relation to two parameters, and on homogeneous and linear differential equations of the fourth and sixth order, obtained for their above-mentioned derivatives. Integral representation of these functions and certain relevant developments in infinite series.

January 29—Niels **Bjerrum**: Studies on ion-association. (1) The influence of ion-association on the activity of ions by degrees of association which are not very great. An approximate method is given of calculating the influence of this association on the activity of ions.—Th. **Madsen**: The avidity of diphtheria anti-toxin (Th. Madsen and S. Schmidt). The rate of reaction for the neutralisation of diphtheria with anti-toxin varies considerably for different anti-diphtheric sera. This appears from experiments both *in vitro* and *in vivo*, and is of considerable importance as regards the curative qualities of the serum.

February 12.—C. **Wesenberg-Lund**: Contributions to the biology of the genus Daphnia. The author has investigated numerous races of the genus Daphnia from different localities. Remarks are made upon the systematics, the buoyancy theory, and modern studies of heredity in this genus.

February 26.—C. H. **Ostenfeld**: On the origin of the flora of Greenland. Thanks to the collections made by the many recent expeditions (mostly Danish), the distribution of the flowering plants along the whole of the coast of Greenland is now comparatively well known. Thereby a good base for a treatment of the origin of flora and its ways of immigration is created. A not inconsiderable part of the more hardy species are supposed to have survived the ice-age in Greenland, but a closer limitation of this group is not possible. The main part of the flora, however, has immigrated into Greenland after the maximum extent of the ice-covering, and the immigration has probably had its maximum in the post-glacial warmer epoch which existed also in Greenland. Most of the species have come from N. America, and a much smaller number from Europe. This European element consists of (1) high-arctic species, probably immigrated via Spitsbergen, (2) less arctic species from Iceland, and (3) species which have been introduced in the time of the old Norse settlements.

April 23.—G. **Hevesy**: The exchange of atoms in solid bodies in consequence of heat-movements. Explanations can be offered, on one hand, by the velocity with which one substance diffuses into another, and on the other hand by the magnitudes of their electrolytic conductivities. The paper deals principally with the question of the dependence of the velocity of exchange on the constitution of the crystal aggregate of which the solid is built up.—August **Krogh**: The hormone of the hypophysis in the circulation. Through the action on the melanophores in the skin of the frog, very low concentrations of pituitrin can be determined The concentration is found to be higher in the jugular than in the saphenous vein.

Diary of Societies.

SATURDAY, May 29.

Royal Institution of Great Britain, at 3.—Prof. A. Moret: Une Révolution sociale en Égypte vers 2000 av. J.-C.

North of England Institute of Mining and Mechanical Engineers (Associates' and Students' Section) (Annual General Meeting), at 3.—Discussion on Paper by J. G. Taylor on Coal and its Banded Constituents.—Prof. J. Poole: Notes on the Tour in Belgium and Germany (Address).

MONDAY, May 31.

Royal Society of Arts (Indian Meeting), at 4.30.—Lt.-Col. Sir Arnold Talbot Wilson: The Military Record and Potentialities of the Persian Empire.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Major L. M. Davies: Evolution.

Surveyors' Institution, at 5.—Annual General Meeting.

Royal Society of Medicine (Odontology Section), at 5.30.—Annual General Meeting and Clinical Meeting.

Royal Geographical Society (at Æolian Hall), at 8.30.—Dr. F. M. Chapman: Darwin's Chile.

TUESDAY, June 1.

Society of Glass Technology (at University College), at 2.30.—Sir W. M. Flinders Petrie: Glass in Early Ages (Demonstration and Lecture).

Royal Institution of Great Britain, at 5.15.—Brig.-Gen. Sir Percy Sykes: Shah Abbas of Persia, the Contemporary of Queen Elizabeth.

Zoological Society of London, at 5.30.—Secretary: Report on the Additions to the Society's Menagerie during the month of May 1926.—Dr. F. Chapman: Exhibition of Lantern Slides illustrating Bird Life on the Barro Colorado Island.—A. S. Le Souef: On the Habits of the Order Marsupialia.—Prof. R. T. Leiper: (a) Some Parasites of Rats in the Zoological Society's Gardens; (b) The Starling as a Factor in the Spread of Gapeworm Disease in Chickens.—S. Zuckerman: Growth Changes in the Skull of the Baboon (*Papio porcarius*).—S. Hirst: Descriptions of New Mites, including Four New Species of 'Red Spider.'—J. H. Power: Note on the Occurrence of Hybrid Anura at Lobatsi, Bechuanaland Protectorate.—H. C. Wilkie: The Ossicula auditus of the Common Badger (*Meles taxus*).

Röntgen Society (at British Institute of Radiology), at 8.15.

WEDNESDAY, June 2.

Society of Glass Technology (at Research Laboratories, General Electric Co. Ltd., Wembley), at 2.15.—J. W. Ryde: A Communication from the Research Laboratories of the General Electric Co. Ltd., Wembley: Opal Glass.—F. F. S. Bryson: The Electrical Conductivity of Glass at High Temperatures.—Edith M. Firth, F. W. Hodkin, M. Parkin, and Prof. W. E. S. Turner: The Influence of Moisture on the Rate of Melting and on the Properties of Soda-Lime Silica Glasses.—Dr. S. English and Prof. W. E. S. Turner: The Physical Properties of Zinc Oxide containing Glasses.

Royal Institution of Great Britain, at 5.15.—Prof. Dayton Miller: Ether Drift Experiment at Mount Wilson.

Royal Society of Medicine, at 5.30.—Sir Jagadis C. Bose: The Action of Alkaloids and Cobra Venom on the Pulse of the Plant and Animal.

Institution of Electrical Engineers (Wireless Section), at 6.—P. W. Willans: Low Frequency Intervalve Transformer.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—A. Lucas: Problems in connexion with Ancient Egyptian Materials.

Royal Society of Medicine (Surgery Section), at 8.30.—Dr. W. E. Gye: The Origin of Tumours.—J. E. Barnard: Demonstration on Microscopical Methods.

THURSDAY, June 3.

Iron and Steel Institute (Annual Meeting) (at Institution of Civil Engineers), at 10 a.m.—Presentation of Bessemer Gold Medal to Sir Hugh Bell, Bart.—Sir W. Peter Rylands: Presidential Address.—Report on Heterogeneity of Steel Ingots. By a Sub-Committee of Committee No. 5, consisting of Dr. W. H. Hatfield, T. P. Colclough, W. J. Dawson, J. H. S. Dickenson, A. P. Hague, E. F. Law, S. A. Main, T. M. Service, and J. H. Whiteley.—J. H. S. Dickenson: A Note on the Distribution of Silicates in Steel Ingots.—J. H. Whiteley: Ghost Lines and Banded Structure of Rolled and Forged Mild Steels.—At 2.30.—W. H. Dearden and C. Benedicks: Magnetic Changes in Iron and Steel below 400° C.

Royal Society of Medicine (Laryngology Section), at 3.—Sir William Willcox: Nasal Sinusitis as a Cause of Toxaemia.—Dr. A. Logan Turner and Dr. F. E. Reynolds: A Fatal Case of Leptomeningitis following Operation on the Ethmoidal Air Cells: with Microscopical Demonstration of the Path of Infection.

Royal Society, at 4.30.—Dr. A. E. H. Tutton: The Alkali Perchlorates and a New Principle concerning the Measurement of Space-Lattice Cells.—Dr. T. E. Stanton: On the Flow of Gases at High Speeds.—Prof. G. I. Taylor and W. S. Farren: The Distortion of Crystals of Aluminium under Compression. Part I.—Prof. E. V. Appleton, R. A. Watson Watt, and J. F. Herd: On the Nature of Atmospherics. II.—*To be read in title only*:—Prof. C. H. Lees: On the Determination of the Specific Heats of Gases at Constant Pressure and at Constant Volume and their Ratio by Adiabatic Expansion.—T. G. Room: A General Configuration in Space of any Number of Dimensions analogous to the Double-Six of Lines in Ordinary Space.—C. N. Hinshelwood and W. K. Hutchison: A Comparison between Unimolecular and Bimolecular Gaseous Reactions. The Thermal Decomposition of Gaseous Acetaldehyde.—P. A. M. Dirac: (a) The Elimination of the Nodes in Quantum Mechanics; (b) Relativity Quantum Mechanics with an application to Compton Scattering.—A. Fage and L. J. Jones: On the Drag of an Aerofoil for Two-Dimensional Flow.—F. W. Carter: On the Action of a Locomotive Driving Wheel.

Institute of Pathology and Research (St. Mary's Hospital, Paddington), at 5.—Dr. C. S. Myers: Freudian Psychology.

Royal Institution of Great Britain, at 5.15.—Dr. J. Newton Friend: Iron in Antiquity.

Chemical Society, at 8.

FRIDAY, June 4.

Iron and Steel Institute (Annual Meeting) (at Institution of Civil Engineers), at 10 a.m.—Announcement of the Award of the Andrew Carnegie Research Scholarships for 1926–7.—D. Brownlie: Coal Blending.—W. W. Hollings: Notes on the 'Combustibility' of Coke, and Direct Reduction in the Blast Furnace.—Dr. W. Rosenhain, H. G. Bateson, and N. P. Tucker: Effect of Mass in the Heat Treatment of Nickel Steel.—G. R. Woodvine and A. L. Roberts: Influence of Segregation on the Corrosion of Boiler Tubes and Superheaters.—At 2.30.—I. G. Slater and T. H. Turner: The Hardness of Carbon Steels at High Temperatures.—A. R. Page: The Hardening and Tempering of High Speed Steel.—A. E. Cameron and G. B. Waterhouse: The Effects of Arsenic on Steel.—E. D. Campbell and H. W. Mohr: Specific Resistance and Thermoelectro-motive Potential of some Steels differing in Carbon Content.—R. H. Greaves and J. A. Jones: The Ratio of the Tensile Strength of Steel to the Brinell Hardness Number.—H. O'Neill: Deformation Lines in Large and Small Crystals of Ferrite.—A. Osawa: The Relation between Space-Lattice Constant and Density of Iron-Nickel Alloys.—T. E. Rooney and L. M. Clark: The Estimation of Phosphorus in Steels containing Tungsten.

Royal Society of Medicine (Laryngology Section), at 10.30 a.m.—Clinical Meeting.

Philological Society (at University College), at 5.—C. T. Onions: Dictionary Evening.

Royal Society of Medicine (Otology Section), in afternoon.

Geologists' Association (at University College), at 7.30.—Prof. S. H. Reynolds: A Geological Tour in South and East Africa (Lecture).

Royal Institution of Great Britain, at 9.—Prof. J. Garstang: Researches in Palestine.

SATURDAY, June 5.

Royal Society of Medicine (Otology Section), in morning.

Royal Institution of Great Britain, at 3.—Sir Walford Davies: The Triad and the Perfect Fourth; their Uses from Hucbald to the Present Day. (With Musical Illustrations.)

PUBLIC LECTURES.

MONDAY, May 31.

London School of Economics, at 5.—Prof. T. H. Pear: Fitness for Work. (Succeeding Lectures on June 1 and 2.)

Imperial College (Royal School of Mines), at 5.15.—Prof. L. Denoel: Tubbing Deep Shafts, and Subsidence. (Succeeding Lectures on June 1, 2, and 3.)—Sir T. W. Edgeworth David: Past Ice Ages of the World and their Control of Animal and Plant Life, with special reference to the Australian Evidence. (Succeeding Lecture on June 7.)

TUESDAY, June 1.

Gresham College (Basinghall Street), at 6.—Sir A. Walford Davies: Music. (Succeeding Lectures on June 2, 3, and 4.)

THURSDAY, June 3.

Chelsea Physic Garden (Swan Walk, Chelsea), at 5.—Prof. J. McLean Thompson: The Plant as an Engineer. (Chadwick Lecture.)

CONFERENCES.

SATURDAY, May 29.

Association of Women Science Teachers (at Northampton School for Girls), at 12.30.

June 1 and 2.

Réunion Neurologique (in Paris).

SATURDAY, JUNE 5, 1926.

Recruitment for Indian Services.

THE structure of dyarchy originated by the Government of India Act 1919 was carried up another story by Statutory Rules and Orders, 1924, Nos. 354 and 355, issued by the India Office. By those Orders the control of the servants of a local government was put in the hands of the local government up to and including the power of dismissal "for good and sufficient reason." The local government was thus put in a position to secure due diligence on the part of its servants. At the same time, for the protection of the servant from victimisation, these Orders prescribed appropriate inquiry before the infliction of any punishment and set up a suitable system of appeal. The Government of India is the most usual appeal body, and it is interesting to note that special machinery for dealing with such appeals has recently come into being by the appointment of the chairman and other members of the Public Service Commission.

The control of existing servants being in the hands of the local government, it only remained to transfer to the local government the power of making new appointments. This is done by Statutory Rules and Orders 1926, Nos. 390 and 391, recently issued.

Within certain reasonable and necessary restrictions, these Orders give the local government a free hand as to method of recruitment. In this the Orders go beyond the recommendation of the Lee Commission, and rightly. The Lee Commission recommended that in any recruitment by a local government the Public Service Commission should determine "the standards of qualification and the methods of examination." In an article in our issue of July 12, 1924, entitled "Europeans in the Indian Services," we pointed out that that recommendation violated the principle of provincial autonomy, and it is very fortunate for the future of dyarchy that the new Orders make the local control of the transferred services effective by transferring also in full measure the power to appoint and control the government servants engaged in the administration of these services.

In one point only do the Orders show any distrust of dyarchy. The local government is prohibited from lowering the standard of admission without the previous sanction of the Governor-General in Council. It is not clear why it should be suggested that any local government would have a desire to lower the standard. It is true that in India, as in Great Britain, there are always 'people of influence' going about trying to thrust their incompetent relatives into 'soft jobs,' but surely the local government of a governor's province is sufficiently strong to deal with these people without this particular piece of support. This lack of trust is a universal characteristic of our nation; each of us is perfectly convinced of his own impeccable honesty, but at the same time considers it necessary that his neighbour's honesty should be safeguarded.

This, however, is the only blemish, and it is a slight one. For the rest, the local government is given all the freedom a reasonable local government could ask. It is free to recruit in any manner it pleases, so long as it does so by means of a competitive examination or on the advice of a permanent board of selection set up by itself.

At the same time, the position of an existing servant is safeguarded by the condition that any appointment that would adversely affect him requires the previous sanction of the Governor-General in Council. This very effective safeguard, along with the Orders regulating dismissal, should completely allay the fears which the Indian civil servant has sometimes felt as to the security of his position.

These fears have never been shown by the young men at the British universities who furnish the recruits. The true state of affairs is masked by the fact that at the present time the London competition selects fewer Europeans and more Indians than in pre-War days. Because of this, people jump to the conclusion that our universities are no longer prepared to send their best to India. That is wrong. They send their best to the competition as much as ever they did. The study of the university records of the European Indian civil servants recruited now and before the War shows the standard of the present-day entrant to be fully as high as that of the pre-War entrant. The true explanation lies not in the deterioration of the European condidates, but in the improvement of the Indian candidates.

Scott's Polar Journey and the Weather.

Scott's Polar Journey and the Weather: being the Halley Lecture delivered on May 17, 1923. By Dr. G. C. Simpson. Pp. 31. (Oxford: Clarendon Press; London: Oxford University Press, 1926.) 2*s.* 6*d.* net.

IT was natural for Dr. Simpson to choose the subject of Antarctic weather for his Halley Lecture, 1923, in view of the important contributions he has himself made to our knowledge of Antarctic meteorology. Dr. Simpson commences with a lucid exposition of the chief meteorological features, with particular reference to the relation between radiation and air temperature, to the formation in the atmosphere of inverted temperature gradients when the sun is low or below the horizon, to the blizzards which disperse the inverted temperature gradients and thus raise the surface temperature, and to the effect of these on sledging conditions, including the friction on sledge runners. He then reviews the main vicissitudes experienced by Scott on his journey to and from the South Pole, and discusses the importance of the weather in contributing to the disaster which finally overtook the party.

The serious blizzard experienced by the outward-bound party in an unfavourable position at the foot of the Beardmore Glacier delayed them, not only during the time they were laid up, but also on the lower reaches of the glacier, the surface of which became covered with soft snow in which the sledges sank to the cross pieces. This delay was, however, partly offset by bridging of the crevasses with snow. Followed the ascent to the 9000 ft. plateau and the traverse to the Pole, the disappointment of finding that Amundsen had forestalled the party, and the return to the head of the glacier. The effort of sledge-hauling at this altitude in a mean temperature (January) of −19° F. was undoubtedly tremendous, and the party naturally looked forward to a rise in temperature on descent of the glacier. The temperature did rise, only to fall again before the bottom was reached, and to fall still further as the party, now reduced to four, pushed northwards along the Ross Barrier. At this stage of the journey, Scott met generally light northerly winds, insufficient to blow away the softer surface snow, while the favouring southerly winds for which they prayed were infrequent and not of sufficient force to cause the thorough mixing of the air which would have raised the temperature and improved the surface. These conditions lasted until Oates made the supreme sacrifice, the party falling always further and further behind their time table. Finally, only eleven miles from One Ton Depôt and plenty, the blizzard came, but a blizzard of such strength as to render travel impossible and of such duration (at least ten days) as to cause the final catastrophe. These points are discussed by Simpson in detail and in graphic language.

Scott himself maintained that his arrangements were adequate, and that no one in the world would have expected such conditions so early in the autumn. In his message to the public, he says: "Our wreck is certainly due to this sudden advent of severe weather which does not seem to have any satisfactory cause. I do not think human beings ever came through such a month as we have come through. . . ." Dr. Simpson makes it clear that conditions were unusual, not indeed in the occurrence of such low temperatures but in the duration of the cold period unrelieved by blizzards. Herein lay the unforeseen element. Though the onset of the very severe blizzard on March 19 was the actual cause of the disaster, it was, tragically, the absence of blizzards and the consequent intense cold for some time previous to this date which rendered the disaster not only possible, but even probable.

Biology and Human Life.

(1) *Life and Evolution: an Introduction to General Biology.* By Prof. S. J. Holmes. Pp. v+449. (New York: Harcourt, Brace and Co., Inc., 1926.) 3.50 dollars.

(5) *In Search of Reality.* 1: *Organic Evolution.* By J. E. Williams. Pp. 256. (London: Gerald Duckworth and Co., Ltd., 1925.) 7*s.* 6*d.* net.

(6) *The Growth of Biology: Zoology from Aristotle to Cuvier, Botany from Theophrastus to Hofmeister, Physiology from Harvey to Claude Bernard.* By the late William A. Locy. Pp. xiv+481. (New York: Henry Holt and Co., 1925.) 4 dollars.

(1) AS Prof. Holmes points out in the preface to his volume, biology has during the last half-century exerted a profound influence upon human thought and human action, particularly through the theory of evolution and through modern views on the relation between heredity and environment. No one can lay claim to a liberal education unless he has made himself acquainted with at least the rudiments of the science. Prof. Holmes has made a bold and, on the whole, a successful attempt to cover the whole field of modern biology in such a way that his book can be read with interest and profit not only by the elementary student but also by the general reader. The treatment is competent, comprehensive and clear, and the book is eminently readable. With an eye presumably on recent developments in the United States, the author has devoted a good deal of space to the evidence for organic evolution. The problems of development and heredity are dealt with clearly and skilfully, and the practical bearing of our modern knowledge is brought out in a final chapter entitled, somewhat grimly, "The Eugenic Predicament." Our only criticism of the book is that the illustrations are, on the whole, rather poor and imperfectly reproduced.

(2) Dr. Keen's little book is one of the most effective contributions we have seen to the Fundamentalist controversy, and it is not surprising that several editions of it have been called for during the last three years. Dr. Keen is a distinguished surgeon who has seen in his own lifetime the rise of the Darwinian theory and the final acceptance by men of science and by all intelligent laymen of the doctrine of evolution. Throughout it all he has retained a firm belief in Christianity, and he finds no difficulty in harmonising his religious beliefs with a full acceptance of the theory of descent. This gives special point to his judgment of the Fundamentalist outbreak.

> "The recrudescence of the warfare over Evolution, which for many years had subsided and almost disappeared, except sporadically, is a strange and surely only a passing phenomenon. The illogical and futile attacks upon science by some of the miscalled Fundamentalists, and an illogical and even absurd attempt to prove that the Bible contains and anticipated the discoveries of modern science, are doing immense harm to religion. There is serious danger, if present tendencies triumph, that intelligent people—those who eventually mold the thought of the world—will be alienated from the Church and finally driven from it" (p. 18).

There is also a danger, as events have shown, that the transference of political power to a half-educated democracy may tend to repress clear and honest thinking. There is need, therefore, for the biologist to present the case for evolution in a simple and convincing way.

This Dr. Keen succeeds in doing, in an original and effective manner. Believing that facts carry more weight with ordinary people than arguments, however logical and clearly presented, he has given in a series of short and incisive chapters a plain statement of specific facts, most of them drawn from his own personal experience as a surgeon and anatomist, facts which, to his mind, "absolutely demonstrate the solidarity of animal life, more especially in the case of the vertebrates, such as fish, birds, other mammals and man, the highest mammal." He discusses, for example, the homologies of the vertebrate skeleton, the extraordinary similarity of the internal ear throughout the vertebrate series, the similar effects of the endocrine secretions, the analogies of development, and so on. The instances are not new, but they are vividly presented and rammed home with the weight of personal experience and conviction. There are three excellent little plates.

(3) In "Plain Speaking" we have a collection of essays, of very diverse dates, from the pen of another veteran, the Rev. T. R. R. Stebbing. In one he discourses delightfully on the group he has made peculiarly his own, the Crustacea; others deal with teleology, thaumaturgy in the Bible, miracles, the origin of language, wolves and wild boars in France. A mixed bag, certainly, but particularly well written and readable.

Of special interest in the present connexion are the autobiographical details which are vouchsafed in

"An Address on receiving the Medal of the Linnean Society." The author took holy orders in the year 1858 and was plunged straightway into the violent controversies that attended the birth of Darwinism. Being young and enthusiastic and fond of a scrap, he joined in the fray. What followed is best given in his own words:

> "I approached the reading of Charles Darwin's 'Origin of Species' with an easy confidence that I should be able to smash up his heresy and others like it. Instead of which I became an ardent convert, and very soon went on to deliver lectures and preach sermons, harping continually on the new views. These expressions of opinion were, it appeared, very agreeable to those who agreed with them, but very annoying and distasteful to the others." (p. 10).

One or two papers of this kind written in the 'seventies are here reproduced. It required a good deal more courage then than now for a parson to come boldly out on the side of evolution.

(4) Sir Oliver Lodge's thesis is that "there is no essential opposition between Creation and Evolution. One is the method of the other." His book is frankly popular, and makes little demand on the reader's intelligence. Sir Oliver is, as one would expect, interesting and suggestive on cosmical evolution, but not quite so good on the evolution of living things, though his discussion of the essential characteristics of life (pp. 118-119) is sound and penetrating. The spirit of Victorian optimism permeates the book.

(5) Mr. Williams' essay in search of truth deserves more serious consideration. He also is concerned with the reconciliation of science and religion, and sets out to inquire how two cardinal beliefs of orthodox religion fare at the hands of science—the belief in human survival and the freedom of the will. Both are denied by the materialistic determinism which is orthodox in science. Mr. Williams justly claims that the decision in these matters is too important to be accepted second-hand, and has set himself the task of examining the evidence for himself in order to come to a personal and considered judgment. The present volume gives us only the first fruits of his inquiry. He writes:

> "Although the real issues outlined above must, no doubt, be fought out in the psychological arena, since the basic problems—those of individual immortality and responsibility—relate to spiritual and psychic rather than to physical processes, the preliminary battle-ground undoubtedly lies in the realm of biology, in the theories of heredity and organic evolution. Before it is possible to consider the infinitely complex problems of human and animal behaviour in their relation to immortality and spiritual reality, it is necessary to come to some conclusion upon the much more simple, though still intensely difficult, problems of physiological development" (p. 22).

Accordingly, Mr. Williams states and discusses the modern views on development, heredity and evolution, and builds up from them an ingenious and highly speculative theory, based on Brailsford Robertson's autocatalyst theory, J. T. Cunningham's views on hormones and heredity, and the late William Bateson's suggestion in 1914 that perhaps after all differentiation has come about by the progressive unpacking of an original complexity. Mr. Williams has read and mastered his literature in a very competent manner, and his theory will be of interest to those who think that a mechanistic explanation of heredity and evolution is still a possibility.

It is not clear just how far Mr. Williams believes in his own theory, for he tells us at the end of his book that he has deliberately pushed some modern lines of thought far beyond the limits sanctioned by their authors, into the realms of pure speculation, in the effort to see how far physico-chemical explanations can possibly carry us. He concludes by asserting that the most important factor in change is the behaviour of the animal itself, and that "the true origin of physiological evolution appears to lie within the complex factors which determine animal behaviour." Having thus whetted our appetite, Mr. Williams refers us to a second volume, which we shall await with interest.

(6) Dr. William Locy's posthumous book takes us into the calmer realms of history, and shows us something of the way in which biological discoveries have been made and new theories evolved. Special attention is given to the human note, portraits and biographical details being supplied with a lavish hand. The illustrations throughout are interesting and well chosen, particularly those taken from the old Herbals and the works of the early anatomists and microscopists. Perhaps too much attention is paid to personalities and individual discoveries—one certainly gets no very clear view of the general growth of ideas. For this defect the author's method of arrangement is partly responsible, for he is too much inclined to follow up the various lines of research singly and in isolation from progress in other directions—hence a certain disjointedness in the treatment.

One might complain, too, that some periods are treated in far too great detail compared with others of greater importance, that in particular too much space is given to the late Middle Ages, while the nineteenth century is treated rather cursorily. But it is true that the book does not profess to bring the story in any detail past about the middle of last century, and one can see that Locy was keenly interested in the early workers; his elaboration of detail about them has been a labour of love. There are other points which lend themselves to criticism, particularly his very low estimate of Aristotle's theory of development as given in the "De generatione animalium," but these need not obscure the real merit and interest of the book. Although interest in the history of biological science has of late years greatly increased in Great Britain, thanks in large measure to Dr. Charles Singer, more attention still should be paid to it for its educative value. For this reason Dr. Locy's book should find a place in every biological library. It is a pity he did not live to write the volume which he contemplated on the history of evolution-theory and genetics.

E. S. R.

Sexual Physiology.

An Introduction to Sexual Physiology: for Biological, Medical and Agricultural Students. By F. H. A. Marshall. Pp. xii+167. (London: Longmans, Green and Co., Ltd., 1925.) 7*s*. 6*d*. net.

IT is a relatively simple matter to interpret a science in a popular way to an audience that is entirely ignorant of it: it is a far more difficult thing to simplify the complicated for those who, keenly interested, strain eagerly at the threshold of their professional careers, since if great care is necessary in the selection of one's subject matter, still greater must be taken in the method of its presentation. Whatever else may be taught, it is imperative that the student of science shall, from his initiation, be made aware of what science is and of the discipline that must be self-imposed by those who serve. We may be sure that not all those who insistently urged Dr. Marshall to write this book, knowing how great was the need for it, recognised that they were setting him so difficult a task. He was to take his standard work on "The Physiology of Reproduction," refine it, and make it palatable to such as possess but a rudimentary knowledge of biology, to students of agriculture, medicine, and of pure science.

This small and remarkably inexpensive book that Dr. Marshall has written adequately presents that essential minimum of information relating to the subject of sexual physiology which ought to be possessed in common by every biologist, be he pure biologist, agriculturist, medical, or sociologist. In our opinion, the apprentice of pure biology cannot read the author's larger work too early in his career and should not be encouraged to begin with the volume under review. Medical and agricultural students will be well advised to use this book as a supplement to the usual text-book of general physiology. Those who are, or who intend to be, active in the field of sociology should be compelled to read and digest it before being allowed to enunciate doctrines or remodel laws concerning the social aspects of human reproduction. The book will be largely used. We therefore submit to the author certain criticisms in order that he may consider them against the time when the call will come for the second edition.

Chapters i.-v., dealing briefly with the anatomy and physiology of the reproductive system, the sexual cycle, pregnancy, parturition, the puerperium, and lactation, adequately present the essentials of these subjects. Certain alterations can be suggested. In the illustration of the sperms of different species it is a mistake to show two figures from the frog and the boar, differing in size and form, unless some explanation of this difference is appended. The alert student will imagine that sperm dimorphism, of which he will read later, is of the magnitude suggested by this illustration. Instead of stating that in the bee the female "gives rise to two kinds of eggs, one kind developing without fertilisation and giving rise to drones or males while the eggs of the other kind, which are fertilised by stored-up sperm, develop into workers and queen, both of which are females," would it not be better to say that if an egg is fertilised it develops into a female, a queen or a worker; if it is not fertilised, it gives rise to a male, either sexually functional or else a drone? The statement that "in certain hermaphrodite species the two sorts of sex cells are produced simultaneously by the same individuals, but in these the spermatozoa and ova are found at different seasons, the individual animals sometimes functioning as males and sometimes as females," is an instance of simplification that ends in profound obscurity. Finally, we think that the author is mistaken in his occasional choice of the teleological form of presentation. Those of his fellow-teachers who rigorously avoid this all too simple method of teaching already find it sufficiently difficult to break the student of this habit of thought.

Chapter vi., on internal secretion, is clear, simple, and necessarily dogmatic. The author is misled by his authorities when he states that following ovariotomy in the hen the erectile structures about the head remain unaffected. In point of fact, following ovariotomy, if the right gonad does not become active, the head furnishings undergo a very marked diminution in size.

In Chapter vii., on heredity and sex, the author enters the less familiar field of the genetical aspects of sexual physiology. In order to make the survey of the subject complete, this was necessary; but the result is distinctly unfortunate, for this chapter is marked with inaccuracies and much of it is extremely obscure. The plea of simplification cannot excuse the repeated teaching that the gametes or the chromosomes carry the hereditary characters. The sex-chromosomes do not differ from the autosomes in their behaviour. It is incorrect to state that "the Y-chromosome may seem to be wanting altogether so that it was thought formerly that the male had one fewer chromosome than the female." It is an established fact that in many forms there is in one sex one unpaired sex-chromosome. The attempt to explain in simple terms and briefly Goldschmidt's Time Law of Intersexuality is not successful.

Chapter viii., on fertility, will provoke the student to serious thought, being rich in philosophy and admirably written. The only statement which we think is unnecessarily obscure is that "in certain breeds of fowls Pearl has found further that one of the factors for increased egg production is sex-linked, being present in the cock only and transmitted by him to the next generation of hens." The chapter and the book ends with an apt quotation from Keynes' article on "Reconstruction in Europe," and the student reading this will not fail to realise how far he has travelled since first he opened this excellent work.

F. A. E. Crew.

A Woman of Science.

Hertha Ayrton, 1854–1923: a Memoir. By Evelyn Sharp. Pp. xv + 304 + 5 plates. (London: Edward Arnold and Co., 1926.) 15s. net.

In her memoir of Mrs. Ayrton, Miss Evelyn Sharp has given an excellent account of the life and work of a remarkable woman, and has appropriately dedicated the book to Madame Curie as a co-worker in science and democracy for whom Mrs. Ayrton had a high regard.

The volume of some 300 pages is divided into twenty chapters and has five illustrations. It is well printed and, so far as the reviewer has been able to check, its contents are very accurate. Only two slight errors have been noticed, namely, on pp. 140 and 303 where "Morley" appears instead of "Mordey," and on p. 229 (3 lines from bottom) where the word "After" should read "Before."

From the book it appears that in early childhood, Phoebe Sarah Marks (as she then was) showed marked intelligence and originality, and displayed unusual ability and resource. These facts were noticed by her well-to-do and talented relatives, the Hartogs, who, in consequence, gave her an education her parents were unable to afford. Miss Marks' girlhood was nevertheless a strenuous one, and when barely sixteen years of age she took a post as governess in a private family so that she might help to support her widowed mother and invalid sister. Through her relatives she was introduced to many persons of influence and repute, several of whom aided Miss Marks in her ambition to enter Girton College, which had then been recently founded for the higher education of women. Although her examination records at Girton were not brilliant, her supporters never lost confidence in their protégé, and this confidence was amply justified by her subsequent achievements.

Before proceeding to Girton, Miss Marks took great interest in physics and mechanics, and helped one of her boy-pupils to make a model steam engine. Further evidence of the scientific bent of her mind was given by the invention of a "sphygnometer," whilst at Girton, and of a "line divider" shortly after she came down; the latter instrument was put on the market by Messrs. Stanley, of Great Turnstile, Holborn, and was described before the Physical Society of London.

Short accounts of Miss Marks' first meeting with Prof. Ayrton in 1882 and of their marriage in 1885 are given in Chapters vii. and ix., whilst Chapters x. and xi. describe Mrs. Ayrton's classical researches on the electric arc, and her admission to the Institution of Electrical Engineers. The origin and progress of Mrs. Ayrton's painstaking work on sand ripples are then described in some detail, and in a manner creditable to both worker and biographer. These researches led to the award of the Hughes Medal (for original discovery in physical science) by the Royal Society in 1906, thus giving further confirmation of her success in science, which had previously been acknowledged by her election as member of the Institution of Electrical Engineers.

A considerable portion of Miss Sharp's book is devoted to the part Mrs. Ayrton took in the Suffragist movement in Great Britain, in which both author and subject were keenly interested. Mrs. Ayrton's many activities in this campaign must have interfered seriously with her purely scientific work, but in spite of this, she managed to carry out several investigations. She extended her studies on sand ripples and associated phenomena, and developed a new type of carbon for producing steady arcs for cinemas and searchlights.

The closing chapters of the book deal mainly with the "Ayrton Anti-Gas Fan," invented shortly after the first gas attack in the War. This invention was a development of Mrs. Ayrton's sand ripple studies and of the vortices which accompany the production of ripples. Immense difficulties were experienced in getting the authorities to give the fan a fair trial; this was largely due, in the inventor's opinion, to its extreme simplicity. Even when the fan was adopted, it was sent to the front in insufficient numbers and without proper instructions for its use.

In conclusion, one may say that this book is an admirable record of the life and work of a woman distinguished alike as scientist, suffragist, and humanitarian.

T. M.

The Yorkshire and Nottinghamshire Coalfield.

Memoirs of the Geological Survey, England and Wales. The Concealed Coalfield of Yorkshire and Nottinghamshire. By G. V. Wilson. Second edition. Pp. vi+283+5 plates. (London: H.M. Stationery Office; Southampton: Ordnance Survey Office, 1926.) 8*s.* net.

THE second edition of the memoir on the Concealed Coalfield of Yorkshire and Nottinghamshire has just been issued by the Geological Survey of Great Britain. The first edition by Dr. Walcot Gibson was published so far back as 1913; at that date the development of this important coal area had only just commenced and our knowledge of it was relatively slight. Since that date numerous boreholes have been put down, a good many shafts sunk, and not a few important collieries have been developed and are now working and raising coal, and in consequence a vast number of data concerning the geology of this area has been accumulated. The present volume, more than double the size of the first one, embodies the results of the knowledge thus acquired.

The memoir appears at a very fortunate moment when this coalfield is undergoing intensive development, and, as may be gathered from the recent report of the Coal Commission, it is to-day one of the few remunerative coal-producing districts in Great Britain and bears every indication that its future will prove to be of great national importance. The present volume will be of the utmost use, and possibly no portion of the report will be more carefully studied than Chap. iv., which deals with the configuration, structure and limits of the coal basin. In this respect the eastern boundary of the basin is the one on which the greatest amount of discussion centres, and it is a point which will seriously affect the working of the entire coalfield. Thus the first report of the Royal Commission on Mining Subsidence, which dealt particularly with the area described in this memoir, which the Commission has spoken of as the Doncaster Area, points out that an effective scheme for dealing with the flooding due to colliery subsidence must be governed largely by the position of the eastern boundary of the coalfield, as to which geologists are still in doubt. The present report shows that this doubt still subsists. The first report issued in 1871 placed the boundary of the concealed coalfield 2 or 3 miles east of the Trent; the final report of the Royal Commission on Coal Supplies of 1905 adopts the view of Prof. P. F. Kendall, which places the boundary 20 to 30 miles east of the Trent. The present report shows that in all probability both views are right, and that in the neighbourhood of Newark the limit assigned in the older report is probably correct, whilst to the east of Lincoln the "line approximates more nearly to that suggested by Professor Kendall."

The volume before us contains a mass of information; it discusses the various formations in detail, then proceeds as stated to consider the configuration of the coal basin, and finally contains a large number of valuable records of sections derived from shaft sinkings and borings. The appearance of this volume at the present moment will be exceedingly welcome to all interested in this important coalfield.

Our Bookshelf.

Ergebnisse der Biologie. Herausgegeben von K. v. Frisch, R. Goldschmidt, W. Ruhland, H. Winterstein. Erster Band. Pp. viii+670. (Berlin: Julius Springer, 1926.) 36 gold marks.

THE vast and ever-increasing flood of indiscriminate publication—including observations of every degree of importance and trustworthiness—which at present constitutes a real menace to the ordered progress of biological science, brings in its train the need of organised publication of 'potted extracts' of contemporary biological literature. An admirable publication of this kind summarising modern advances in our knowledge of the functional as opposed to the anatomical side of zoological science was Winterstein's great handbook of comparative physiology, which, commencing to appear some fifteen years ago, has recently reached completion. The new "Ergebnisse der Biologie" may be regarded as a continuation of Winterstein's handbook, to deal with contemporary literature in the subject as it appears. The scope of the new periodical is, however, rather wider, as its purview will cover comparative physiology in the broadest sense, including such subjects as plant physiology, experimental embryology, animal psychology, and the study of heredity.

That the work will be well done is guaranteed by the names of the distinguished quartet of editors. The opening volume deals with the comparative physiology of the skin of vertebrates (Biedermann), the ascent of sap in plants (Bachmann), the relations of the plant-cell to chemical salts (Kaho), ammonia, nitrate and nitrite as sources of nitrogen for the higher plants (Prianischnikow), the social psychology of birds (Katz), and the migration of birds (Wachs). The contemplation of these titles indicates how wide is the field over which the subject matter is distributed, but it also indicates clearly what will be the future of the periodical—not a systematic survey of all the literature appearing within its boundaries, but rather a series of summaries of isolated and restricted portions of the subject by competent specialists. Such a system, although lacking completeness, is probably on the whole of greater real use to students. Thus in the volume under review the first article is in effect an excellent and well-illustrated text-book of 342 pages upon its subject.

The new periodical will have to be added to the libraries of all university schools of biology.

Practical Coal Production. Preliminaries of Coal Mining: Prospecting, Explosives, Development, Drainage, Ventilation. Compiled by Frank H. Kneeland. Pp. vii+419. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926.) 15*s.* net.

THIS little work contains a brief description of American coal-mining practice in certain branches of the industry. There are six chapters, the contents of which are: (1) Prospecting, (2) explosives and blasting, (3) development operations, drifting, tunnelling, shaft sinking, (4) planning, projection, development, (5) drainage, (6) ventilation and ventilation equipment. When it is seen that the whole work only comprises 413 pages, it will be obvious enough that no one of these subjects can have received anything like adequate treatment, and a perusal of the work leaves on one's mind the impression that the information conveyed is of a decidedly 'scrappy' nature. To prevent misconception, it may be pointed out that Chap. iv., which is headed "Planning, Projection, Development," refers entirely to the lay-out of the surface and does not attempt to discuss the infinitely more important question of the lay-out of the underground workings.

The work deals entirely with American practice, and in that respect will afford little or no assistance to mining engineers in Great Britain. For example, in dealing with shaft sinking, the author states that circular, elliptical and other forms of shafts are used, but he practically confines his attention to the rectangular shaft; this is the only form that he considers when discussing the size of shafts, as indicated by the following statement: "Main hoisting shafts vary greatly in size, some being as small as 5 × 10 ft., whilst others are as large as 15 × 60 ft. in the clear." He makes no attempt at discussing the relative advantages or disadvantages of the two types of shaft, but, in conformity with general American practice, takes the rectangular type more or less for granted.

The book throughout contains many little bits of useful information, though occasionally we find a mass of detail which is scarcely necessary, as, for example, the elaborate instructions for priming and attaching the fuse to a blasting cartridge. Such information is quite unnecessary for the practical mining engineer, and is in any case out of place in a book, as it is always far better and more rapidly learnt by actual experience; it is, in fact, one of the weak points of the work that it appears in places to be addressed to the beginner at the very outset of his career, and in others to be written for the experienced mining engineer.

Telephone Communication Systems. By Prof. Royce Gerald Kloeffler. (Engineering Science Series.) Pp. vii+284. (New York: The Macmillan Co., 1925.) 17*s.* net.

THE author gives a brief account of the whole field of telephony, laying stress on the latest developments of the art. In the United States there are more than 15 millions of telephones in use and thousands of miles are bridged between many pairs of them. Sound waves would take four hours to travel through the air from New York to San Francisco. With the help of electricity, however, they go over the transcontinental line in about the fiftieth of a second. By General Squier's method the same wire can also, theoretically at least, carry twenty-four simultaneous telephone messages, although in practice arrangements are seldom made to carry more then five distinct messages simultaneously. The development of the thermionic valve repeater has placed long-distance telephony on a sound engineering basis. The invention of electric filters which only allow waves of definite frequencies to pass through them led to multiplex telephony.

Heaviside's and Pupin's loaded cables are still used for submarine work and in long-distance land lines. In the latter case, however, valve repeaters are now largely used. It is pointed out that appreciable reflection losses occur when two lines having different electric constants are joined together. These losses are quite distinct from attenuation losses. We are glad to see that a sharp distinction is made between electrostatic and electromagnetic interference. The former is particularly troublesome on telephone circuits. When there are high-tension circuits in the neighbourhood, the electrostatic induction sometimes makes the potential difference between the telephone wire and the earth so great that there is a risk of a serious shock. In the concluding chapter the elementary principles of radio telephony are clearly explained. The book can be recommended to electrical engineering students who desire to get a general insight into the theory and practice of telephony.

Elementary Electrical Engineering: a Lecture and Laboratory Course intended for Students preparing for the First National Certificate Examination in Electrical Engineering. By Prof. O. R. Randall. (Technical School Series.) Pp. vi+233. (London: Sir Isaac Pitman and Sons, Ltd., 1926.) 5*s.* net.

THE combination of lecture work with laboratory experiments given in this book is good, but we are doubtful as to the educational value of some of the mathematical demonstrations given. For example, after saying that the average and effective values of the ordinate of a sine wave are $2/\pi$ and $1/\sqrt{2}$ times its maximum value respectively, it is stated that these relations may easily be demonstrated by drawing the curves and finding their mean heights. The industrious student, therefore, is expected to draw the sine curve, and the curve the ordinates of which are the squares of the sine, and get their mean heights. He doubtless knows that the results will come out within one or two per cent. of the numerical values of the mathematical expressions given above, but he will probably prefer to take the easier course of accepting the author's word that they are correct. We are told that if the three vectors representing the currents in a three-phase system are added together they form a closed triangle and their resultant is therefore zero. We think that this is looking at the matter the wrong way round. Since the algebraical sum of the three currents is by Kirchhoff's law always zero, their resultant, that is, the effective value of their sum, must of necessity be zero, and therefore the three vectors form a triangle. This is true whatever the shape of the current waves may be. We fully recognise that the mathematical knowledge of many of the candidates preparing for the national certificate is limited, but we think that some of the proofs given are too sketchy.

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 182. Abt. 9: *Methoden zur Erforschung der Leistungen des tierischen Organismus*, Teil 1, 2 Hälfte, Heft 1. *Spezielle Methoden: Tierhaltung und Tierzüchtung. Züchtung von wirbellosen Tieren.* Pp. 214. (Berlin und Wien: Urban und Schwarzenberg, 1925.) 9·60 gold marks.

THE present instalment of the encyclopædic work edited by Prof. Abderhalden is concerned with the keeping and rearing of animals for scientific observations. Dr. Kammerer discusses the subject in so far as Reptilia and Amphibia are concerned, and his experimental researches are familiar to all zoologists. This article is followed by one by Dr. Heitkertinger on the general apparatus and technique used in rearing insects. There are also separate articles by different specialists dealing with particular methods applicable to the Apterygota, the "Amphibiotica," Orthoptera, Corrodentia and Rhynchota. These different sections are something more than guides to the technique concerned, since the life-histories and behaviour of representatives of the various orders are discussed in detail, with numerous bibliographic references. The most extensive contribution is that by Dr. F. Zacher on the Orthoptera: this might almost be regarded as a complete synopsis of the biology and economy of that group. The remainder of the Insecta is to be dealt with in future issues. A. D. I.

Cellulose Ester Varnishes. By F. Sproxton. (Oil and Colour Chemistry Monographs.) Pp. 178. (London: Ernest Benn, Ltd., 1925.) 15*s.* net.

THIS volume of the series of oil and colour chemistry monographs is an excellent statement of the properties of the cellulose esters used for varnishes and of the finished products prepared therefrom. Particular attention has been given to those physical properties, viscosity, solubility, swelling, dispersion, and so on, which are important for the practical utilisation of cellulose esters in varnish making. In fact, pp. 58-92 constitute one of the best and most readable accounts of physical behaviour of cellulose esters available in so short a space. The nature and properties of the solvents of cellulose esters and the reasons for using them are adequately dealt with. Chapters dealing with the manufacture, application, and examination of cellulose ester varnishes furnish all the information which can reasonably be expected in a volume of this character. The subject matter is presented clearly throughout, and the work may be recommended to all those who desire an accurate statement of the present position of a growing branch of industry.

The Birds of the Riviera: being an Account of the Avifauna of the Côte d'Azur from the Esterel Mountains to the Italian Frontier. By Collingwood Ingram. Pp. xv+155+6 plates. (London: H. F. and G. Witherby, 1926.) 12*s.* 6*d.* net.

MR. COLLINGWOOD INGRAM has produced a book on the birds of the Riviera which will be useful to ornithologists among the many English-speaking visitors to that region. The scope of the work excludes the Italian portion of the littoral, but, on the other hand, it includes the whole of the French department of Alpes Maritimes, a fact which brings many strictly alpine species within its purview. The arrangement is systematic, and the text is not burdened by descriptions of those species which will be familiar to British readers at home and are dealt with in the ordinary text-books upon British birds. In addition to English and scientific names, the French and Niçois equivalents are conveniently given. The illustrations include numerous sketches by the author and a number of plates by well-known artists.

Flora of the Presidency of Madras. By J. S. Gamble. (Published under the Authority of the Secretary of State for India in Council.) Part 7: *Nyctaginaceæ to Euphorbiaceæ.* Pp. 1161-1346. (London: Adlard and Son and West Newman, Ltd., 1925.) 10*s.* net.

A MELANCHOLY interest is attached to this review, since the author of the work under notice died while it was still in the press, though he was able to correct all but the last few sheets of the proofs. It is greatly to be regretted that Mr. Gamble did not live to complete the flora, for he had an unrivalled knowledge of the region and its flora.

Part 7 now issued begins the Monochlamydeæ, and comprises the families according to the Genera Plantarum sequence from Nyctaginaceæ to Euphorbiaceæ with some minor deviations, *e.g.* the Hernandiæ are separated from the Lauraceæ forming the family Hernandiaceæ to include Gyrocarpus. Four new genera, twenty-five new species (mostly first described in the *Kew Bulletin*), and eleven new combinations are included. C. E. C. F.

Die gasanalytische Methodik des dynamischen Stoffwechsels. Von Dr. Wilhelm Klein und Maria Steuber. Pp. 99. (Leipzig: Georg Thieme, 1925.) 5·40 gold marks.

THE authors bring together certain well-known methods of determining metabolism by means of the respiratory exchange. The most space is devoted to a description of the Zwetz-Geppert method, which has not been used in England or America for a good many years. With the exception of the student apparatus of Benedict, which does not give the respiratory quotient, and an inadequate account of Krogh's latest apparatus, no description of any of the numerous variants of portable metabolism apparatus is given. The book contains nothing useful which is not already available in convenient form to English and German readers. The few references to the literature are given with little care.

E. K. R.

Qualitative Inorganic Analysis. By Dr. D. R. Snellgrove and Dr. J. L. White. Pp. xi+281. (London: Methuen and Co., Ltd., 1926.) 7*s.* 6*d.*

THE explanations and practical hints given in this book are more detailed than is usual and will be found of value. The standard is that required in B.Sc. honours examinations. The authors appear to dislike tabular presentation in group separations, but there can be little doubt that this form is more convenient in laboratory work and in recording the results obtained in practical examinations. The book is printed on thick paper and does not remain open easily, both disadvantages in laboratory use.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dutch Pendulum Observations in the Atlantic and the Pacific.

I AM able to give the following particulars of the proposed pendulum observations in the Atlantic and the Pacific. In compliance with the request of the Geodetic Committee, the Minister of Marine has resolved that H.M. Submarine K XIII, appointed for service in the Dutch East Indies, will make the voyage to Java via the Panama Canal, in order to enable Dr. Vening Meinesz to make pendulum observations in the Atlantic and the Pacific. The main object of this voyage being scientific, the route has been fixed in accordance with the wishes of Dr. Vening Meinesz.

On May 26 the submarine will start from Helder; it will be at Fayal (Azores) July 4-6, and at Las Palmas (Canaries) June 12-16. From there it proceeds to the Porto Rico deep, crossing for the second time the middle Atlantic ridge, and thence by the Mona Passage to Curaçao, where it remains from July 5 until 17. It will be at Colon, July 20-22, and at Panama, July 22-26. In the Pacific it will at first sail westward to reach the deep sea, and then return to the coast; on August 6-12 it will be in Mazatlan and will reach San Francisco, August 20. It starts from there for the crossing of the Pacific on September 2; it will be at Honolulu on September 14-27, at Guam on October 16-28, and at Yap on October 30-November 2. Before reaching Guam it passes the Nero deep (5268 fathoms). From Yap it sails to Manila by the Straits of Surigao, crossing the Manila deep, where the greatest known sea depth (5350 fathoms) has been sounded. It remains at Manila from November 11 until November 17 and sails then for Ambon, where it stays from November 24 until November 29. Via the Banda deep it reaches Bima (Sumbawa), where it remains from December 5 until December 8, and will arrive at Surabaya on December 10 after a voyage of 195 days, 109 of which are sailing days. The whole length of the track is nearly 20,000 miles.

In the light of the experience which Dr. Vening Meinesz has gained of the new pendulum apparatus on his voyage to Port Said (NATURE, April 10, p. 531), some improvements have been made in the workshop of the Meteorological Institute of de Bilt. The suspension apparatus with one axis, to be placed parallel to the keel of the ship, has been replaced by a support with double gimbals in order to avoid the sliding of the pendulums caused by the pitching of the vessel. Probably by this means it will be possible to make observations at a lesser depth below the surface of the sea, and perhaps in favourable circumstances at the surface itself. This modification necessitated the connexion of the recording apparatus with the support; the former is now placed with the slit in a horizontal position above the former. For the guidance of the rays of light a system of prisms has been added.

The accuracy of the observed time signals during this voyage will be increased by the loan from the U.S. Coast and Geodetic Survey, with the consent of the Secretary of Commerce of the United States, of a wireless recording set. Special thanks are due to the Director, Mr. E. Lester Jones; the Assistant Director, Mr. R. L. Faris, and the Chief, Division of Geodesy, Dr. W. Bowie, for their valuable co-operation in this matter.

The time signals to be used will be first those of Bordeaux, then those of Annapolis, and afterwards those of Balboa. The co-operation of the U.S. Naval Observatory at Washington has been obtained for the control of these signals. During the voyage in the Pacific rhythmic time signals will be given by the powerful radio station of Malabar (Java), controlled by the Observatory at Lembang. This will control also the time signals of Manila, which may be used in the western part of the Pacific.

At the request of Commander J. H. L. Luymes, Hydrographer of the Dutch Marine and member of the Geodetic Committee, the Hydrographer of the U.S. Navy sent a set of charts of the Pacific where the most recently obtained sea depths are noted. For the determination of the sea depth during the voyage the submarine will be provided with a sonic depth-finder of the type of the British Admiralty, constructed by Messrs. Hughes and Sons of London, with regard to which the Hydrographer of the British Navy, Captain Douglas, has rendered much valued assistance. With regard to deep soundings, the voyage of the submarine may also give valuable contributions.

I will not digress into a discussion of the advantages that may be derived for science from the observations of Dr. Vening Meinesz. I will but mention that as the track runs for a great part of the length not far from and nearly parallel to the equator, the question whether this is elliptic or not will probably be solved. The observations in general, and especially those near the coasts, as well as those near the edges of and above the great deeps, will be of much interest for the study of isostasy and other geophysical problems concerning the constitution of the earth's crust.

I may perhaps be allowed to express the hope that the example given by the Dutch Navy in the investigation of purely scientific questions will soon be followed by other nations.

J. J. A. MULLER.

Zeist, May 1.

Optical Rotatory Dispersion.

SINCE the publication of Prof. T. M. Lowry's article in NATURE of February 20, 1926, p. 271—an article which, I observed, drew a gentle remonstrance from Prof. Armstrong in the issue of April 17—I have felt that some rejoinder was desirable, but was held back by the fact that adequately to criticise Prof. Lowry's views would require considerably more space than the article itself, since almost every statement made, far from possessing the definiteness which Prof. Lowry attributes to it, is highly controversial, and it usually requires less space to make an assertion than convincingly to refute it. But perhaps I may be allowed to point out that so far back as 1916 (*J.C.S.*, 109, 1211-1216, 1222-1224) I offered a reasoned criticism of most of the views which Prof. Lowry has so industriously advocated in the last few years, and that hitherto Prof. Lowry has not attempted any reply to these criticisms. Incidentally it may be suggested that Prof. Lowry does his thesis some disservice by a policy of aloofness from valid criticism directed against it. It may, of course, be that the criticisms are unanswerable, in which case Prof. Lowry's views require modification.

In addition to the criticisms already made, I would add here one or two more. In the first place, Prof. Lowry's views depend entirely upon some observations of Biot, made many years ago, according to which he found that the rotation dispersion of a mixed solution of oil of terebenthene and oil of lemon was identical with the sum of the dispersions of the same substances separately (*Compt. rend.*, 1836, **2**, 543; see also *Ann. Chim. Phys.*, 1852 [iii], 36, 430). Now the accuracy with which Biot could carry out his observations was very much less than that possible at the present time, which may perhaps be illustrated by the fact that whereas Biot thought that quartz conformed to his simplest law of rotation dispersion, Prof. Lowry himself has shown that a Drude expression of no less than three terms is necessary to represent its behaviour. Further, it has not been shown with modern accuracy, either that the rotation dispersions of terebenthene and oil of lemon conform to Prof. Lowry's definition of simple dispersion, or that when mixed together they conform accurately to his definition of anomalous dispersion. Practically all modern work has demonstrated very clearly the fact, of which Biot was aware, that only in exceedingly few cases, if indeed in any, can one obtain, by mixing together two optically active liquids, purely additive results. It is doubtful, therefore, whether it is even worth while to repeat Biot's experiment.

Again, Prof. Lowry seems to be unduly partial towards the evidence which he adduces in favour of his views. Thus, for example, he says: "Tschugaeff has shown that anomalous rotatory dispersion can be produced by superposing the opposite partial rotations of two radicals in the same molecule, as in *l*-menthyl *d*-camphorsulphonate." This statement is utterly misleading. Tschugaeff found the dispersion of *l*-menthyl *d*-camphorsulphonate to be anomalous, and he *suggested* that this might be due to the superposition of two opposite partial rotations, but he certainly did not *show* that this is actually the case. It suits Prof. Lowry's view, however, to regard Tschugaeff's assumption as equivalent to a demonstration, but he makes no reference to the fact that in *l*-menthyl *d*-camphorsulphonate there are not two asymmetric centres in the molecule, but actually five—and even six if Prof. Lowry's idea of the asymmetry of the carbonyl group be adopted—so that the rotation dispersion of menthyl camphorsulphonate should be a very complex affair if superposition of asymmetric centres in the molecule plays a part in it.

It would easily be possible to extend these remarks.

T. S. PATTERSON.

Organic Chemistry Department,
University of Glasgow,
April 26.

I FIND it difficult to discover what reply Prof. Patterson expects to his courteous letter of April 26. From the two experiments which he cites I gather that he wishes to call in question the general proposition that *anomalous rotatory dispersion in transparent media is due to the superposition of two normal rotations*[1] *of opposite sign*. He has, however, described these two experiments in such a way that it is difficult to believe that either Biot's or Tschugaeff's paper was before him when he wrote his letter. In particular, Biot's synthesis of an anomalous rotatory dispersion, by superposing two normal dispersions of opposite sign (*C.R.*, 1836, **2**, 540), does not depend, as he suggests, on the existence of an additive law of optical rotatory power in mixed liquids, since in the first instance the liquids were not mixed but were contained in two separate tubes, the superposition of rotations being purely optical. A precisely similar result was obtained when the two liquids were mixed, but there are no numerical data in the paper which would justify the assertion that Biot "found that the rotation dispersion of a mixed solution . . . . was identical with the sum of the dispersions of the same substances separately"; nor does my acceptance of the general proposition set out above depend on any such assumption.

In the same way, Tschugaeff's experiment (*Ber.*, 1911, 44, 2023) was not a mere numerical exercise in the summation of optical rotations, but a definite test to find out whether anomalous rotatory dispersion could be produced by "intramolecular superposition" as well as by Biot's process of "extramolecular" superposition. His experiment showed that an alcohol and acid, the opposite rotations of which would have given rise to anomalous dispersion if superposed by either of Biot's methods, also gave rise to anomalous rotatory dispersion when united into a single molecule by the elimination of a molecule of water. This successful synthesis has been generally accepted as evidence of the continued existence of the opposite partial rotations of the two radicals after esterification;[2] and its success does not depend, as Prof. Patterson appears to think, on the accuracy of the law of optical superposition, which Tschugaeff himself regarded as only a "first approximation." Nor is it necessary that the component "normal" rotations in any of these syntheses should conform to the law of "simple rotatory dispersion."

Since, as I have shown (*J.C.S.*, 1925, **127**, 606), there are at least six different ways (mathematical, physical or chemical) in which normal rotatory dispersions may be superposed to produce anomalous rotatory dispersion, there is plenty of room for diverse opinions as to the particular form of superposition which gives rise to this effect in any given case; but I do not think that any useful purpose would be served by a discussion in the columns of NATURE of these applications of a general principle which was established once for all by Biot in 1836.

T. M. LOWRY.

Cambridge, May 1.

Hardness of Copper-Tin Alloys.

IN NATURE of January 23 I described some experiments on the hardness of various materials, the hardness being measured by the pressure which the material can withstand.

Since that time the same test has been applied to many of the metallic elements, and it is intended to form as complete a table as possible of the hardness of those to which this method is applicable.

Some experiments have also been made on the hardness of alloys, and its variation with the relative proportions of the constituent metals.

An example for copper-tin alloys is given in the accompanying diagram (Fig. 1). These alloys exhibit an extraordinary range of hardness passing from 48 tons/inch^2 (pure copper) to about 6 tons/inch^2 (pure tin), but rising to 220 tons/inch^2 when one-third of the volume is tin (speculum metal). The hardness of the latter is about that of rather a low temper spring steel, though the other physical properties of the two are very different.

I found that small quantities (a gram or less) of the required alloys could be conveniently made by melting the proper proportions of the constituents under borax in the closed end of a hard glass tube, using a gas blowpipe with a little oxygen added. If the process is properly carried out, the fused metal becomes embedded in a solid glass globe hanging by a narrow neck to the end of the glass tube On breaking the globe when cold, the alloy is found as a bright and nearly spherical bead.

---

[1] A 'normal' rotatory dispersion is defined as one in which α, $d\alpha/d\lambda$, and $d^2\alpha/d\lambda^2$ remain constant in sign throughout the region of transparency. In an 'anomalous' dispersion, changes of sign may occur in all these quantities, giving rise respectively to a reversal of sign, a maximum and an inflexion in the dispersion curve.

[2] The statement which Patterson describes as "utterly misleading" is a close paraphrase of the words used by Tschugaeff himself in describing his experiments in the Faraday Society's general discussion on "Optical Rotatory Power," when he claimed that he had shown "that anomalous dispersion may be produced by the *superposition of the partial rotations produced by two asymmetric complexes within the molecule of an active body*." (*Trans. Faraday Soc.*, 1914, 10, p. 73).

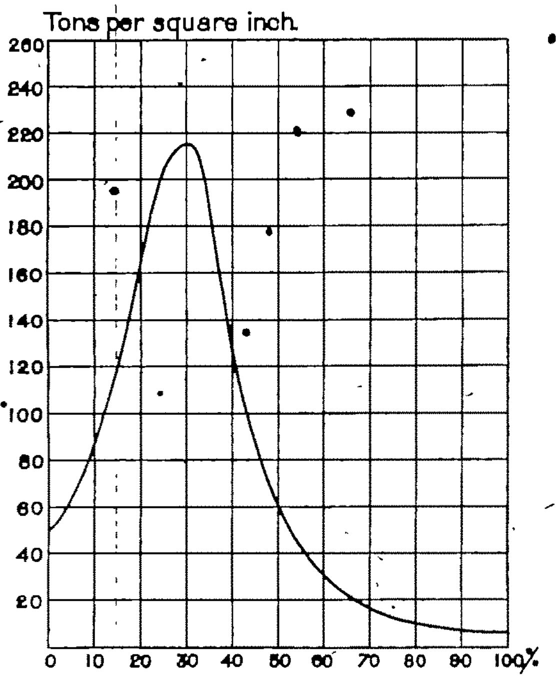

FIG. 1.—Diagram showing the hardness of copper-tin alloy in terms of the volume-percentage of tin The ordinates give the hardness of the alloy in tons per square inch, the abscissæ are the percentages of tin by volume.

The glass remains clear and uncoloured, and it may be assumed, therefore, that there has been no loss by oxidisation. A. MALLOCK.

9 Baring Crescent,
Exeter.

Egyptology in Victorian Dress.

As the reviewer of "Descriptive Sociology" (NATURE, April 24, p. 578) accuses me of misrepresenting the divergent views of chronology, while making an *ex parte* statement himself of the 'demolition' of a view which he dislikes, I trust I may be permitted to outline the facts.

All scholars agreed in accepting what the Egyptians recorded as to the beginning of the history by the first dynasty about 5500 B.C., until Bunsen in 1845 started a truncation of this to 3600 B.C., rejecting the records because of our ignorance of the monuments. Yet the Egyptian view was maintained in Germany until 1884 or later. Since then, most important discoveries of monumental material have led Berlin scholars to go back to 4186 B.C., which is still the date accepted by officials of the Berlin Museum. Further, museum authorities in England, France and Belgium consider that some centuries earlier is a more likely date, but I did not quote them, as they vary. Behind all this shortening there is still the Egyptian statement of 5500 B.C. There is no general acceptance of any one view, much to the confounding of European pre-history which hangs on the debate. To attempt to give here the reasons for any of these views would be far too extensive a matter; but impartiality requires that all of them should be stated, as I have done without expressing a preference.

However repugnant the compulsory livery of Herbert Spencer may be, to myself or others, I hope readers of NATURE will find in the "Descriptive Sociology" a fuller statement of Egyptian science than has yet been issued, beside the linking of the prehistoric ages with the later conditions which has not been written before. FLINDERS PETRIE.

BY "the Egyptian statement of 5500 B.C." Sir Flinders Petrie means the *modern* calculations based on the fragments preserved by ecclesiastical copyists of the Egyptian priest Manetho's "History of Egypt," written under one of the Ptolemies. His book contained a general review of the Pharaohs "with the lengths of their reigns, and the total duration of each dynasty" (H. Brugsch, "A History of Egypt under the Pharaohs" (trans.), London, 1879, I. 13). In the first place, a chronological series of such a purely relative nature obviously cannot contain an objective date such as 5500 B.C. for the first dynasty; nor, on the other hand, can a modern calculation—even if it only amounts to the sum of the lengths of the dynasties added to a given date B.C.—be legitimately considered an "Egyptian statement." In the second place, the evidence from the monuments has shown the "absolute necessity of supposing in the list of Manetho contemporary and collateral dynasties, and thus of diminishing considerably the total duration of the thirty dynasties" (*op. cit.* 32). Precisely the same thing happened in Babylonia, where the scribes made lists of the lengths of the dynasties and of their sums, and even of the sums of the total lengths of contemporary dynasties in different cities. Moreover, the necessity of making allowance on this account in dealing with Manetho's records was already appreciated by Brugsch in 1877, as is shown by the quotation above from the English translation of his "Geschichte Ägyptens unter den Pharaonen."

In 1917, Dr. Ludwig Borchardt published a reconstruction of the Palermo Stone and its then newly discovered fragment in the Cairo Museum (which he—unlike Gauthier, Gardiner and Petrie himself—considers to be part of a separate, though similar tablet), and by calculations based on this reconstruction convinced himself that the first dynasty must have begun at about 4186 B.C. This was accepted by certain German scholars at the time, *e.g.* Schaefer, the Director of the Berlin Museum: but not by Eduard Meyer, who was not impressed, and maintained his own chronology, published some years earlier, and from that time until this generally adopted (with slight differences) in Great Britain, in America, and on the Continent. One of the most important of these "slight differences" is Hall's addition of 200 years to the Second Intermediate Period, which brings the date for Menes back to 3500 B.C, instead of 3300 B.C. It is to this modification, proposed not only by a museum curator but an historian as well, that Sir Flinders refers when he says, "museum authorities in England, France and Belgium [not historians] consider that some centuries earlier is a more likely date." As the last date mentioned by him has been "4186 B.C.," the reader naturally assumes that he means "some centuries earlier" than that, instead of Meyer's 3300 which he really has in mind.

Borchardt's 4186 B.C. was "demolished" by Peet in the *Journal of Egyptian Archæology* for 1920, pp. 149 ff. Recently the process has been repeated by Eduard Meyer in his "Die ältere Chronologie des Ägyptens und Babyloniens." The reader has only to pick up half-a-dozen books written in the last three years in Germany to see how unanimously the 'shorter' dating has been accepted

THE REVIEWER.

Relative Intensities of Band Lines in the Infra-red Spectrum of a Diatomic Gas.

IN a previous theoretical discussion of the relative intensities of band lines in the infra-red vibration-rotation spectrum of a diatomic gas by one of us (E. C. Kemble, *Proc. Nat. Acad. Sci.*, 10, 274, 1924, and *Phys. Rev* 25, 1, 1925) the formula

$$a = \text{Const.}\ \frac{\bar{p}}{\nu}e^{-E''/kT} \quad \ldots \quad (1)$$

was derived. Here a denotes the area under the absorption coefficient curve for the line in question when plotted on a frequency scale, and $\bar{p}$ is the mean statistical weight of the two states involved in the transition; E'' is the energy of the lower energy level or initial state for absorption; ν denotes the frequency of the line. Comparison of this formula with the experimental absorption curves then available for the HCl band at 3.5μ indicated fair agreement between theory and observation, provided that $\bar{p}$ was calculated from the statistical weight formula

$$p = 2m + 1 \qquad m = \tfrac{1}{2}, \tfrac{3}{2}, \tfrac{5}{2}, \ldots \quad (2)$$

in which m denotes the nuclear rotational quantum number.

Fowler (R. H. Fowler, *Phil. Mag.* 49, 1272, 1925) and Dieke (G. H. Dieke, *Zeit. f. Phys.* 33, 161, 1925; cf. also E. C. Kemble, *Zeit. f. Phys.*, 35, 286, 1925) have shown that the summation rule leads to the above formula, but with the restriction that the statistical weight formula must be

$$p = 2m \qquad m = \tfrac{1}{2}, \tfrac{3}{2}, \tfrac{5}{2}, \ldots \quad (3)$$

thus giving $\bar{p}$ the series of valnes 2, 3, 6, 8, ...

In order to obtain a decisive test of the statistical weight formula, and also to verify the asymmetry of intensity of the two branches implied in formula (1) (the *R* branch should be more intense than the *P* branch in absorption), the writers have just completed a series of observations on the HCl band mentioned above, using very short absorption tubes. The data permit the determination of the integral absorption coefficients a for the lines observed, and the values thus obtained are in complete harmony with the summation rule.

Using a quartz prism spectrometer we have measured the absorption curves for six absorption paths ranging in length from 0·1 cm. to 3 cm. Curves were drawn of the areas of individual absorption lines plotted against tube length. The initial slopes of these curves give the desired values of a. The accompanying table shows the relative values of a deduced from the experiment, taking the value for the third line of the positive branch arbitrarily as unity. The absolute value of a for this line is 49×10^{10} sec.$^{-1}$. With the exception of the line −6, which is doubtful on account of the strong absorption in the quartz prism, the agreement between the experimental values of a and those computed from the theoretical formulæ (1) and (3) is within 4 per cent. of the absorption of the line +3. For all but two of the lines it is within 3 per cent. The maximum error becomes 10 per cent. if we use formulæ (1) and (2), and we are convinced that (2) is incorrect.

TABLE.

Line	+1	+2	+3	+4	+5	+6	+7
	0·500	0·853	1·000	0·959	0·774	0·542	0·333

Line	+8	+9	+10	−1	−2	−3	−4	−5	−6
	0·185	0·094	0·048	0·485	0·765	0·842	0·768	0·605	0·460

One surprising result of the investigation was the magnitude of the absorption with very short tube-lengths. The maximum observed absorption with a 1 mm. absorption path and a relatively broad slit was 16 per cent. From the shape of the area—tube length curves we can obtain at least a rough idea of the shapes of the lines, which are clearly very much narrower and deeper than previously supposed. Calculation indicates that radiation of wave-length corresponding to the centre of the strongest line is almost completely wiped out by the absorption in the first few millimetres of gas. The variation in shape of the area—tube length curves from line to line gives clear evidence of isotopic doubling and of the change in the doublet spacing due to the rotational isotope effect.

Examination of Dead Sea Water for Eka-Cæsium and Eka-Iodine.

SEVERAL years ago it occurred to me that if eka-cæsium (element 87) is capable of permanent existence, it ought to be found in the Dead Sea. For ages rivers, streams, and rain, all charged with various salts, have poured into that sea, with practically no outlet save evaporation, so that an exceptionally high concentration of salts has resulted. It was not until July 1925 that I was able to visit Palestine and the Dead Sea. Summer is a particularly suitable time to obtain the water, as the enormous evaporation of surface water under the blazing sun causes a marked depression in the level of the Dead Sea, the water evaporating more rapidly than it is replenished by the Jordan, the rate of evaporation being thus estimated as exceeding six million tons of water per diem. Hence the accessible surface waters are more highly charged with dissolved salts than at other periods. This is reflected in their density, for which published data give values round about 1·1546 during the cooler months (Stutzer and Reich, March 1907). My sample was collected at the northern end of the Sea, at a depth of 2 feet, about 50 yards from the shore, and several miles west of the mouth of the Jordan. Its density at 18° C. was 1·2089, and thus more nearly approached the value given by Bernays for a depth of 300 metres, namely, 1·253.

Numerous analyses of Dead Sea water have been published from time to time and the presence recorded of the following ions: Na, K, Mg, Ca, Fe, Al, Cl, Br, I, SO_4, CO_3 and NO_3. My sample contained small but appreciable quantities of strontium, which does not appear to have been observed before. The amount of iron in the waters near the northern shore may now be expected to increase, in view of the erection of a number of crude dwellings on the beach, constructed of wood and flattened-out petrol tins. Many such tins lie also in pools and ditches hard by, imparting a deep ochreous stain to the salt that has crystallised out.

Assuming eka-cæsium to manifest in its salts the same gradation in properties as the other alkali metals, the chloride should be more soluble than the corresponding potassium salt and the chlorplatinate less soluble. After removal of all metals save those of the alkali group from a portion of the sea water, sodium chloride was fractionally crystallised out and potassium chlorplatinate precipitated from the concentrate. Gravimetric analyses showed that if any eka-cæsium were present, its amount was too small to be detected in this way with my limited supply of material. A sample of the chlorplatinate was accordingly sent to Messrs. Adam Hilger, Ltd., who submitted it to X-ray analysis in their laboratory. Several photographs were taken and good lines obtained in the region where eka-cæsium *L* radiations would fall. A line of wave-length 1 037 was recorded, and it was at first thought that this might correspond to the $L\alpha$ radiations of eka-cæsium; but this was apparently not the case, since no corresponding $L\beta$ line could be detected.

The optical spectrum of a sample of potassium chloride, reduced from some of the chlorplatinate, was also photographed by Messrs. Hilger, but the only impurities we were able to identify were traces of sodium and calcium. It would appear, therefore, that eka-cæsium does not exist in the waters of the Dead Sea. Consideration of its position in the Periodic Table, between radon and radium, would suggest that eka-cæsium may itself be radio-active and short-lived, which latter property might render its detection extremely difficult.

A search was likewise made for the presence of eka-iodine (element 85) on the assumption that its silver salt would more be insoluble in water than silver chloride. The latter was fractionally precipitated and exposed to X-ray examination, but without result.

Influence of Electrical Field on the Adsorption of Neutral Molecules.

Not only the adsorption of ions, but also the adsorption of undissociated molecules, depends on the direction and strength of the electrical field at the interface between the adsorbing body and the solution. This circumstance is illustrated by the electrocapillary curves which are obtained if a solution in contact with mercury contains organic substances.

According to Gouy, at a sufficient distance from the maximum the lowering of the interfacial tension by the organic substance vanishes, which means that an intense electrical field prevents the adsorption of organic molecules. The reason for it is that such a field, as it has been recently shown by one of the present writers (*Zeitschr. f. Phys.* 35, 792, 1926), tends to expel organic molecules having a lower dielectric constant and to attract water molecules. The adsorbing action should therefore reach a maximum in the absence of the ionic double layer, *i.e.* at the maximum point of the electrocapillary curve. As a matter of fact, if a molecule being adsorbed charges the mercury surface positively, the maximum of adsorption is somewhat displaced with respect to the maximum of the electrocapillary curve towards the region of negative charge (the case of aliphatic acids and alcohols) and vice versa.

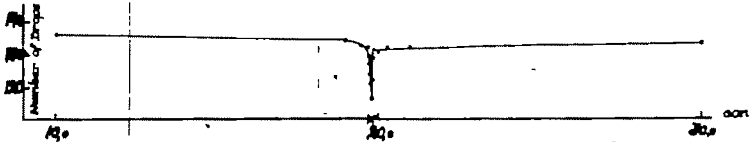

Fig. 1

Starting from this consideration it was natural to look for similar phenomena in the case of solid adsorbing substances. Silver iodide proved a very suitable object in this respect. Investigations of Lottermoser and Fajans have shown that silver iodide precipitated from a solution containing an excess of silver ions is charged by these ions positively, whereas in the presence of an excess of iodine ions it is charged negatively. The potential difference between the solution and solid silver iodide varying with the concentration of silver ions in the same way as in the case of a silver electrode, the point at which concentrations of iodine ions and silver ions are equal corresponds for silver iodide to the maximum point of the electrocapillary curve, and near to it a maximum of adsorption for neutral molecules should be expected.

The method adopted for the measurements was the following: to 20 c.c. of an acidified 0·5 N solution of silver nitrate containing a definite quantity of caprylic acid, a similar solution of potassium iodide was added in small portions. After each addition the concentration of caprylic acid in the solution was determined by its surface tension, measured with a stalagmometer. The data obtained in one series of experiments are plotted on Fig. 1. In the proximity to the point of neutralisation a sharp minimum in the number of drops is observed, which corresponds to a minimum value of caprylic acid concentration in the solution, *i.e.* to its maximum adsorption by the precipitate. The maximum point is somewhat displaced in the direction of an excess of potassium iodide, just as in the case of the adsorption on a mercury surface.

We intend to apply this method to the study of electrocapillary curves of solid metals.

Infra-red Emission from Gaseous Explosions.

The catalytic effect of water and other substances on the speed of explosions of mixtures of carbon monoxide and oxygen has been studied from the point of view of infra-red emission. This has been rendered possible by the use of a Downing galvanometer kindly loaned to us by Prof. A. V. Hill. With this galvanometer and a Hilger infra-red spectrometer, it is a comparatively easy matter to survey the infra-red spectra of gaseous explosions. The explosion spectrum of carbon monoxide and oxygen is qualitatively the same as that of the flame, but the ratios of the intensities of the 2·8μ and the 4·4μ bands are widely different in the two cases. For the explosion of the gases dried over P_2O_5 this ratio is nearly 1 : 1 for a 35 cm. tube, and for the flame 1 : 11. When the gases are saturated with water vapour the ratios are 2 : 1 and 1 : 10 respectively. The intensity of infra-red emission is markedly greater for the dry than for the wet gases, although the speed of explosion in the former is slower. The ratios of the deflexions obtained for the dry and wet gases were about 3 : 2 for the 2·8μ band, and 3 : 1 for the 4·4μ band. The absorption of infra-red radiation by the water vapour in front of the explosion wave is negligible (cf. Hettner, *Ann. Phys.*, 1918, 55, 496). This we have checked by absorption measurements on the wet and dry explosive mixtures. Thus the decrease in the infra-red emission which occurs when water is added to the explosion of carbon monoxide must be ascribed to some cause operating on the hot gases themselves.

Two mechanisms may be put forward to explain the catalytic action of water which take into account the bearing of the decrease in the emission of infra-red radiation on the increase in the speed of reaction. The reduction in the intensity of the radiation may be due either to its absorption or to the prevention of its emission by the water molecules. In the latter case, the internal energy of those activated molecules which emit the 2·8 and 4·4μ bands may be converted by collision with the water molecules into kinetic energy. It is difficult to decide between the two possibilities, but in view of the high transparency of flames to their own radiation, the collision mechanism would appear to be the more probable of the two explanations.

Ethyl iodide and ethyl nitrate are still more powerful catalysts for the carbon monoxide and oxygen explosions than water, and the addition of a few per cent. of these substances reduces the intensity of emission of 2·8 and 4·4μ bands to about one per cent. of that emitted by the pure dry mixture. Here again the absorption in front of the wave is insufficient to account for the results.

A Very Rare Halo.

ON Sunday, May 16, at 16.25 I noticed a double halo round the sun. There was much cumulus and fracto-cumulus at the time, but this cleared off later, and at about 17.30 the sky was clear except for some clouds near the horizon; at this time both halos were well seen, each extending to well over a semicircle. Except for the cumulus near the horizon the sky seemed at first sight to be absolutely blue and cloudless, but by looking carefully in the neighbourhood of the halos very faint strands of cirro stratus were seen. Both halos had a tinge of red on the side nearest the sun, but otherwise were white; they were equal in brightness except for a short time when the inner halo brightened on the right-hand side of the sun for some 30° or so, the colour at the same time becoming rather more marked. Before sunset both halos faded, the inner one disappearing first. The radius of the inner halo to the middle of the band was from 18° 30′ to 18° 40′ as measured with a sextant. Better measurements, perhaps, were obtained from a photograph taken on a panchromatic plate through a Wratten A (deep red) filter; this gave the radii for the inner halo of 17½° to the inner edge and 21° to the outer edge, for the outer halo 22½° and 26½° respectively. The photograph was taken with a wide angle lens, and allowance was made for distortion away from the centre of the plate in making the above measurements.

Three halos are known inside the halo of 22°; the first has a radius of 7½° to 10°, the second 17° to 18°, the third 18½° to 20°. The halo seen here was obviously the second, or Rankin's halo. Besson (*Comptes rendus*, 1920, 170, 334) mentions this halo as having been recorded six times. There is some uncertainty as to the exact radius, and the matter is of some importance in connexion with the theory of these abnormal halos (see Besson and Humphreys, *Monthly Weather Review*, 1923, pp. 254, 255); for this reason, and also because Rankin's halo is excessively rare, I have gone into the matter rather fully. Halos are difficult to measure accurately, and the above measurement of 17½° is probably as accurate as any previously made; on several occasions when this halo has been observed the measurements were admittedly not very accurate. So far as I know it has never been photographed before.

On May 16 the two halos were seen over a wide area, reports having come from the counties of Suffolk, Essex, Kent, London, Surrey, Sussex, and Hampshire. As seen here in a nearly clear sky, they formed the most striking meteorological phenomenon that it has ever been my good fortune to witness.

The Transmission of Signals from a Horizontal Antenna.

IN the course of a mathematical investigation of the propagation round the earth of electromagnetic waves from a horizontal antenna, the result has emerged that, when the earth is regarded as a perfect conductor, the components of electric and magnetic force are zero both when the earth is regarded as surrounded by a conducting Heaviside layer and when no layer is present. Finite conductivity of the earth must thus be assumed in order to account for the propagation, and it is then found that the resulting forces are a small vertical electric force and a much larger horizontal magnetic one. The electric force is due to the 'space waves,' the magnetic force to the 'surface waves' described by Sommerfeld (*Annalen der Physik*, vol. 28 (1909), p. 665); the result of the analysis is in remarkable agreement with the conclusions he there expresses. The magnetic force may be analysed into perpendicular components, each of which consists of two simple harmonic oscillations differing in amplitude and phase, results of the same general type being obtained both with and without the Heaviside layer.

Numerical investigations of the magnitudes of the forces and their variation with distance from the source are in progress.

Rustless Steel and Flexible Glass 5000 Years Ago?

WHILST looking up the literature connected with ancient glass, in which I am interested, I came across a book by M. A. Wallace-Dunlop, published in 1883, entitled "Glass in the Old World."

An account is there given of the alleged opening of the first and second pyramids of Gizeh.

As these pyramids are known with tolerable certainty to have been built between 3969 and 3845 B.C., we may conclude that the things found in them when first opened must have been made at least five thousand years ago.

It is stated, on the authority of one Ben-Abd-er-Rahman, that in the year A.D. 829 El-Mamoum, son of Haroun-al-Rasched, was the first who succeeded in penetrating the tomb of Cheops, and found there the mummy of the king, and that he also entered the west pyramid (second pyramid ?), and that there was found "thirty treasures filled with store of riches, and utensils, and with signatures made of precious stones (signet rings ?) and instruments of iron and vessels of earth, and with *arms which rust not*, and with *glass that might be bended and not broken*." The italics are mine.

Those ancients have a most exasperating way of anticipating our new ideas.

Harrow.

Transmission of Stimuli in Plants: A Correction.

IN a communication dated May 22, Prof. Ricca asks me to point out that there is an error in his letter as printed in NATURE of May 8, p. 655. There it is stated that the closing of the pinnules from base to apex of a pinna indicated times of transmission of the stimulating substance from the base to the apex of the pinna of 5, 4, 3½, 2½, 2 min. This of course should read, 5, 4, 3½, 2½, 2 sec.

The Element of Atomic Number 61; Illinium.

By J. A. Harris, L. F. Yntema, and Prof. B. S. Hopkins, University of Illinois.

An important result of the development of Moseley's atomic number rule has been the impetus it has given to the search for missing elements. It is true that later arrangements of the Periodic Table indicated that eka-cæsium, eka- and dwi-manganese, and eka-iodine were missing, but there were no theoretical grounds for supposing that eka-neodymium might exist until Moseley's rule showed that element number 61 was still to be identified. Moseley's work was of inestimable value to one engaged in completing the list of chemical elements for several reasons—first, it gave definite information as to the existence and location of gaps in the Periodic Table; secondly, it gave a basis for the calculation, prior to its discovery, of the X-ray spectrum of an element and indicated a technique by which lines in that spectrum might be identified; and, finally, it originated a method of examination so searching that a mixture of two elements, so closely similar in chemical properties as to be almost inseparable, could be definitely analysed. Were it not for the work of Coster and Hevesy on the X-ray examination of zirconiferous minerals, the presence in them of element number 72 would probably be still unsuspected and hafnium (or celtium) would still be listed among the rare earths. Chemical tests made on zirconium ores had frequently indicated the non-homogeneity of zirconium, but they could not give the definite proof afforded by an X-ray analysis.

The proof that a rare earth element was missing, the atomic number of which would place it between neodymium and samarium, explained the sharp break in the sequence of properties that comes in the rare earth group between those two elements. The differences in solubilities of the double salts formed by rare earth nitrates with magnesium nitrate appear to be quite uniform, excepting in the case of neodymium and samarium, since fractional recrystallisation of that double salt will accomplish a strikingly sharp separation of those two elements. There is the same break in the sequence of solubilities of other salts, in basicity, as indicated by the rate of hydrolysis, etc. It also appears that the absorption spectra show the same general variation, and, as will be shown later, the absorption bands of element number 61 seem to fit into the regular sequence.

Because element number 61 might be expected to share the striking similarity in properties and the common occurrence in minerals of the other members in the rare earth group, it seemed logical to institute a search for it in monazite sands, a mineral in which the first members of that family, the so-called cerium earths, predominate. Since that mineral is rich in neodymium, 60, and in samarium, 62, it would be surprising to learn of the absence of 61 there and its presence in a mineral containing little or none of 60 and 62.

The original material used in the investigation was the rare earth residue remaining from monazite sands after the extraction of thorium and part of the cerium for use in the manufacture of Welsbach mantles. It was given to this laboratory by the Lindsay Light Company of Chicago. After the remaining cerium was removed by the usual methods, the other rare earths were fractionally recrystallised as double magnesium nitrates. Very pure neodymium and samarium, the latter subjected to further purification by other methods, were sent to the Bureau of Standards at Washington for use in an extensive investigation being pursued on the infra-red arc spectra of the rare earths. It was found that a number of identical new lines were present in both samples, and the suggestion was made that they might be due to the presence of a small amount of a new element. Eder had noted the same phenomenon. Later, when the ultra-violet arc spectra of neodymium, samarium, and of intermediate fractions containing both were examined, lines common to all three were found. However, X-ray analysis of those same samples showed no indication of the presence of an element with atomic number 61. Prandtl and Grimm had subjected rare earth material to separation by the same method and then to a fractional precipitation with ammonia, and could find no evidence of the missing element by X-ray analysis.

It seemed that the solubility of the double magnesium salt of element number 61 is very similar to that of neodymium, and its separation by recrystallisation of that salt offered little hope of success. The order of solubility of the bromates of the cerium group earths is the reverse of the order obtaining with the double magnesium nitrates, and that suggested a means of separating neodymium and thus concentrating element number 61. It is easier to separate a small amount of one element from a larger amount of a second if the former is in the less soluble end of the series of recrystallisations. Accordingly the neodymium-rich material thought to contain element number 61 was converted to bromate and again recrystallised.

A marked change in the absorption spectra of the solutions that began to appear after repeated recrystallisation indicated the probable concentration of the missing element. Two bands, one at 5816 Å.U. and another at 5123 Å.U., that had shown very faintly in supposedly pure neodymium, became stronger in some fractions as the other neodymium bands disappeared. Because these two bands, if assigned to element number 61, find their places in a more or less regular sequence shown by bands of neighbouring elements, it was thought they might belong to that element.

X-ray analysis confirmed the theory and showed the presence of element number 61 in those fractions. A mean value of five determinations of 2·2781 Å.U. was found for the $L\alpha_1$ line and one determination of 2·0770 Å.U. for the $L\beta_1$ line. A faint indication of the $L\beta_3$ line was also noted. It is assumed that these results prove the presence of element number 61.

The name assigned to the element is Illinium (Il).

There are several reasons that may be advanced to explain why the element escaped detection by means other than X-ray analysis. It must be extremely rare. Its solubility in a series of fractional recrystallisation is next to that of the very abundant neodymium, which tends to spread into the illinium-rich members of a series. The large number of absorption bands exhibited by both neodymium and samarium would tend to mask its absorption spectrum. Finally, the solubility of its double magnesium nitrate, which salt is commonly used for the separation of closely related elements, is close to that of neodymium. Evidence supporting this latter is found in the fact that the absorption bands at 5816 Å.U. and 5123 Å.U. found in supposedly pure neodymium purified by that method are shown to belong to illinium.

The identification of illinium as the missing rare earth completes the list of rare earth elements. Work has been instituted involving the extraction of several hundred pounds of the crude material with the purpose in view of obtaining enough of the element in pure enough state to study its properties, its relationship to other members of the group, and its atomic weight.

The Periodic System, Chemical Bonds, and Crystal Structure.[1]

By Prof. A. SOMMERFELD, For. Mem. R.S., University of Munich.

A GREAT advance was made in the Bohr theory of the Periodic System by the discovery of Stoner and of Main-Smith that the numbers of electrons in the different subdivisions of the $L, M, N, \ldots$ shells are not equal, as Bohr originally assumed, but unequal. The details of the new scheme are given in the following table, which shows the sub-groups of the shells, with the numbers of electrons in each:

TABLE OF X-RAY LEVELS.

	n_{11}	n_{21}	n_{22}	n_{32}	n_{33}	n_{43}	n_{44}
K	2	..	..	..	..	..	..
L	2	2	4	..	..	..	..
M	2	2	4	4	6	..	..
N	2	2	4	4	6	6	8
	n_1	n_2		n_3		n_4	

It will be noticed that the K-shell is single, the L-shell triple, the M-shell fivefold, and so on, in agreement with X-ray data (three L absorption edges, etc.). For the principal quantum numbers we still have of course $n=1$ in the K levels, 2 in the L levels, and so on.

At the top of the table is the quantum number notation which we find necessary for classifying X-ray spectra. There are, besides the principal quantum number n, two subordinate ones which we write as suffixes. They are denoted either by k_1 and k_2, or by k and j, and it is understood that while $k_1=k$, $k_2=j+\frac{1}{2}$; j is the so-called inner quantum number, and is, according to our scheme (developed in a previous lecture), half-integral, in the same way as in the alkali spectra. The two types of spectra are analogous, as is emphasised especially by Landé. We increase the magnitude of j, merely for typographical reasons, by $\frac{1}{2}$, so as to obtain a whole number k_2, in agreement with our practice in the case of the alkalis.

The numbers in the body of the table are now throughout equal to $2k_2=2j+1$. But $2j+1$ is the quantum weight, or number of orientations of the angular momentum j in a magnetic field, so that Main Smith and Stoner make the number of electrons in a given energy level equal to the quantum weight, $2j+1$, of that level.

At the foot of the table the numbers n_k describing the orbital types are given. We must direct special attention to the fact that any two shells that form a 'relativity doublet' in the X-ray spectra belong to the *same* orbital type n_k, which is in complete opposition to the original view from which the relativity formula was derived.

In replacing n_k by n_{kj}, we are introducing the same problem as has arisen in the case of the visible spectra. The characteristics of the orbit of a single electron ought to be fully determined by two quantum numbers, n and k, together with a third, m, to give the orientation of the orbit in space; that is to say, corresponding to the three degrees of freedom of the rotating electron, we should have altogether three quantum numbers. But we have already seen (in the earlier lectures) that even with hydrogen we require a j in addition to n, and k, or three quantum numbers merely for the characteristics of the orbit, which is thus not fully described without four numbers. We need not be surprised then when the same problem arises with X-ray spectra, so that here also a single orbit must be described not as an n_k orbit but as an n_{kj} orbit. May we hope that the solution of the difficulty will be found along the lines of the new quantum mechanics introduced by Heisenberg and developed, for example, by Dirac? It is true we are confident that this will dispose of the old difficulties as to half-quantum numbers, and so on, that arise especially in the anomalous Zeeman effect; but it seems unlikely that it will succeed in providing a new degree of freedom for the orbital electron. Most probably we shall be compelled to make a new hypothesis that will introduce this into the Hamiltonian function of the system. In this connexion we may recall the striking suggestion of S. Goudsmit of the 'spinning electron' (proposed, in some respects, by Porson previously, though Porson gave no definite relations to quantum numbers); it may be that here we shall find the explanation of the missing degree of freedom.[2]

The j of the individual electron must not be confused with the j of the whole atom, the outermost shell of which is composed, in general, of several orbits of the type in question. This latter j we will distinguish by a bar, so that $\bar{j}$ refers to the atom as a whole; moreover, it refers to the atom in its fundamental or unexcited state. In other words, $\bar{j}$ is the inner quantum number of the fundamental term. In 1925 I enunciated two theorems in the *Physikalische Zeitschrift*, about this $\bar{j}$ of the fundamental term and its relation to the position of the element in the periodic table:

1. Every completed sub-group is distinguished by $\bar{j}=0$.

---

[1] From a series of University of London lectures on "Atomistic Physics," delivered at the Royal College of Science during March 1926.

[2] Indeed, from a paper of Heisenberg and Jordan, now in print in the *Zeits. f. Phys.*, it appears that both new mechanics and 'spinning electron' are needed in order to account for the relativity doublet arising between two levels that differ by j and not, as in the original theory, by k.

2. The element immediately following or preceding the one that completes a sub-group has a value of $\bar{j}$ that is identical with the j of the sub-group to which the element belongs.

The following scheme will give examples of these theorems:

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.	XIII. ….	XVII	XVIII.
$j=$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{3}{2}$	$\frac{5}{2}$ ….	$\frac{5}{2}$	$\frac{5}{2}$
$\bar{j}=$	$\frac{1}{2}$	0	$\frac{1}{2}$	0	$\frac{3}{2}$	..	$\frac{3}{2}$	0	$\frac{3}{2}$	..	..	0?	$\frac{5}{2}$ ….	$\frac{5}{2}$	0

The Roman figures give the number of electrons in the outermost shell (whichever that is) in the various cases. The numbering is from the beginning of that shell, and applies equally well to the N shell as to the M, and also to the L shell in so far as it has enough electrons.

I can only touch very briefly on the spectroscopic evidence for this scheme, and must omit all details: $\bar{j}=0$ is found for column II. in helium and the alkaline earths, and for column IV. in tin and lead, and probably also in ionised nitrogen (N^+). For column VIII. it is established by neon (we considered in our second lecture the neon $^1S_0$ term); for column XII. it is doubtful, and XVIII. (nickel, palladium, platinum) will have to be considered further below. $\bar{j}=\frac{1}{2}$ denotes, in column I., the s term of the alkalis, and in column III. the $^2P_1$ term of aluminium, gallium, indium, and thallium; and so on for the others.

Of course we may expect in addition that the azimuthal quantum number of the last-bound electron will be the same as the k of the Periodic System, *i.e.* as the first suffix in n_k. This is indeed the foundation, on its spectroscopic side, of Bohr's theory of the Periodic System. However, this k is different, in the case of atoms having several valency electrons, from the 'group quantum number' l, introduced (though their notation is different) by the work of Russell and Saunders on the alkaline earths. The exceptions to the Bohr scheme which iron and titanium, for example, appear to provide are founded on a confusion between k and l which Russell and Saunders were the first to avoid.

We come now to chemical applications. We may state the basic principle of chemical binding as a tendency towards the formation of complete sub-groups. The complete group of eight electrons has been familiar for some time, and it is well known how the simplest binary compounds approach this inert-gas configuration from both sides. The next in importance is the 'two-shell,' typified especially by helium, in which two electrons rotate in opposite directions, so that their moments cancel out. As an example of this we may cite $LiH = Li^+H^- = He_3He_1$.[3] However, the elements zinc, cadmium, mercury, belong to this class too, having a pair of outer electrons bound in a similar manner, and we know of many very stable compounds which are approaching this configuration. I will mention only a few, such as PbO (or PbS), in which the lead is divalent or, in other words, is reduced to the two-shell of mercury, having given two electrons to the oxygen or sulphur. PbO is actually more stable than PbO_2, although in the latter compound the lead has what used to be regarded as its 'correct' valency. We may note also the compounds of monovalent thallium and of trivalent arsenic, antimony, and bismuth, all of which are aiming at the two-shell or helium type. Main Smith and Stoner have thus left no room for doubt that in future chemists, in their speculations about affinity, will have to take into account as equally authenticated, not only the eight-shell of the inert gases, but also the two-shell.

We come now to the so-called eighteen-shell which is, one supposes, completed at the ends of the triads by nickel, palladium, and platinum. There is no doubt that the following elements—copper, zinc, silver, cadmium, gold, mercury—in their chemical compounds are often reduced to the eighteen-shell. But is this shell in fact complete, like the inert-gas shell? What are the conclusions of spectroscopy as to the fundamental states? With palladium the position is clear and unambiguous: the fundamental term is here a $^1S_0$ term lying well below the other levels. Palladium has thus a completed shell. This does not hold for nickel or platinum. In nickel the fundamental term is a ^3F term, with a $^3D'$ level slightly higher, and in platinum a $^3D'$ term. This is reflected in the chemical and spectroscopic behaviour of the following elements—copper, silver, and gold. Silver is without exception monovalent; on the removal of its single valency electron it goes over into the stable palladium configuration. Copper is mono- and divalent; gold mono- and trivalent. Here then, in addition to the valency electron, one or more of the electrons of the core of the atom may be detached. The core in the case of copper and gold is not completed, which agrees with what we have found for nickel and platinum.

The same impression is gained from their spectroscopic behaviours. Silver has a simple spectrum resembling that of the alkalis, while the spectra of copper and gold show in addition to the alkali doublet system a large number of foreign lines. It is very characteristic that Fräulein Stücklen[4] has found for the most stable state of copper not the s term of the doublets, but one which probably belongs to a quartet system. That corresponds exactly to the uncompleted shell of nickel. The position of an element in the periodic table thus gives us very decided clues for unravelling its spectrum.

The behaviour of nickel and platinum and, what is intimately bound up with them, the behaviour of copper and gold, must be regarded as a partial exception to our rule about resultant moments of momentum $\bar{j}$; $\bar{j}=0$ is indeed the mark of a completed sub-group, but in some cases the last electron, which might have performed this rôle, is, from considerations of energy, more easily accommodated elsewhere.

We come now to the final members of those sub-groups which are distinguished from the following sub-group by a different value, not of k but of j, so that they belong to the same orbital type, n_k, as the following elements. It appears that this division is less well marked, and makes itself less noticeable chemically than the close of the sub-groups already considered. If we take first the division between n_{43} and n_{44} (for $n=4$) in table I., we find that this occurs in the rare earths; and corresponding to it is the difference between cerium earths and ytterbium earths, which is especially noticeable magnetically. The curve for the paramagnetism of the ions rises, according to Cabrera and Stefan Meyer, to a maximum, then falls off almost to zero at the end of the cerium earths, reaches a higher maximum with the ytterbium earths, didymium, and holmium, and falls finally to zero at cassiopeium ($Z=71$).

---

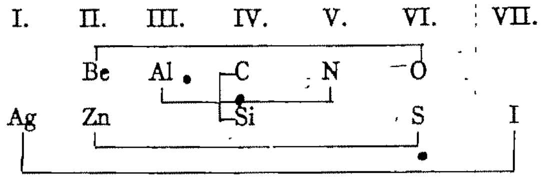
[3] He_3 denotes a He-configuration with nuclear charge 3, $=Li^+$, and similarly for He_1.

[4] *Zeits. f. Phys.* 34, 562, 1925.

The close of the sub-group n_{33} appears, as we have already said, not to be noticeable spectroscopically; in contrast to this we have found that the close of n_{21} is marked by $j=0$ in tin and lead, and probably also in carbon and silicon. But how about the chemical effects of the close? Are there compounds which are aiming at the four-shell as there are for the eight-, two-, and eighteen-shells? The answer will be of great interest for the understanding of chemical compounds, and towards it I can make the following contribution, based on an observation of H. G. Grimm relating to the crystal structure of certain diamond-like compounds. The subject is treated in a paper by Grimm and myself in the *Zeitschrift für Physik* (1926), where also the above remarks about copper, silver, and gold may be found.

The characteristic structure of diamond is known from the work of Sir William Bragg. Diamond is built up simply of tetrahedra in such a way that every carbon atom is surrounded by a tetrahedron of other carbon atoms. Zinc sulphide crystallises in the same arrangement, as zincblende, with each zinc atom surrounded by a tetrahedron of sulphur atoms and vice versa, but it also crystallises in another way, as 'wurtzite'; in this, while we still have interpenetrating tetrahedral systems, the structure is not cubical but hexagonal; the tetrahedra are merely disposed in a different way, in relation to one another, from that which occurs in the diamond. We will classify both together as tetrahedral structures. The crystal carborundum (CSi), so important technically, is likewise tetrahedral, with different modifications, which are distinguished by the way in which diamond- and wurtzite-structures alternate with one another in the hexagonal *c*-axis. As a result of this alternation the repetition-distance is here extraordinarily large—almost 40 Å.U., indeed, in one of the modifications.

Now, however, we have this to consider: this tetrahedral structure occurs not only in the fourth column of the periodic table (*e.g.* in carbon, silicon, carborundum, germanium, tin), but also in compounds of neighbouring elements; those neighbours being equally distant on opposite sides from the fourth column. We may in fact state as a definite theorem that tetrahedral symmetry occurs *only* in such binary compounds as have both components at most three places from a four-shell, and both equally distant.



It is very natural to assume that in all these compounds the mechanism of the bonds is the same as in the diamond. This is quite obviously a non-polar bond, since it unites two similar atoms, and we conclude that in zinc sulphide it is also non-polar; *i.e.* the compound is not $Zn^{++}S^{--}$. This is confirmed by X-ray intensity measurements, which, according to H. Ott, certainly do not correspond to Zn^{++} and S^{--}, but probably to neutral Zn and S. The idea of a four-shell would have suggested even the reverse picture, Zn^{--} and S^{++}, since the sulphur atom must give up two electrons if it is to be reduced to the four-shell of silicon, and zinc must acquire two to reach that of germanium; however, the intensity relations seem rather to indicate neutral Zn and S. Similarly, beryllium oxide, in contrast to magnesium oxide and calcium oxide, is at least not the polar salt $Be^{++}O^{--}$. In calcium oxide and calcium carbonate tetrahedral structure is not observed, nor is it to be expected theoretically, since calcium is not two places before a four-shell.

I prefer not to go further at present into the mechanism of the reciprocal binding of such four-shells; even in the simplest case of the diamond we know nothing certain about it. It is most probable that the binding is performed by pairs of electrons, each of which goes round two carbon atoms, as in G. N. Lewis's theory of the sharing of electron pairs.

In conclusion, then, we have found that the theory of the Periodic System shows at what elements we are to expect completed sub-groups. In addition to the inert-gas eight-shell, the shell of eighteen, and even more that of two electrons, is a goal at which the elements in a stable compound are aiming. The four-shell, on the other hand, is evidenced by a tetrahedral crystal structure, which points to the same kind of binding together of the atoms as we have in the diamond; this binding is not performed by the electrostatic attractions of polar ions of the usual sign, but is probably a matter of neutral atoms. It seems reasonable to hope that the great chemical problem of the non-polar bond will be brought nearer its solution by a close study of tetrahedral crystal structures.

The Shipworm.[1]

By Dr. W. T. CALMAN, F.R.S.

ALTHOUGH nowadays iron ships no longer fear the *calamitas navium*, as Linnæus called it, the shipworm still remains a constant source of anxiety to harbour engineers in many parts of the world. For example, the damage caused by it to wharves and jetties on the shores of San Francisco Bay, during the years 1919 and 1920, was estimated at no less than 15,000,000 dollars.

Within the last few years a good deal of attention has been paid to the shipworms by investigators in

---

[1] Substance of two lectures delivered at the Royal Institution on April 17 and 24.

Great Britain and, more especially, in America, and noteworthy additions have been made to our knowledge. Only a few of the more striking results can be touched on here.

The question of how the shipworm excavates the wood to form its burrow has been much discussed. The earlier observers had no doubt that the valves of the shell—which they called the teeth—were the instruments of excavation, but some later writers have supposed that the wood was acted on by a solvent secretion and then rubbed away by the fleshy foot. Lately Mr. R. C. Miller, in America, has been able to watch the animal at work, by laying bare the inner end of the burrow and cementing a cover-glass over the opening. He found that the sucker-like foot adheres now to one part and now to another of the inside of the burrow, and the animal is wedged firmly in position by the swelling up of a fleshy lobe lying over the back of the shell. A rocking movement of the valves produced by alternate contractions of the two adductor muscles causes the rows of minute teeth on the surface of the valves to rasp away the wood, and, as the foot shifts its position after each stroke, the boring proceeds evenly and the circular form of the burrow is preserved. In hard and fine-grained wood, microscopic parallel scratches can be observed which are the tool-marks of the excavator.

Most bivalved molluscs feed on minute living organisms and organic particles suspended in the water, and the food-collecting function of the so-called gills is at least as important as their respiratory function. It is possible that the shipworm obtains a part of its food in this way, but it also swallows the fine sawdust produced by the rasping movements of its valves, and the stomach and intestine are found on dissection to be crammed with wood-pulp. This does not prove that the wood is actually a source of food, for some related molluscs (Pholadidæ) that bore into rock, similarly swallow the innutritious mud produced by their boring operations. As compared with the Pholadidæ, which burrow only to get shelter, the elongated worm-like shape of the shipworms (some of which are six feet long) suggests the need for continued boring to obtain food while keeping in touch with the surrounding water at the mouth of the burrow. Recent work, however, shows that the wood is actually digested. Potts has observed phagocytic ingestion of wood-particles in the 'liver,' while Harrington found that an extract from the same gland acted on sawdust to produce glucose. Dore and Miller, in America, have analysed the borings after passing through the alimentary canal of the shipworms and compared the composition with that of the wood itself. They found that while the amount of lignin remained unchanged, the cellulose was reduced by 80 per cent. and the hemicelluloses by 15-56 per cent.

This, however, is not the whole story. It seems to be well attested that, in certain circumstances, the shipworm ceases to bore and shuts itself completely off from the wood by continuing the shelly lining over the end of its burrow. Where this has been done, the only source of food-supply will be the suspended particles drawn in by the respiratory current. The same is probably true of the somewhat mysterious giant shipworm, *Kuphus arenarius*, which does not bore into wood but lives vertically embedded in the mud of mangrove swamps with only its siphons projecting from the surface.

The practical man, when confronted with problems such as those presented by the shipworm, is sometimes apt to pay too little heed to the history of the subject and to waste time in finding out for himself facts that were discovered and recorded long ago. The learned Sellius, two hundred years ago, was at pains to confute the suggestion that the shipworm could emerge from its burrow and swim away to bore into a fresh piece of timber. Such a supposition was natural enough when nothing was known of the microscopic free-swimming larvæ, but it is surprising to find it revived in an official report issued only three years ago by the Department of Scientific and Industrial Research.

It is characteristic of the shipworm that it may appear suddenly in places that have previously been free from its depredations. Thus we find records of great outbreaks of shipworm in Holland in 1730, 1770, 1825 and 1858, at San Francisco in 1917, and so on. In most of these cases the damage is severe for two or three years, then the attack dies away and little or nothing is heard of the pest in the intervening periods. When one of these outbreaks occurs, the practical men generally begin by attributing it to importation of infection from abroad. In Drake's time the shipworm was commonly regarded as having been brought from the New World. In the eighteenth century the East Indies were supposed to be its place of origin. Linnæus concisely says of it, "ex Indiis in Europam propagata." In the recent San Francisco outbreak something was said of importation from Europe.

It is possible that some truth may underlie these beliefs. The commonest species of shipworm in northern Europe, *Teredo navalis*, has been found in places so widely separated as the Cape of Good Hope, Australia and San Francisco, and there is every probability that this wide range, unusual in a marine invertebrate, is due to the species having been carried to these distant parts in the timbers of ships. But it is unlikely that the individual outbreaks can often be due to this cause. It is certain that in most cases the shipworms have lurked unnoticed in odd corners until rapid multiplication owing to favourable conditions has directed attention to them. It becomes of importance, therefore, to determine what these favourable conditions are.

Individual outbreaks have sometimes followed years of deficient rainfall, leading to increased salinity in the waters of bays and harbours, and attempts have been made to find out the degree of salinity which is most favourable. It was found at San Francisco that *Teredo navalis* was active and apparently thriving at a salinity of 15 per thousand, that is to say, in water containing rather less than half the amount of salt usually found in ocean water. As the water was diluted the animals became less active until at 4 per thousand they withdrew into their burrows. While enclosed in the wood, however, they remained alive, though inactive, for three weeks in fresh water, ready to resume operations when replaced in salter water. It would be interesting to know how the free-swimming larvæ are affected by changes of salinity, but there appear to be no detailed observations on this point.

All these observations, however, have been made on a single species, *Teredo navalis*. There are many other kinds of shipworms and, although we know little of their habits, we do know that they differ greatly in the degree to which they can adapt themselves to water of reduced salinity. *Teredo navalis*, which can flourish in water only half as salt as that of the oceans, probably owes its evil reputation to the fact that its tolerance for brackish water enables it to invade estuaries and harbours where the water is commonly less salt than that of the sea outside. It is the common species in the North Sea and comes up the Thames as far as Greenwich. At Plymouth, another species, *Teredo norvagica*, appears to be the commonest, and it will probably be found to prefer salter water. On the other hand, various tropical species ascend rivers, such as the Ganges and the Zambezi, to places where the water is quite fresh. There is even a report that a shipworm occurs in Lake Tanganyika, although no specimens have yet been seen by naturalists.

It should be clear, then, that an accurate determination of the existing species of shipworms and of their conditions of life is of great importance from a strictly practical point of view. How far we are from having this knowledge is perhaps only realised by those who have tried to determine collections of shipworms from different parts of the world. But that is no reason why such knowledge as we have should be neglected. In some recent investigations on the efficiency of certain poisons when used to protect wood against attack by shipworms, the authors do not even trouble to tell us what species of shipworm was used in their experiments.

A study of the shipworm suggests some considerations bearing on current biological theories. For example, like all highly specialised organisms living under peculiar conditions, the shipworms raise in the most striking way the problem of adaptation. The form of the body, the shape of the shell-valves with their file-like rows of teeth and the pivots on which they rock, the disposition of the muscles, the sucker-like foot, the alimentary canal—all these and many other details of structure co-operate to form a mechanism which is unintelligible except as a device for boring into and feeding on wood. The mutation theory of evolution teaches that organisms have evolved by sudden changes of structure which had no relation to the needs of the organism and only an accidental fitness for its mode of life. It is scarcely exaggeration to say that according to this school the shipworm bores into wood and feeds on it because it happens to find itself provided with suitable implements for doing so. If that were all the help to be got from the theory of evolution, it would be better to go back to the doctrine of special creation.

Obituary.

DR. H. B. GUPPY, F.R.S.

HENRY BROUGHAM GUPPY, who died at Martinique on April 23 on the voyage home from Tahiti, began work at a time when a medical training was the usual method of approach to a scientific career. Like other eminent naturalists, he started that career as a surgeon in Her Majesty's Navy. But the inspiration of the islands of the great oceans remained throughout his life as the directing force of his painstaking investigations of the problems relating especially to geographical distribution which they suggested.

In 1878 Dr. Guppy visited the China Seas; but his great opportunity came in 1881, when he was appointed surgeon to H.M.S. *Lark*, which was commissioned for survey work in the western Pacific. Two volumes on the Solomon Islands, published in 1887, contain the results of three years' study on the ethnology, natural history, and geology of this somewhat difficult group, where it was necessary to 'dare a little' in order to learn. The problem of coral-reef formation especially attracted him, and in 1888 he was able to continue his study of the problem on the Keeling-Cocos Islands, a classic locality, as the subsidence-theory held by Darwin was the result of a brief visit to the Islands during the voyage of the *Beagle*. Guppy, who examined all the islands and islets, more than twenty in number, concluded that these small atolls and horse-shoe islands only assume their characteristic form after the island has been thrown up by the waves (see NATURE, 39, 236, 1889). Later, in his physical and geological monograph of Vanua Levu, Fiji (1903), he describes as "one long story of emergence" the building up of the island by reef-formation on a submarine basaltic plateau.

The problem of the stocking of coral islands had interested Dr. Guppy from the first, and between 1890 and 1896 he made a careful study of British plants from the point of view of dispersal by water—a paper on "The River Thames as an Agent in Plant Dispersal" was read at the Linnean Society in 1892. This prepared him for three years' intensive work in Fiji and Hawaii (1896–99), and later on the west coast of South America (1903–4). The fruit of these observations was "Plant Dispersal" ("Observations of a Naturalist in the Pacific," vol. 2, 1906), an eminently suggestive work and a mine of information on the floras, especially littoral, of the islands and eastern shores of the Pacific, and the means of dispersal which have been effective in their formation. General problems are also discussed; and the hypothesis of a great Pacific land-area is dismissed: "We have much to learn before it would be safe to look to hypothetical changes of sea and land to explain difficulties in distribution." The problem of fruit and seed became the *motif* of his work, and his "Studies in Seeds and Fruits; an Investigation with the Balance" (1912), is a study of mechanical and physiological problems bearing on means of dispersal. These were preparatory to his second book on this subject, "Plants, Seeds, and Currents in the West Indies and the Azores" (1917), a record of his personal observations during visits to the Islands, and a valuable contribution to the study of Island floras. The award of the Linnean Medal of the Linnean Society in the same year, and his election shortly after to a fellowship of the Royal Society, were a well-earned recognition of long years of quiet, steady, fruitful work carried out with remarkable singleness of purpose.

A. B. R.

REV. W. A. B. COOLIDGE.

BY the passing away, in his seventy-sixth year, of the Rev. William Augustus Brevoort Coolidge, at the Swiss home which he had built for himself, Châlet Montana, Grindelwald, another famous mountaineer, who carried on the great traditions of the pioneers of the Alps, is removed from our midst. Not merely was he a climber of the very front rank, but the most erudite of the band, possessing a wonderfully complete personal knowledge of the Central European Alps—of their topography and physical geography, their history, and that of the countries in which they are situated. Familiarly and equally conversant with English, French, and German, he was a prolific writer in all three languages, conveying his exceptional knowledge with conciseness yet with fascinating interest. He wrote, for example, the articles on Switzerland in all the three later editions of the "Encyclopædia Britannica," those portions on the geography and history of the country being not only of great value and meticulous accuracy but also of eminent literary merit. Besides his well-known guidebooks (to the Dauphiny Alps, Lepontine Alps, Adula Alps, Mountains of Cogne, and the Bernese Oberland), and his editions of Ball's "Alpine Guide" and Murray's "Handbook of Switzerland," he wrote a most charming book, "The Alps in Nature and History," in which his wide knowledge of the history, antiquities, folk-lore, religious and political development of the playground of Europe is used for our instruction in a truly delightful manner.

Coolidge was a singular combination. An American citizen throughout his life, born near New York and at school in the United States, he became an undergraduate of Exeter College, Oxford, where he took a first in modern history and won the Taylorian scholarship for French. He was afterwards elected to, and retained to the last, a fellowship at Magdalen. Moreover, from 1883 until 1895 he acted as curate at South Hinksey, having taken holy orders. In 1909, however, he removed permanently to Grindelwald, where he had built the Châlet Montana as a home for himself and his priceless library of Alpine literature.

For thirty-five years Coolidge spent the long vacations and some winter ones in climbing and exploration, in his best days accompanied by that wonderful guide, Christian Almer; during this time he climbed practically every peak in the whole of the Swiss, French, and Italian Alps. Elected a member of the Alpine Club in 1870, and an honorary member in 1904, he edited the journal of the Club for the ten years 1880–1889. His greatest claim to fame, however, is in the realm of topographical and physical geography, the whole of his writings on these subjects being characterised by a degree of accuracy which renders them pre-eminently trustworthy and of high permanent value.

A. E. H. TUTTON.

MR. F. S. SPIERS.

BY the death of Mr. Frederick S. Spiers, science loses one who was well known for his ability as an organiser, particularly of affairs related to physical chemistry. Mr. Spiers was born on October 21, 1875. His father was a Dayan or Judge of the Jewish Court. He was educated at the Central Foundation School, Finsbury Technical College, and at the Central Technical College, South Kensington, and obtained the degree of Bachelor of Science (London). He was an associate-member of the Institute of Electrical Engineers and a fellow of the Institute of Physics.

Mr. Spiers was best known for his work as secretary of the Faraday Society, which he assisted to found in 1902. He was an indefatigable organiser. With his help the Society has become one of the most important organisers of scientific discussions in the country. These are noted for the way in which they have brought American, Continental, and British workers together. His ardour was so keen that sometimes it had to be checked owing to the exiguous character of society finances. In 1920 he added to his work that of secretary to the newly founded Institute of Physics, and in this post has shown a like activity and alertness in bringing to the attention of the Board every possible way of amplifying its work. For both of these societies he has proved himself a man whom it will be difficult to replace.

During the War, Mr. Spiers stimulated the formation of a nitrogen products committee of the Faraday Society. As a result of the reports of this committee, in part drafted by him, important researches were carried out by the Munitions Inventions Department. He also organised for the British Science Guild the successful exhibitions of British Scientific Products held in 1917 and 1918. For his work in connexion with the War he received the Order of the British Empire.

Mr. Spiers was well-read in all branches of physical chemistry, but his daily work gave him no opportunity for research. Two papers only appear in his name; one on the electromotive force of Clark cells (*Phil. Mag.*, 1896), and one on contact electricity (*Phil. Mag.*, 1899). His outlook was, however, much wider than his scientific work. He was a Hebrew and Talmudical scholar, and his love for music amounted to a passion. He was keenly interested in all forms of applied art, and at one time was engaged in the production of decorative metal work by electrodeposition. The gold medal and diploma of the Franco-British Exhibition (1908) was awarded for some of this work. The attendance at his funeral was a testimony to the large amount of work that he had done for Jewish education. He was a member of the Jewish Board of Deputies.

His slight body was unable to stand the physical strain of all his activities. On several occasions he had been obliged to rest. For a couple of days before his death he took holiday, but returned on the Friday feeling rather worse than better. In the afternoon (May 21) he was found by one of his office staff leaning back in his chair. He had passed peacefully away.

News and Views.

Limitations of space forbade more than reference in our issue of May 29 to the recent birthdays of Sir Edward A. Sharpey-Schafer, F.R.S., and Sir W. M. Flinders Petrie, F.R.S. Sir Edward Sharpey-Schafer was born in London on June 2, 1850. Assistant professor of physiology in University College, London, from 1874 until 1883, he afterwards became Jodrell professor there, leaving in 1899 to occupy the chair of physiology in the University of Edinburgh. Sir Edward is especially distinguished for the great variety of his work in physiology, for his series of brilliant investigations into the nervous system, for his fruitful exploitation of histological methods, for his valuable discovery of the function of the suprarenal glands, and for the success with which he has applied physiological research to results of practical importance. A leader in physiological and histological inquiries, he has stimulated the prosecution of research, with noteworthy issues, through large numbers of student disciples. Sir Edward's earliest communication to the Royal Society was made so far back as April 3, 1873. The paper, printed in abstract in the *Proceedings*, was entitled "On the Structure of Striped Muscular Fibre"; afterwards the paper appeared in full in the *Philosophical Transactions*, but the title was changed to "On the Minute Structure of the Leg-muscles of the Water-beetle." As general secretary of the British Association from 1895 until 1900, Sir Edward rendered distinct service to science. He was president of that body at the Dundee meeting, held in 1912, delivering an address on the nature, origin, and maintenance of life. At the Oxford gathering of 1894 he was president of the physiological section. Awarded a Royal medal by the Royal Society in 1902, he was Copley medallist in 1924. Sir Edward is a foreign member of the Reale Accademia Nazionale dei Lincei, Rome.

Sir W. M. Flinders Petrie, probably the foremost of living Egyptologists, was born on June 3, 1853, at Charlton, a descendant, on his mother's side, of Capt. Matthew Flinders, R.N., hydrographer and geographer, who is credited with having first suggested the name 'Australia' for the island continent. Sir Flinders, who was educated privately, began archæological survey and research work more than fifty years ago. He was then specially interested in ancient British remains. In 1881 he took up research work in connexion with the pyramids at Gizeh, and thence onwards down to recent days he conducted surveys and excavations in Egypt, exhibiting results which his countrymen have regarded with gratitude and admiration. Between 1888 and 1890 he was at work in the Fayum. In 1894 Sir Flinders founded the Egyptian Research Account, which ultimately became, in reconstruction, the British School of Archæology in Egypt. In 1906 he was awarded the Huxley medal of the Royal Anthropological Institute. Among his numerous publications may be cited "A History of Egypt," "Ten Years' Digging in Egypt," "Religious Life in Ancient Egypt" (1924).

A movement to stimulate the study of pre-Roman Italy, which may be expected to have far-reaching effects on our knowledge of the early cultures of the whole Mediterranean area, has been inaugurated by the National Etruscan Congress, which was held at Florence at the end of April and the beginning of May, when, according to the report of the Milan correspondent which appears in the *Times* of May 25, a number of papers dealing with the language, culture, religion, and antiquities of the Etruscans were read. Prof. Luigi Pareti, professor of ancient history in the University of Florence, supported the theory that the Etruscans arrived in Italy by land and not by sea, traces having been left of their passage across the Alps; and further, that they were descendants of the lake-dwellers of the Emilian region. The problem of the Etruscan language was discussed by Prof. Bartolomeo Nogara and Prof. Trombetti. The latter distinguished three linguistic strata in the Mediterranean basin, of which the Basque is the oldest. The Etruscan he assigned to the second group with the languages of Anatolia. A paper by Prof. Sogliano, which is said to have attracted much attention, supported the view that Pompeii was probably Etruscan and that the Temple of Jove in that city was the Roman substitute for a true tripartite Etruscan temple. Details of Prof. Sogliano's argument will be awaited with much interest in the hope that they will throw further light on the question of the extent of the Etruscan element in Roman culture, and particularly in Roman religion. Committees were appointed to supervise the publication of two series of volumes, one dealing with the culture and institutions of the Etruscans, the other containing monographs on Etruscan centres. At the conclusion of the Congress, visits were paid to the tumulus of Montecalvario at Castellina del Chianti, Vetulonia, Populonia, and Volterra.

The sixth annual report of the British Non-Ferrous Metals Research Association, which has just been received, is a remarkable record of progress. The expenditure on research during the coming year, including certain investigations the direction of which is shared with other bodies, will amount to about 20,000*l*. We are glad to see that the list of new members who have joined the Association during the year includes many large users of non-ferrous metals, such as railway companies and electrical firms, and also manufacturers of scientific instruments, as well as smelters and manufacturers of metals and alloys. The Association owes much to the energy and knowledge of its Director of Research, Dr. R. S. Hutton, while its policy of encouraging research work in the universities and other public institutions, by appointing salaried workers under the direction of scientific men of standing, has proved beneficial to all parties. It has now been found necessary to establish a small central laboratory, accommodation for which has been provided by the University of Birmingham. The report contains an account of the position of the investigations already in progress, and also of the new investigations which have been begun, the latter including work on annealing furnace practice, the working properties of zinc, plumbers' joints, and alloys suitable for use at high temperatures. In the last-mentioned field interesting results have been obtained and published. The report is obtainable from the offices of the Association, 71 Temple Row, Birmingham.

A JOINT committee representing the Royal Society of Edinburgh, the Royal Physical Society, and the Royal Scottish Geographical Society, has made the first award of the Bruce Memorial Prize to Mr. James Mann Wordie, of St. John's College, Cambridge, for his geological and oceanographical work in Arctic and Antarctic regions. Mr. Wordie accompanied the ill-fated Shackleton expedition of 1914–1916 to the Antarctic, and was present with Dr. Bruce in Spitsbergen in 1919 and 1920. Later he led an expedition to Jan Mayen, while in 1923 his attempt to reach the east coast of Greenland was frustrated by heavy pack ice. As a result of his visits to polar regions he has made several valuable contributions to the knowledge of ice-formation at sea, of bottom deposits of Antarctic seas, and of Arctic geology. The Bruce Prize, founded to commemorate the work of Dr. W. S. Bruce, is awarded biennially for notable contributions to science, the outcome of personal visits to polar regions, its object being to stimulate further exploration. The medal (Fig. 1), which forms part of the award, is slightly modified from that designed by Dr. Bruce to commemorate the Scottish National Antarctic Expedition of 1902–1904.

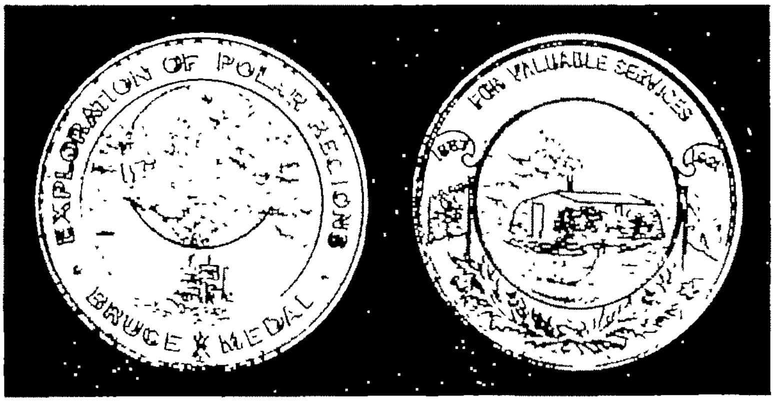


FIG. 1.

THE *Journal of Geophysics and Meteorology*, vol. 1, No. 2, issued under the editorship of the late Dr. Friedmann, former Director of the Central Physical Observatory at Leningrad, contains twelve papers, all of which are in Russian, save one, which is in German (with a Russian summary); but short summaries of the Russian papers are given, six in English, one in French, and four in German. The contents relate mainly to meteorology, but a useful summary of magnetic results obtained at Pavlovsk (now to be known as Slutzk) is included; these are for the years 1912–1923, for which Pavlovsk data have not hitherto been published, the Annales of the Central Physical Observatory being temporarily suspended. The diurnal inequalities of each of the three elements of magnetic force are given in the mean for each of the twelve years: the seasonal variations of the diurnal inequalities are not indicated. An interesting article by Kurt Wegener (Hamburg) deals with the artificial production of rain, describing an attempt in this direction and the reasons why failure in this and all such attempts must be expected.

DURING the present century there have been several great volcanic eruptions in Japan, especially those of the Usu-san (Hokkaido) in 1910, the Asamayama (central Japan) in 1908–14, and the Sakurajima (southern Japan) in 1914. These are all well-known active volcanoes. The great eruption of Tokachi in Hokkaido that began on May 24 took place, however, from a volcano that was supposed to be extinct, and from a crater that has been occupied by a lake within historical times. The first explosion ejected the water from this lake. Later in the day there were two other explosions, accompanied or followed by an outflow of lava. By the last explosion part of the wall of the crater was blown away. Several hamlets and the greater part of the town of Furyono have been destroyed, and 900 persons are reported to have been killed by floods and lava-streams.

ON his return from a tour of British West Africa, Mr. Ormsby-Gore, Under-Secretary for the Colonies, gave some of his impressions to a representative of the *Times*. The Gold Coast Colony has made remarkable progress during the last five years, due largely to the great development of motor roads and transport facilities. Work is also proceeding on the construction of a modern deep-water harbour at Takoradi, which will be of great value in the two staple trades, cocoa and manganese-ore. Nigeria shows great prosperity and, with a large surplus balance in the past year, is justified in proceeding with the development of its transport. The present road system is entirely inadequate and a serious hindrance to the development of cotton growing. Mr. Ormsby-Gore will outline in his report a continuous programme of railway construction of anything from 100 to 150 miles a year for the next five years. The provinces of Sikaso, Zaria, and Kano alone may be expected to increase their annual cotton output to 250,000,000 bales of 400 lb. each of a fine type of American cotton. When a new type of cotton, on which the Agricultural Department is now experimenting, is produced, the middle belt of Nigeria will yield also an important crop of export cotton. In conclusion, Mr. Ormsby-Gore expresses himself as strongly opposed to any extension of the length of residence of European officials in West

Africa. The leading commercial firms are tending to reduce rather than to extend the period of stay of their officials.

THE key idea of Prof. J. McLean Thompson's lecture before the Royal Society of Arts upon "The Sea Transport and Storage of Fruit," published in the Society's journal for February 26, appears to be that the fruit carried to Great Britain has to be regarded as a 'living passenger.' Thus regarded, it is desirable to harvest and keep it under such conditions before shipping, that the fruit has ripened normally, and then in transit, if conditions are suitably adjusted, it may be possible, without the expense of cold storage methods, to keep it at that condition of restful dormancy which often seems to follow in living fruit and seed upon the attainment of maturity. Prof. McLean Thompson was apparently not in a position to discuss methods by which, under commercial conditions of storage, ripe fruit, of apples and oranges, has thus been kept in good condition for several months without resort to cold storage. He makes, however, a plea for further endowment of research at the great ports of Britain at which our imported food supplies enter, in order to enable a more thorough exploration of the methods, individual to every fruit, by which he hopes that ultimately we may succeed in transporting and storing suitably mature fruit by a treatment which will be based on a recognition of its needs as a living organism at a certain stage of existence. The chairman, Sir Halford John Mackinder, endorsed Prof. McLean Thompson's plea for research, but added the advice to the commercial interests involved that they should recruit from universities and colleges scientific practitioners prepared to apply scientific knowledge under commercial conditions to the workaday problems presented by the 'rough and tumble of trade' conditions under which shipping, transport and storage of fruit must take place.

IN the annual report of the Rockefeller Foundation for 1924 Dr. George Vincent, the president, surveys the activities of the Foundation for that year. These include a contribution of 350,000 dollars towards the publishing of an international journal for abstracts of the biological sciences, reports on the progress of medical education in various countries, and contributions for travelling fellowships. Grants were made to various medical schools in Great Britain, Canada, the United States, and China, funds provided for nursing education at Yale University and other schools and hospitals, campaigns organised against yellow fever, malaria, and hookworm disease, contributions made to the Health Section of the League of Nations towards epidemiological intelligence and study tours arranged for health officers, and assistance given to mental hygiene projects in the United States and Canada. The income of the Foundation in 1924 amounted to 8,191,506 dollars, and the disbursements to 7,288,822 dollars. The report also contains reports of the directors of sections, summaries of the work being carried out in various lands, and lists of publications of members and others directly associated with projects in which the Board participated.

IT is reported that archæological and historical discoveries of considerable importance have been made by Sir Aurel Stein, who has been engaged during the last two months on a tour of investigation in the Upper Swat on the Indian frontier. This area abounds in stupas, rock-carved reliefs, and other Buddhist remains, and for many years it had been anticipated that, given settled conditions, it would prove a profitable field for archæological exploration. That its strategic importance has long been recognised is indicated by the strongholds of old-time chieftains which abound, and it is an examination of the topographical features in this connexion that has led Sir Aurel Stein to a conclusion of very considerable historical interest. According to a dispatch from the Simla correspondent of the *Times* which appears in the issue of May 27, Sir Aurel believes that he has succeeded in identifying in a part of the Swat hills known as Torwal the site of Aornos, the fortress described by Arrian which Alexander captured in 327 B.C. This is usually considered to be the greatest achievement of his remarkable march on India. The topographical features of this suggested site appear to correspond with the description given by Arrian. Sir Aurel Stein himself showed some years ago that the suggested identification of Aornos with Mahaban was untenable on the ground that the summit of that mountain did not correspond with the extensive plateau which figures in the Greek account. The probability that Alexander's march to India led him to Bajaur and the Swat valley has now been greatly strengthened. It is further reported that Sir Aurel Stein has discovered two Buddhist shrines mentioned by Chinese pilgrims, a stone bearing the miraculous footprints of Buddha and a boulder with an impression of Buddha's drying clothes, which shows signs of continued local worship.

PROF. G. H. HARDY, Savilian professor of geometry in the University of Oxford, has been elected a corresponding member of the Vienna Academy of Sciences.

THE following have been elected foreign associates of the National Academy of Sciences of the United States of America: Prof. Jacques Hadamard, professor of analysis at the Ecole Polytechnique, Paris; Prof. Richard Willstätter, formerly professor of chemistry at the University of Munich; Sir Frank Dyson, Astronomer Royal, Great Britain; Prof. Max Planck, director of the Institute of Theoretical Physics at the University of Berlin.

THE thirty-first annual congress of the South-Eastern Union of Scientific Societies will be held at Colchester on June 9–12 under the presidency of Mr. Reginald A. Smith, of the Department of British and Medieval Antiquities, British Museum. The presidential address, "Essex in Pre-Saxon Times," will be delivered on June 9; other papers promised include "The Plant Communities of the Seashore," by Dr. E. J. Salisbury, "Dr. Wm. Gilberd, of Colchester, Author of 'De Magnete,'" by Mr. C. E.

Benham, "Some Curious Aspects of Evolution," by Mr. E. C. Stuart Baker, and "The Correlation of the Lower Palæolithic," by Mr. S. Hazzledine Warren

We much regret that, by an oversight, the name of Ives Delage was included in the column of Contemporary Birthdays in our issue of May 8. Prof. Delage died on October 8, 1920.

Erratum. Nature of May 22, p. 720, col. 1. In formula at bottom of column, for "$\cos 2/\phi$" read "$\cos \phi/2$."

Applications are invited for the following appointments, on or before the dates mentioned:—A lecturer in mechanical and civil engineering at Loughborough College—The Registrar (June 7). An assistant lecturer and demonstrator in chemistry and an assistant lecturer and demonstrator in engineering at the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (June 14). A reader in mechanical engineering at King's College, Strand—The Academic Registrar, University of London, South Kensington, S.W.7 (June 17). A professor of botany at the University College of Wales, Aberystwyth—The Secretary (June 19). A professor of Arabic, Persian, and Hindustani at Trinity College, Dublin—The Secretary (June 21). A professor of chemistry and assaying at the Indian School of Mines, Dhanbad—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (June 21). A junior technical officer for development work in connexion with instruments and small precision apparatus—The Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (June 26, quoting references No. A. 95). A curator of the Colchester and Essex Museum, Colchester—The Town Clerk, Town Hall, Colchester (June 28). A librarian for the University of Aberdeen—The Secretary, The University, Aberdeen (June 30). An assistant in the industrial engineering division and an assistant in the science library of the Science Museum, South Kensington—The Director and Secretary, Science Museum, South Kensington, S.W.7 (June 30). A lecturer in zoology, with special reference to the comparative anatomy and embryology of vertebrates, in the University of Edinburgh—The Secretary to the University (July 23). A temporary junior assistant (metallurgist) under the directorate of metallurgical research, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18. Instructor lieutenants in the Royal Navy—The Adviser on Education, Admiralty, Whitehall, S.W.1. A lecturer in botany at the Birmingham Municipal Technical School—The Principal.

Our Astronomical Column.

Comets.—Ensor's Comet maintained the anomalous position of its tail for a full month. On March 16 the tail was 80° from the prolongation of the radius vector from the sun; on April 3, nearly 70°; and on April 13, about 60°. Since matter expelled from the head under solar repulsion would initially proceed along the radius vector, it would seem that the tail was not due to such repulsion: it is not easy to explain its direction, for there was no definite nucleus that could be regarded as a centre of repulsion. On April 13 the comet had sunk to magnitude 17 and was not followed for longer.

Finlay's periodic comet is due to return to perihelion about June 23. It will not be very well placed for observation at this return, being low in the morning sky just before dawn.

The following ephemeris for 0^h is from the B.A.A. Handbook:

	R.A.	N. Decl.
June 11.	2^h $11{\cdot}5^m$	11° 6′
19.	2 46·8	14 18
27.	3 21·9	17 4

It will be better placed in July, owing to its northward motion. It was last seen in 1919.

Comet Pons-Winnecke will return to perihelion in June 1927. An ephemeris by Mr. F. E. Seagrave indicates that it will approach the earth within 4½ million miles on June 26, when its horizontal parallax will be 190″. A well-defined object at that distance would serve admirably for deducing the solar parallax, but it is rather too much to expect that the comet will have a sufficiently definite nucleus for this purpose.

Minor Planets.—A note by B. Asplind in *Astr. Nach.* No. 5442 demonstrates that the hitherto unidentified planets Simeis 59 and Simeis 60, discovered in 1916, are identical respectively with 1029 (discovered last year and named La Plata) and with 962 (discovered in 1921). This identification affords material for a great improvement in the orbit elements of these planets. The following planets have been recently named: 829 Academia, 830 Petropolitana, 917 Lyka, 962 Aslog, 984 Gretia, 1026 Ingrid.

The Spectrohelioscope.—A description of this instrument by Dr. Hale has already appeared in the *Proceedings of the National Academy of Sciences*, 10, 361, 1924, and in Nature, 114, 628, 1924. In the April number, 1926, of the *Publications of the Astronomical Society of the Pacific*, Dr. Hale gives other details of his instrument, which is now permanently set up at his new solar laboratory in Pasadena. Recent observations indicate its wide scope as an important instrument of research and not merely as a very useful scouting auxiliary of the spectroheliograph. The observations are made visually with the hydrogen line *Hα*. Besides the prominences around the sun's limb, it is usually possible to see prominences projected on the disc as dark areas, and bright or dark flocculi, including hydrogen vortices around sunspots. In addition, by setting the second slit on different parts of the *Hα* line, on occasions when there are great line distortions due to high radial velocities, the instrument admits of observations being made in rapid succession of, for example, a brilliant eruption on the violet side of the line and, on the red side, of a dark absorbing mass descending rapidly into the hydrogen vortex. Dr. Hale suggests the possibility of a photographic attachment for reproduction of these rapid changes in the form of moving pictures. An account is given of phenomena, accompanying the very large sunspot of January 1926, and another spot in February, which could be seen with the spectrohelioscope. The author describes modifications he is introducing into the construction of an improved instrument for precision measures of some of these solar phenomena, which it is now possible to study in great detail. We hope to publish shortly an illustrated account of the instrument and of Dr. Hale's recent work with it.

Research Items.

THE SOCIAL ORGANISATION OF THE POMO INDIAN.—A detailed descriptive study of a concrete example of social organisation in its actual working is given by Mr. Edward Winslow Gifford in his "Clear Lake Pomo Society," which is published by the University of California as vol. 18, No. 2, of the *Publications in American Archæology and Ethnology*. This is not an abstract analysis, but is an account of the households, their members, and their affinities one to another, familial and social, as well as their occupations and their activities, ceremonial and other, in the Eastern Pomo village of Cigom on the eastern shore of Clear Lake, Lake County, California. A census by a former inhabitant made in 1919 totalled 235 individuals, 25 per cent hailing from neighbouring villages. These 'foreigners' residing in the village invariably do so because of marriage. All but two of the twenty living-houses were occupied by two or more families, the number of entrances and the number of fires in each house corresponding to the number of families The nucleus of the family was a man, his one wife (monogyny being the rule), and their offspring In size the family group varied from one to ten, but the average was four and a half individuals. Of blood relationships noted, 36 were matrilineal, 16 patrilineal, 5 were neutral, and one unknown. In half the cases the newly-married couple lived with the husband's father, in half with the bride's father. The chieftainship was hereditary, each chief heading a group related to him, usually through females, but there was no village or supreme chief. Among the Eastern Pomo, of eight cases of succession to the chieftainship, four were from the mother's brother to sister's son, one doubtfully so, two from brother to brother, and one from father to son. Among the Northern Pomo, of three cases two were from father to son, and one from mother's brother to sister's son. There was an occasional custom of naming a child for a grandparent, more frequently paternal than maternal.

THE TORADJA OF CENTRAL CELEBES.—Dr. Walter Kaudern, in the second part of his "Ethnographical Studies in Celebes" (Goteborg: Elanders Boktryckeri Aktiebolag), deals with the migrations of the Toradja. It is generally agreed that the Toradja are not the aboriginal inhabitants of Central Celebes. Nor are they a uniform race: two distinctly different types are found, the majority of the people being of a rather dark brown type with round broad face and short broad nose; while the less numerous light brown type has a comparatively oval face, the nose being long and narrow, straight or slightly curved. Apparently the two types were already mixed when they reached Central Celebes. Taking the three big Toradja groups, the Paloe, the Koro, and the Poso Toradja, and basing investigation on accounts of migrations in historic times, legends of prehistoric migrations, inferences from the direction of the home of departed spirits, and cultural, linguistic, and other relations, it would appear that the migrations proceeded along two principal routes, both beginning in the south-east in the tract of Malili on the coast of the Bone Gulf. One went to the north-west to the regions west of Lake Poso, the other went first almost due north and then sent out branches to the north-east and north-west. The former route was that of the Koro Toradja, the latter that of the Poso and Paloe Toradja. The latter only formed part of the easterly stream of people, and moving on in front of the Poso Toradja, spread farther to the north and north-west. Present knowledge is not sufficient to justify any statement as to the kinship of Poso and Paloe Toradja, though there appears to be no essential difference. These migrations were still going on in the eighteenth century. Their cause is obscure; it may have been over-population of the cultivated areas; and attempts to fly from epidemics, of which there is legendary record, may have been a contributory cause.

FOOD OF TERNS.—Dr. W. E. Collinge gives an account (Blakeney Point Publication, No. 26) of his investigation of the food of terns, undertaken at the invitation of the National Trust, in consequence of numerous complaints by local fishermen that these birds were destroying the inshore industry in flat fish. The author found that the food of the terns in the vicinity of Blakeney Point consisted of 40·32 per cent. of fish, of which 25·48 per cent. was food fishes and 14·84 per cent. sandeels. The food fishes were entirely whiting, haddock, herring, and whitebait, and in no single instance was there any trace of flat fish in the stomach contents. He concludes, therefore, that any recent scarcity of flat fish in the Blakeney Point area can in no way be attributable to the terns living there. This vindication should go a long way towards reassuring the local fishermen and enlisting their goodwill in the preservation of this nesting site.

A MALELESS RACE OF DAPHNIA WHICH PRODUCES EPHIPPIAL EGGS.—Dr A. M. Banta (*Zeitschr. f. induktive Abst. und Vererbungslehre*, Bd. 40, 1925) describes a maleless race of *Daphnia pulex* in which nevertheless the characteristic ephippial or 'winter' eggs are produced and developed without fertilisation. The author notes the characters by which this race differs from other types of *D. pulex*. Males have not been found in this race, in spite of long observations on the stock and experimental efforts to cause their production. The usual parthenogenetic ('summer') and ephippial ('winter') eggs are produced, and in every phase of their ovarian and post-ovarian development resemble the corresponding two types of eggs produced by other Daphnidæ, and their homology with these is beyond doubt. These ephippial eggs—which the author suggests should be called pseudo-sexual eggs—readily hatch without fertilisation. This race is possibly identical with the race found in Spitsbergen, in which similar behaviour has been suspected. The author suggests that the race represents a possible step in advance in the evolution of Cladocera in that (1) it has the ephippial egg adapting it to habitats in which periods of drought or low temperature preclude the survival of active Cladocera or of the usual parthenogenetic eggs, and that (2) it possesses the obvious advantage that the non-occurrence of males leaves every individual productive of eggs of the type called forth by the particular temporary conditions of the environment.

CHANGES IN THE BOTTOM FAUNA OF ILLINOIS RIVER AND PEORIA LAKE.—R. E. Richardson (*Bull. Illinois Nat. Hist. Survey*, vol. 15, 1925) records the changes in the bottom fauna of Lake Peoria from 1920 to 1922. In a former paper it was shown that during the six or seven years preceding 1920 there had been an almost complete extermination of the older normal bottom fauna over a stretch of about 90 miles of the Illinois River, including Peoria Lake, and practically complete oxygen exhaustion. This was associated with a large increase (about eight times) in the animals slaughtered in the Chicago stockyards between 1914 and 1918, with a corresponding increase in the waste matter entering the sanitary canal which discharges into the Illinois River. Heavy mortality among the fresh-water snails occurred; in August 1917 dead snails acres in extent were seen floating down the river past Peoria and Havana. The present paper indicates a slight though measurable improvement in the condition of the bottom fauna in the two years 1920–22, but the increase in kinds was almost wholly confined to the group of tolerant Sphæriid snails which survived the destruction of 1915–18. The extension of the range of these snails was parallel to the tremendous increase in numbers of tubificid worms, which ranged so high as 69,000 per square yard opposite Rome in August 1922 and is taken as an indicator of bad bottom. The material was collected by a Petersen bottom sampler. Species that have disappeared from Peoria Lake since 1914 include all but three or four of a total of more than 40 species of fresh-water mussels, all the snails of the family Amnicolidæ, and all but one species of the formerly important and conspicuous family Viviparidæ. The author gives a list of the missing species in the same Bulletin, Article 6.

THE ABSENCE OF AN INNATE SEXUAL CYCLE IN CLADOCERA.—Weismann's view that in Cladocera there is an innate sexual cycle quite independent of environmental influences is contradicted by observations by Dr. A. M. Banta (*Amer. Natur.*, vol. 59, 1925), which indicate that stock recently derived from fertilised eggs of *Moina macrocopa* is neither less nor more prone to produce males, under appropriate environmental conditions, than stock which has descended 300 generations since last undergoing sexual reproduction.

THE SYMBIOSIS OF A FERN AND AN ALGA.—Alfred Limberger records some observations (*Sitzungsber. Akad. der Wissensch*, Wien, Abt. I. 143, pp. 1-6) which make very much more precise our knowledge of the relation existing between the little water fern Azolla and the blue-green Alga Anabæna, which is always found in small cavities in the leaves There are four species of Azolla distributed over different parts of the globe, but in all cases this blue-green alga is associated with the fern; the intimacy of the relation thus established between two plants of very different type has been a matter of speculation. Limberger succeeded, by cultivating Azolla over winter on fairly dry soil in a cold greenhouse, in obtaining a stock of the fern quite free from the blue-green alga. So long as this plant was kept growing under normal conditions next summer, it grew perfectly well and no significant difference could be noted between the alga-infested and the alga-free cultures of the fern. Curiously enough, with two different species of Azolla thus freed from Anabæna, another blue-green alga, Oscillatoria, was found infesting the fern though not entering the leaf cavity, as if the fronds of this little fern had some definite chemotactic attraction for blue-green Algæ or special facilities for their nutrition. With the algæ-free Azolla, Limberger repeated some previous cultures of the plant in food solution with and without nitrogen. It was now found that the fern free from Anabæna died or grew very poorly in nitrogen-free solutions, whilst the fern with Alga in the leaf cavities flourished. Definite evidence seems thus to be provided for the possibility of nitrogen fixation by the alga, which under unfavourable conditions of growth is utilised by the fern. When other sources of nitrogen are present, the alga seems of little use to the fern, in fact may grow so excessively as to become a nuisance.

AN UPPER CRETACEOUS FLORA.—Under the title "The Flora of the Ripley Formation," Edward Wilder Berry describes, in *Professional Paper* 136 of the United States Geological Survey, an Upper Cretaceous flora of some 135 species. The total number of genera represented is 71; of these a supposed Alga Halymenites, and a form referred to Selaginella, are of doubtful botanic affinity; in addition there are six species of ferns, 9 gymnosperms, 9 monocotyledons, and 105 dicotyledons, of which only 10 belong to sympetalous genera. While nearly all the ferns and conifers found appear to have a wide distribution "as befits their ancient lineage," most of the dicotyledons are recorded for this Ripley formation only, and of the 28 per cent. that occur elsewhere, most of them are only recorded from Greenland, which is perhaps the place of origin of the Upper Cretaceous flora of North America. Sixteen of the Angiosperm genera recorded have not been recognised in post-Cretaceous deposits, and the author points out that the contrast between Upper Cretaceous and Eocene floras is usually under-estimated, in part owing to the habit of laying stress upon the coming of the Angiosperms in Upper Cretaceous time, which it is "the fashion to picture—as a sudden and overwhelming event."

THE MICROSCOPIC STRUCTURE OF COAL.—A most interesting lecture on this subject, given before the Royal Society of Arts by Dr. Reinhardt Thiessen of the United States Bureau of Mines, is published in the Society's journal for April 23. After a brief introductory statement of the manner in which various kinds of coals may be pictured as arising progressively from plant remains such as may accumulate under the conditions of the peat bog, where vegetable decay is very slow and in the lower layers of the peat has practically ceased, Dr. Thiessen proceeded to analyse the various types of appearance found in bituminous coals, the clarain, vitrain, fusain, etc., of British writers, into terms of plant remains recognisable by microscopic study. Under the microscope Dr. Thiessen recognises two main classes of constituent: (1) the compressed woody and fibrous fragments of plants, the anthraxylon, and (2) indefinite masses made up of finely macerated plant material, macerated wood, cuticle, spores, etc., grouped under the term 'attritus.' From this lecture it would appear that the methods of study of the coal mining geologist and the palæobotanists are converging at present in their application of new methods of technique with the aid of the microscope to reveal the minute structure of the compressed fragments of plants embedded in the rocks (Harris, NATURE, May 8, 1926, p. 670).

COLORADO RIVER.—The remarkable characteristics of the Colorado River, U.S.A., form the subject of Water Supply Paper No. 556 issued by the U.S. Geological Survey. The river is of exceptional value for irrigation and water power, as it combines in proper sequence for full development and use a large quantity of water, great concentrations of fall, reservoir sites for the control of flow, sites for power plants, and several million acres of irrigable land below the district in which power can be developed. The drainage basin comprises 244,000 square miles and covers parts of seven States. The most urgent need of the basin is flood protection for cities, towns, and large irrigated areas near Yuma and in the Imperial Valley. It is stated in the report that property to the value of one hundred million dollars and the prosperity of many thousands of inhabitants on both sides of the international boundary between the United States and Mexico are seriously menaced by the lack of efficient control works, and this menace is increasing yearly, the maintenance of banks and levees becoming more difficult and costly as time goes on. Mr. La Rue, the writer of the report, has made systematic inspection of the basin since 1914, and the information collected, including geological diagrams and photographs, is intended as a basis for outlining a comprehensive scheme of development for the river and for selection of a site for earliest development.

AN ANCIENT SPECIMEN OF URANINITE.—Another estimate of the age of the earth's crust has been formed from the examination of a sample of uranium lead found in South Dakota. The results of this investigation, carried out by T. W. Richards and L. P. Hall, are published in the *Journal of the American Chemical Society* for March 1926. The atomic weight, corrected for the influence of a known thorium content, is 206·02. Since the sample is nearly pure uranium lead, its age is about $1·5 \times 10^9$ years.

PENETRATING COSMIC RADIATION.—In a recent communication to NATURE, M. L. N. Bogoiavlensky, writing from Leningrad, gives the results of some investigations made by him in the Caucasus, in a region of radium deposits, on "Highly Penetrating Rays of the Earth." A close survey has been made of the penetrating radiation in an area of about 11,000 square yards, traversed by cracks in travertin, containing radio-active material. The results when plotted give equi-radiation lines roughly parallel to the cracks. A measure of the penetrability of the radiation was obtained by the use of lead screens *beneath* the electrometer at the various observing stations, indicating γ-radiation from a radio-active material at 22 stations out of 92. At the other 70 stations a more penetrating radiation only was observed. The minimum screened values varied, showing a variation (even in this small area) of the ionisation due to a more penetrating radiation than that from radium. At these stations the use of side screens was without effect. Experiments in other places over soil of low radium content gave varying values for the ionisation and showed also a very small absorption of the radiation by lead screens. M. Bogoiavlensky's results would appear to supplement those of Hoffmann, who explains the effects by the existence of a more penetrating radiation from radium than the previously known hardest rays from radium C. Against this, Hess has pointed out that the result is explicable on the assumption that the cosmic rays do not appreciably ionise a gas, but only the softer secondary, etc., rays due to these.

SECONDARY RADIATION FROM THE SURFACE OF THE EARTH.—In the *Physikalische Zeitschrift* (March 15, 1926) Hess discusses the very penetrating 'cosmic' radiation and the difference between the absorption co-efficients in water obtained by Kohlhörster and by Millikan. He takes exception to the use of lead as a screen for absorption measurements on account of the appreciable radium content of different lead samples, and for this reason questions Hoffmann's deduction that the penetrating radiation at sea level can be wholly explained as the result of known radio-active elements. Hess points out that this explanation will not fit the fact that the ionisation first decreases and then increases with increasing distance above the earth. He points out further that the key to the results obtained by Hoffmann and by Behounek may lie in the circumstance that the 'cosmic' radiation experiences the Compton effect on scattering, with consequent formation of softer γ-rays, if it is a fact that the ionisation by the softer derived radiation is much greater than that of the primary rays. Already, in 1912, Hess suggested that a part of the differences between measurements of penetrating radiation on land and water might be referred to differences in the secondary radiation from the surfaces.

THE CRYSTAL STRUCTURE OF CATECHOL.—The crystal structure of catechol has been determined by W. A. Caspari, using the rotating crystal method with the three crystallographic axes as rotation axes. Diagrams obtained by projection of the photographs on paper are given in the *Journal of the Chemical Society* for March 1926. From these the number of molecules per unit cell has been deduced as eight, and their manner of disposition is discussed.

NUTRITIVE VALUE OF SYNTHETIC FATS.—From experiments carried out with albino rats and described in the *Proceedings of the Imperial Academy of Japan* for January 1926, the approximate nutritive values of synthetic fats containing fatty acids of an uneven number of carbon atoms have been tabulated. As a check, the food values of fats containing fatty acids of an even carbon atom content were determined under similar conditions. No sharp line of division could be drawn between these two classes of fats as regards their nutritive value.

INTENSITY OF ILLUMINATION AND PHOTOCHEMICAL CHANGE.—Berthoud and Bellenot's experiments on the effect of the intensity of illumination on the velocity of the interaction of iodine and potassium oxalate have been repeated by F. Briers, D. L. Chapman, and E. Walters to test their theory, and their conclusions are presented in the *Journal of the Chemical Society* for March 1926. They found that the rate of reaction is proportional to the intensity of illumination and not to the square root, as found by Berthoud and Bellenot. It was noticed that the reaction continued after shutting off the light, and values for the life of a hypothetical catalyst are given.

ENERGY RELATIONS OF SOUND WAVES.—A very interesting paper giving measurements in connexion with acoustical apparatus was read by B. S. Cohen to the Institution of Electrical Engineers on April 29. The researches were carried out in the laboratories of the General Post Office. A knowledge of the efficiency of telephone lines and apparatus is necessary in telephone engineering, and much of this knowledge is of equal importance to the radio engineer. The frequency of the waves used in speech extends from a frequency of about 100 to a frequency of about 6000, a range of six octaves. By means of a suitable electric filter it has been proved that good quality speech can be transmitted when all waves having frequencies exceeding 2500 are blocked out. Practically perfect speech is obtained when only waves the frequencies of which exceed 5000 are blocked out. To get perfect musical transmission, frequencies up to about 10,000 have to be transmitted. With a normal voice the average speech energy entering a telephone transmitter is about 100 ergs per second. A good violin gave a fairly uniform output of 600 ergs per second at a frequency between 192 and 1300. A male voice intoning twelve vowel sounds at conversational loudness with a fundamental of frequency 129 had an output of 56 ergs per second, and a female voice intoning a vowel with a fundamental of 129 had an output of 40 ergs per second at conversational volume. The characteristics of the ear have been investigated by American engineers. The threshold of audibility for a normal ear varies from an acoustical pressure of 0·15 dyne per square cm. at 60 frequency to 0·001 dyne per sq. cm. at 1000 frequency. Between 1000 and 4000 frequency the sensitivity remains approximately constant at 0·001 dyne per sq. cm. Many methods are suggested for measuring the acoustical efficiency of apparatus, and some useful curves are given.

The Abyssinian Sources of the Nile.[1]

IN pursuance of the policy to carry out a complete investigation of the hydrological conditions existing in the basin of the Upper Nile, the Egyptian Government has recently published the report of an expedition to the Equatorial Lake Plateau, and has followed this up with the present volume which deals with Lake Tana in Abyssinia, whence the Blue Nile flows to the Sudan and Egypt.

The importance of this lake in the schemes for the control of the Nile waters, and protection from very low floods, depends on the practicability of utilising it, and the Albert lake similarly, for storing up the water of an abundant rainy season to supplement the supply of a year of meagre rainfall.

This report describes the work which was carried on from the spring of 1920 to the summer of the following year by Dr G. W. Grabham, Government Geologist of the Sudan, and Mr. R. P. Black, of the Physical Department of Egypt. This was the third occasion on which the Abyssinian Government had given permission for studies of the lake and the Blue Nile's outlet from it to be carried out; the earlier ones having been made by Mr. C. E. Dupuis in 1903, and by Mr. R. B. Buckley in 1916. On the present occasion, however, the work was much more detailed and complete, since the observations of levels and discharges were carried on until May 1924, thus providing discharge data over a period of 34 months, including three flood periods.

The southern shore of the lake, where the Blue Nile leaves it, was the part which the expedition examined and surveyed in detail, and they arrived at the conclusion that the lake is of recent formation, owing its origin to a lava flow from the west which has dammed back the drainage of the shallow valley in which the lake now lies. This lava lying on the plateau basalts of Abyssinia furnishes a solid foundation for the construction of a regulator to control the discharge from the lake. In order that the lands and buildings which lie near the lake should not be inundated as the result of controlling the outflow, a regulator is proposed which will allow regulation through a range of three metres below the present normal lake level. This would provide a reserve supply of about 3500 million cubic metres of water to supplement the supply of Egypt in years of abnormally low flood.

The meteorology and geology of the plateau in the neighbourhood of the lake were carefully studied, and especial attention was paid to evaporation, which is an important factor on large lakes, and Lake Tana has an area of 3060 square kilometres. Observations carried out both with evaporimeters on land and by means of tanks floating on the lake, resulted in determining the rate of evaporation to range from 1·5 mm. per day in August to 6·0 mm. in April, giving a total loss of 1480 mm. in the year. The volume discharged at the outlet varied from about 10 cubic metres per second at the end of the dry season to about 500 cubic metres per second when the lake was at its highest level in September. This amount represents a very small fraction of the flood of the Nile at Assuan, in fact less than one-fiftieth of the volume entering Egypt at the highest stage of the flood; so from this point of view Lake Tana's contribution is unimportant; but if by means of a regulator the volume corresponding to a three metres change of level, 3500 millions of cubic metres, were available in the case of an exceptionally small low-stage supply, the situation in Egypt would be greatly improved.

The cost of the necessary works is put very approximately at about two and a half million sterling, but this might be materially increased if much road-making up to the lake should be necessary.

A large amount of information is given on the country and the people inhabiting the region near the lake, and also on the various routes which lead up to it. The work was carried out in somewhat difficult circumstances, since the surveying, levelling, and measurement of discharges aroused much suspicion locally, although the party were furnished with letters of authority by the Abyssinian authorities at Addis Abeba; but with tact and patience this difficulty was overcome and the work was successfully brought to a satisfactory conclusion.

The report contains sixteen hydrographical and meteorological diagrams of much interest besides maps of the lake, and the Blue Nile outlet, while thirty-four very fine photographs give an excellent presentation of the country, the lake shore, and the gorge of the Blue Nile near the lake.

H. G. L.

International Biology.

IN an interesting address on "International Biology" delivered at the third Pan-American Scientific Congress held at Lima, Peru, a little over a year ago, and recently published (*Bull. Pan-American Union*, Dec. 1925), Prof. Vernon Kellogg cited a number of cases in which it is, or would be, of obvious advantage to have international action in matters of biological science. The almost complete stamping out of yellow fever in the western hemisphere is one of the most striking results of co-operative work—a conspicuous example of useful international biology, for all the fighting of disease and the developing of public health activities rest ultimately on biological research and on the applications of the results of such research.

The successful control of insect pests of crops affords another example, for Prof. Kellogg points out that of the fifty most serious insect enemies of crops, orchards, and stock in the United States, more than three-fifths are immigrants, *e.g.* the Hessian fly, flour and grain moths, ox warbles, and the horn fly from Europe, the cotton boll weevil from Mexico, the San José scale from Japan. But he also pointed out that the grape phylloxera went from New England to France, where more than 2,000,000 acres of vineyards were destroyed before a remedy was found, and that the Colorado potato beetle has established itself in south-eastern France and is threatening to invade the potato fields of Germany. The exchange of insects is, however, fortunately not limited to injurious ones. In its native country an injurious insect is more or less kept in check by predaceous and parasitic insect enemies, and it is now a well-recognised part of economic entomological practice to send experts to foreign countries to search for and bring back the native enemies of important insect pest immigrants—there is thus an international exchange of 'good bugs.'

Similarly, there is the exchange of good plants, and Prof. Kellogg points out that a number of regions of the United States owe their present prosperity, and in some cases even the very existence of their agriculture, to the intentional importation of some crop plant from a distant part of the world, *e.g.* the date oases of California and Arizona, the durum wheat areas of the great plains, the rice fields of California and Texas. Prof. Kellogg remarked that the plants which grow in the colder regions of the earth are mostly species which have crept out of the tropics, adapting themselves as they have spread north and south to the conditions of colder climates, and he thinks there are probably ten times as many undiscovered useful plants remaining in the tropics as are to be found in the colder regions. The plant breeders of the United States are striving to select the hardiest of these tropical species and to adapt them for cultivation as far north as they will grow.

The conservation of migrating birds of practical and æsthetic value affords another example of useful international biology, for the extensive migrations of these birds require that conservation shall hold good in the extent of their range. The rational use and protection of the animals of the oceans that wash the coasts of North and South America was also cited, *e.g.* the fur seals of the Pacific were saved from extinction by international agreements made in 1911 between Great Britain, Russia, Japan, and the United States. But the sperm whale is passing, and unless international action is taken it will soon be gone.

Finally, Prof. Kellogg directed attention to the international exchange of human beings—the matter of emigration and immigration with all the perplexing biological problems inherent to it. While many people consider the economic and political significance of the problem, it is incidental to and determined by the biological results. The National Research Council of the United States has a special committee at work on "the scientific problems of human migrations," for it is fully realised that the strength of the nation rests at bottom on the kind of heredity possessed by the people of the nation—it rests at bottom on biological factors

Petroleum in the Maracaibo Region, Venezuela.

THE Maracaibo Basin, situated in western Venezuela, is an area of some 25,000 square miles, embracing the State of Zulia and parts of the States of Mérida, Táchira, and Trujillo; within this region occur the principal oilfields of Venezuela, while those of the State of Falcon, lying to the east, are geologically connected therewith. Though the presence of oil in this country was known in the early days of the Spanish occupation, commercial exploration did not commence until 1878, when the Government granted a small lease in the State of Táchira; progress was slow, however, and it was not until 1912 that important developments were undertaken, resulting in the discovery of the now famous Mene Grande oilfield. To-day practically the whole of the basin area is held under exploration or prospecting licences, and besides Mene Grande, the oilfields of La Rosa, Ambrosio, El Mene, La Concepcion, La Paz, Rio Palmar, Rio de Oro, and some potential petroliferous territory in the south, have been discovered.

Geologically the Maracaibo Basin corresponds with a vast geosyncline, the centre of which is occupied by Lake Maracaibo; the peripheral mountain ranges to the west, south, and east are composed of igneous and metamorphic rocks flanked by Tertiary and Cretaceous sediments, of which the Miocene formation is conspicuous for its associated gas and oil seepages. West and south of the lake the structures trend N.E.-S.W., thus conforming to the prevalent Andean trend in this part of the country; east of the lake, especially in the Bolivar district, the E.-W. influence of Caribbean tectonics is shown by the major folds. The chief characteristic of all the structures within the basin is their great linear development, usually coupled with gently dipping rocks. The best-known folds are the Mene Grande-Curaçao anticline (with its curious 'spurs' or 'lobes' running at right angles, and on which the Ambrosio and La Rosa fields are located), the Rio de Oro and La Tarra anticlines south-west of the lake, and the Rio Poco fold running parallel to the Mérida Range in the south.

The most important field is that of La Rosa, situated 27 miles S.E. of Maracaibo city, the scene of a famous gusher in 1922, Barroso No. 2, which flowed a million barrels of oil in nine days; since then 125 wells on this field have accounted for 12,000,000 barrels of oil. The Mene Grande field yielded 18,000,000 barrels up to the end of 1925, the oil being of an asphaltic nature with gravity 0·956; it is piped to and refined at San Lorenzo, thence shipped by lake steamer to Curaçao and elsewhere. The El Mene field has produced 4,400,000 barrels from about 50 wells and is noted for its low gravity oil (0·850) and high petrol and kerosene yields (35 and 38 per cent. respectively). The other fields are smaller, though in most cases important extensions are anticipated. Mr. Campbell M. Hunter, from whose paper read before the Institution of Petroleum Technologists on April 13 the foregoing details are taken, is of the opinion that production for this year in the Maracaibo Basin will substantially exceed 30,000,000 barrels, thus placing Venezuela as the fifth, if not the fourth, largest oil-producing country in the world, a remarkable rise in a little more than seven years.

University and Educational Intelligence.

CAMBRIDGE.—The Civil Commissioner for the Eastern Division has written to the Vice-Chancellor tendering to the University the congratulations and thanks of His Majesty's Government for the very notable part it played in assisting towards maintaining essential services during the recent critical period. About 4000 students were enrolled for national service, more than 2000 were actually called up for work, and enthusiastic appreciation has been generally expressed by those who secured from the undergraduates services "willingly given and unselfishly and efficiently performed."

Notice is given that a professor of mineralogy, in succession to the late Prof. Lewis, will be elected on June 26. Candidates are requested to communicate with the Vice-Chancellor on or before June 19.

The Council has proposed graces for the conferring of the following honorary degrees among others: LL.D. on Sir Samuel Hoare, Mr. Ramsay MacDonald, and Sir Frederick Maurice; and Sc.D. on Sir Josiah Stamp.

Sir Arthur Shipley, Master of Christ's College, is being re-appointed as representative of the University on the Council of the Marine Biological Association.

Applications are invited for the John Lucas Walker studentship in pathology, value 300*l.* a year and tenable under certain conditions for three years. Applications must be sent to reach Prof. H. R. Dean, Pathological Laboratory, Medical School, Cambridge, before June 15.

EDINBURGH.—In recognition of the work done by students of the University at Leith Docks during the recent strike, Mr. Thomas Cowan, a retired shipowner, has sent a cheque for 10,000*l.* for the general purposes of the University. In a letter sent with the cheque

Mr. Cowan, who was chairman of the Emergency Committee of the Leith Dock Commissioners, states that he was greatly impressed with the enthusiasm, initiative, and working capacity of the 270 students who undertook service at the docks and helped to relieve the congestion of traffic there.

Liverpool.—The Senate and Council of the University have resolved to confer the degree of Master of Science, *ex officio*, on Mr. Herbert Clifton Chadwick in consideration of meritorious services rendered to the staff and students, and of distinction in Zoological research during the period 1897-1922, when he was curator of the Marine Biological Station at Port Erin, Isle of Man.

Two post-graduate research fellows will shortly be appointed to the Munitions Committee Research Fellowships, and applications are invited from graduates of the University engaged in industry or research. The value of each fellowship is 250*l.* for the first year and 350*l.* for a second if the appointment be renewed. Applications should reach the Dean of the Faculty of Engineering before June 15.

Prof. A. Stock of Dahlem, Berlin, has been appointed Director of the Chemical Institute at the Technische Hochschule in Carlsruhe.

Prof. Bohuslav Brauner, director of the Chemical Institut of the Charles University of Prague and an Hon. D.Sc of the University of Manchester, has been elected an honorary member of the American Chemical Society.

The degree of Doctor Rerum Naturalium has been conferred in the Charles IV. University of Prague upon Mr. Edward Browning Sanigar, of Sheffield, for his thesis "The Electrolysis of Complex Cyanides with the Dropping Mercury Cathode." This is the fourth doctorate of this University conferred in recent years on an Englishman.

The Carnegie Endowment for International Peace has three divisions: Intercourse and Education, International Law, and Economics and History. A report on the work of the first division has recently been issued by the Director, Dr Nicholas Murray Butler, who is also president of the Endowment. It tells first of the progress of the arrangements for the restoration of the library of the University of Louvain. A sum of 200,000*l.*, towards which the Carnegie Endowment has contributed 31,400*l.*, has been collected, and this will suffice not only for restoration but also for a maintenance endowment of 20,000*l.* Chief among the projects to which funds were allotted during the year is a conference of representatives of the Press of the United States which was to be held with the co-operation of the Academy of Political Science in May in the vicinity of New York. The Division has also invited some fifty American college and normal school teachers of international law and international relations in the United States to visit Paris, The Hague and Geneva during August and September next. At Geneva this party will be in charge of the American Committee of the Geneva Institute of International Relations, to which the Endowment gave 800*l.* last year. The Committee maintains an office for the reception of English-speaking visitors who come to Geneva to study international co-operation. The report announces the constitution of a Comité d'Administration to serve as an executive committee of the Division for work in Europe with offices at the Centre Européen, 173 Boulevard Saint-Germain, Paris. It is about to issue a new quarterly international review, *L'Esprit International*.

Contemporary Birthdays.

June 5, 1843.	Dr. Samuel Garman.
June 6, 1842.	Mr. Henry Martyn Taylor, F.R.S.
June 7, 1877.	Prof. Charles G. Barkla, F.R.S.
June 7, 1868.	Prof. John S. Townsend, F.R.S.
June 9, 1875.	Dr. Henry Hallett Dale, F.R.S.
June 10, 1866.	Lord Montagu of Beaulieu, K.C.I.E
June 11, 1867.	Prof. Charles Fabry.

Dr. Samuel Garman, the veteran naturalist, foreign member of the Linnean Society, was born at Indiana U.S.A. Graduating at Illinois State Normal University, he came for a brief period under the guidance of Louis Agassiz. Dr. Garman has been on the herpetological and ichthyological staff of the Museum of Comparative Zoology, Harvard University, since 1871. He accompanied the late Alexander Agassiz on most of his South American expeditions connected with deep-sea survey work. Dr. Garman is the author of "The Reptiles of Easter Island" (1908).

Mr. H. M. Taylor was born at Bristol and educated at Wakefield Grammar School and Trinity College Cambridge, graduating (1865) third wrangler. In this year the late Lord Rayleigh was the senior wrangler and the late Prof. Alfred Marshall, the economist second wrangler. Being blind himself, Mr. Taylor has long been personally identified with the production of embossed books on scientific subjects. We believe that he once composed a standard algebraical treatise in Braille type, afterwards read the copy with his fingers, and again, later, read the proof.

Prof. Barkla, a Lancashire man, born at Widnes was educated at University College, Liverpool, going from there to Trinity College, Cambridge, where early he came under the inspiring influence of Sir Joseph J. Thomson. He was appointed Wheatstone professor of physics in King's College, London, in 1909 and since 1913 he has occupied the chair of natural philosophy in the University of Edinburgh Prof Barkla's particular investigations have dealt mainly with X-rays and their absorption and secondary emission by solid substances. He was Nobel laureate in physics in 1917, whilst also in that year he was allotted the Royal Society's Hughes medal.

Prof. Townsend, born in Galway, was educated at Trinity College, Dublin, and at Cambridge. He is a chevalier of the Legion of Honour. In 1914 he received the Hughes medal of the Royal Society for his researches on electric induction in gases.

Dr. Dale is a Londoner. He was educated at Tollington Park School, London, and the Leys School Cambridge, graduating afterwards at Trinity College Last year he was elected one of the secretaries of the Royal Society.

Lord Montagu of Beaulieu was educated at Eton and New College, Oxford. Automobilism and aviation are among his interests. He is a verderer of the New Forest.

M. Fabry, professor of physics at the Sorbonne Paris, was born at Marseilles. In 1918, jointly with Dr. A. Perot, the Royal Society allotted them its Rumford medal in respect of their contributions to optics, particularly for the introduction of a new method of measuring wave-lengths by utilising the luminous rings formed by interference between two reflecting plates. Recently Prof. Fabry lectured before the Physical Society of London on the absorption of radiation by the upper atmosphere.

Societies and Academies.

LONDON.

Royal Society, May 20.—A. V. Hill: The laws of muscular motion (Croonian lecture). In all kinds of contractile tissues there are certain similar, or analogous, processes; so that in discussing properties of striated muscle we are really dealing with very general phenomena. Recent work on the chemical reactions of breakdown and recovery, and the rôle of glycogen, lactic acid and phosphate was discussed. If physiological response of muscle undergoing stretch be less than that of muscle allowed to shorten, why is the tension at any given length so much greater during stretch than during shortening? The answer provides an important clue to the nature of the contractile process. Re-development of contraction after quick release was discussed, and also the 'viscous-elastic' model.

Society of Public Analysts, May 18.—A. Chaston **Chapman**: The detection and determination of glycerin in tobacco. The tobacco is mixed with sodium sulphate (to absorb moisture) and extracted with acetone. The residue from the extract is freed from resins, and its glycerol content determined by a modification of Zeisel's silver iodide method. For a qualitative test the glycerin is separated by extraction and distillation.—Harold **Toms**: The crystalline bromides of linseed and some other oils. The most insoluble bromide of linseed oil, as crystallised from ethyl acetate, is not an ethyl ester, but a glyceride. When hydrolysed with hydrobromic acid it yields, as its only recognisable product, hexabromostearic acid, but this does not prove the absence of tetrabromostearic acid, which is converted by hydrobromic acid into a sticky derivative. The insoluble bromides of perilla, candlenut and para rubber seed oils are identical with the linseed oil bromide. Tetralin is a better solvent than ethyl acetate for crystallising oil bromides.—A. **Bakke** and Paula **Henegger**: The polarimetric determination of sucrose in condensed milk. A modification of the method of Revis and Payne is used, employing mercuric nitrate both as precipitant and as inverting agent. Results agreeing with the gravimetric results were obtained in the winter months, but there was a discrepancy in summer due to such causes as altered period of lactation, period of fresh grass feed, etc., on the original milk.—W. R. **Schoeller**: The separation of iridium from iron. The method used is based on the precipitation of ammonium chloroiridate $(NH_4)_2IrCl_6$; allowance is made for the amount of iron adsorbed by the ammonium chloride precipitate.—H. L. **Smith** and J. H. **Cooke**: The determination of very small quantities of iron. A colorimetric method has been devised in which the sensitiveness of the thiocyanate reaction is very greatly increased. Zinc interferes, and for determining iron in zinc compounds the iron thiocyanite is extracted with a suitable solvent, such as a mixture of amyl alcohol and ether, and the colour of the extract matched.—J. N. **Rakshit**: The determination of total alkaloids, sugar, and oily substances in opium. The alkaloids in an aqueous extract of opium and those remaining in admixture with the opium wax are determined. For the determination of sugar, titration with Fehling's solution after removal of alkaloids gives fairly concordant results. Added oil or wax is indicated by a saponification value differing from that of opium wax, and is approximately determined by the appearance of the opium when heated on a plate over steam.

Royal Meteorological Society, May 19.—E. S. **Player**: Meteorological conditions and sound transmission. (i.) Sounds originating on the surface. Observations were made near the North Foreland, Kent, the sources of sound being the sirens of the light-vessels in the locality. Note-frequency of the sirens did not vary, and, the light-vessels being stationary, distances and bearings remained constant. Examples were met of rapid and continual changes over very short periods in sound intensity, and the effects of humidity, temperature, rain, and the general combination of conditions, were examined. (ii.) Sounds arriving from an altitude. The sources used were aeroplane notes which vary in frequency and obviously occupy positions which are continually changing. Observations of upper-air conditions showed a practically constant fall in temperature, but strata of varying relative humidity. Sound was transmitted well when the variations of these strata were small, and the atmosphere, therefore, more nearly approached a homogeneous state; great or abrupt changes had a destructive effect. Acoustical conditions were often good for surface sounds, while bad for sounds transmitted from an altitude, and vice versa.—J. **Glasspoole**: The wet summer of 1924 and other wet seasons in the British Isles. Maps are given of the rainfall (as a percentage of the normal) of this and other wet seasons over the British Isles since 1870, of from three to seven months' duration. Seventeen such periods are recorded. A comparison of the maps with those for dry periods indicates that while large deficiencies are confined mainly to the south and east of the British Isles, large excesses do occur in the north and west.—C. E. P **Brooks**: Pressure distributions associated with wet seasons in the British Isles. The average pressure distribution over the northern hemisphere during each of the wet periods enumerated above from 1876 to 1924, represented as deviations from normal, fall into two clearly defined types. (*a*) Greatest deficit of pressure over Iceland; (*b*) greatest deficit of pressure over the British Isles. With a pressure distribution of type (*a*) the S.W. winds over the British Isles would be stronger than normal, giving more orographic rain on the western highlands, and in the four periods classed as of this type, the rainfall distribution was found to be mainly orographic. With a pressure distribution of type (*b*) there would be a tendency for depressions to pass directly across the British Islands, giving an excess of rainfall over the whole country (cyclonic type), and with the exception of April-June 1907, all the periods with a pressure distribution of type (*b*) had this type of rainfall distribution. The conditions in the Atlantic Ocean during and preceding these wet periods were then investigated. (1) Favourable to a wet period of the mainly orographic type: N.E. trade wind velocity below normal nine to twelve months before; S.E. trade wind velocity below normal twelve months before; pressure difference, Sydney (Nova Scotia) minus Ivigtut (Greenland) above normal three months before; amount of ice near Iceland below normal during the wet period. (2) Favourable to a wet period of the mainly cyclonic type: Pressure difference, Sydney minus Ivigtut, above normal three months before; amount of ice near Iceland above normal in preceding spring, but below normal during the wet period. The weak N.E. and S.E. trades and the large pressure difference between Sydney and Ivigtut all contribute to a lower temperature in the North Atlantic, which may thus be the chief cause of a wet season in the British Isles. The part played by the Iceland ice is probably to determine the location of the greatest deficit of pressure.

MANCHESTER.

Literary and Philosophical Society, May 11.—John **Walton**: (1) On some Australian fossil plants referrable to the genus Leptophlœum, Dawson. The paper deals with the genus Leptophlœum, Dawson, instituted in 1862 for a fossil stem of Lycopod affinities from the Upper Devonian of Maine, U.S.A. The importance of some of the features exhibited by the type specimen was stressed, particularly in connexion with the relation between this fossil and the Australian fossils which have been referred to *Lepidodendron australe* or *Leptophlœum australe*. Some hitherto undescribed features of the Australian plants were described. (2) A note on the structure of the plant-cuticles in the paper coal from Toula in Central Russia. These cuticles have been referred to Bothrodendron by some authors, and to Lepidodendron by others. In some specimens the presence of the cuticle of the ligular pit can be demonstrated. The evidence for referring these fossils either to one or the other of the two genera is of a conflicting nature, but on the whole it seems in favour of Bothrodendron. There is considerable difficulty in distinguishing between the smaller vegetative branches of Lepidodendron and Bothrodendron.

PARIS.

Academy of Sciences, April 26.—Maurice **Hamy**: A particular case of the diffraction of solar images.—André **Blondel**: The modulation of transmitting stations with valves fed with continuous current.—S. **Winogradsky**: Spontaneous cultures of (nitrogen) fixing micro-organisms. A study of the substances favourable to the growth of Azobacter in earth cultures.—Charles **Nicolle**, E. **Conseil** and P. **Durand**: The agent of scarlet fever. The authors' experiments confirm the views of Dick, that scarlet fever is due to a Streptococcus, and can be prevented by a vaccine.—Axel **Egnell**: Curvature and divergence.—A. **Demoulin**: Conformal geometry of surfaces and of triple orthogonal systems.—F. P. **Bessonoff**: Nearly periodic functions with one complex variable, defined in the whole of a plane.—Paul **Le Rolland**: The measurement of hardness by the pendulum. A claim for priority in the use of the pendulum for measuring hardness of metals.—Eugène **Barré**: The theory of mine craters.—T. V. **Jonescu**: The variations of intensity of the thermionic current when the distance between the filament and the anode is changed.—Léon and Eugène **Bloch**: A second spark spectrum of iron. A comparison of the arc and spark spectra of iron between the wave-lengths 2300 and 1850 Å.U. shows that the arc spectrum and condensed spark spectrum are clearly different, and to such an extent that it is difficult to find in one the lines characteristic of the other.—E. **Dureuil**: The use of magnesium as electrode supports in spectrum analysis. Magnesium as a support in spectrum analysis has certain advantages over the materials commonly used. In the region between 7000 Å.U. and 3500 Å.U. there are only about a dozen strong lines and these do not interfere. Magnesium electrodes can be used for the production of either arc or spark spectra.—René **Lucas**: The rotatory power of camphor. Experiments giving the rotatory power of camphor for different wave-lengths in sulphuric and phosphoric acid solutions, and a discussion of some criticisms of Louis Longchambon.—G. **Bruhat** and M. **Pauthenier**: The rotatory power in the ultra-violet of tartaric acid in dilute solution. Details of experiments are given which show clearly the existence of a dispersion anomaly, with a change of sign in the ultra-violet, even for solutions containing 0·25 per cent. of tartaric acid.—Pierre **Jolibois**, Henri **Lefebvre** and Pierre **Montagne**: The decomposition of carbon dioxide under reduced pressure by the condensed spark. When the circuit is formed with a conductor of negligible self-induction, removed as far as possible from the decomposition tube except in the neighbourhood of the connexions, the dissociation reaches a limiting value of about 90 per cent. and the yield in chemical energy of the first spark is of the order of 20 per cent., the remainder of the energy of the spark being degraded in the form of radiation.—Mlle. Suzanne **Veil**: The decomposition of hydrogen peroxide in the presence of certain hydroxides in suspension. During the decomposition of hydrogen peroxide by the hydroxides of nickel, iron and chromium in suspension, the chemical phenomena correspond with a magnetic variation of the solid phase. The term 'magneto-chemical' is suggested for such reactions.—L. **Abonnenc**: Drops formed in an electric field. Drops forming at the end of a cylindrical tube are generally reduced in weight when placed in an electric field. It is shown that the viscosity of the fluid remains unchanged.—A. **Demay**: The structure of the crystalline massif of Mont Pilat, near Saint-Etienne.—P. **Russo**: The presence of quaternary glacial deposits in the eastern Riff.—P. **Mougin**: The periodicity of glacier increase.—J. **Thoulet**: The region of active submarine volcanoes of the Hawaii Islands in the north Pacific.— —**Theodor**: The formation of the chromoplasts in the Phanerogams.—Mlle. Eudoxie **Bachrach**: The effects of the intoxication of the lactic bacillus by potassium chloride at different temperatures. Under the prolonged influence of a mineral poison it is known that the lactic bacillus undergoes one of two modifications: either it becomes accustomed to the poison or becomes sensitised. It is now shown that according to the temperature at which the strains are cultivated in the toxic medium, either modification can be obtained at will.—A. **Paillot** and R. **Noel**: The origin of the albumenoid inclusions of the adipose body of insects.—**Raymond-Hamet**: A new method of physiological titration of preparations of ergot.—J. **Gautrelet**, R. **Bargy** and Mme. **Vechiu**: The action of chloralose on the nervous system.—Maurice **Piettre**: The acetone method permitting the localisation in the serum albumen of the hæmolysine of a hæmolytic immunoserum.—J. **Sabrazes**: The Spirochætes of typhoid and paratyphoid excreta; their possible agglutinability by the blood of the carrier; their presence in peritonitis by perforation.—Georges **Blanc** and Jean **Caminopetros**: Some experiments on anthrax infection. Experiments are described showing that the skin is not the only part sensible to anthrax infection, the central nervous system being much more receptive.—**Marage**: The influence of the dose of a drug on the defence of the organism

ROME.

Royal Academy of the Lincei, March 21.—Umberto **Cisotti**: The electrostatic field due to any number of thin electrified conductors of cylindrical form and with parallel axes.—Giovanni **Lampariello**: Continuous surfaces which assume finite area.—Orazio **Lazzarino**: Generalisation of Joukovsky's formula on the motion by inertia of a semi-rigid gyroscope.—Guérard des **Lauriers**: Dini's problem.—A **Kolmogoroff** and G. **Seliverstoff**: The convergence of Fourier's series.—Bianca **Nannei**: Immediate effects and hereditary effects in the torsion of a bismuth wire.—Paolo **Straneo**: Physical bases for an extension of the theory of hereditary phenomena.—A. **Proviero**: The use of damping in seismographs. The use of damping in seismographs is unnecessary and, although a damped apparatus gives trustworthy values of the term μ^2, it is almost replaceable by a single non-damped apparatus and is certainly of less advantage than two non-synchronous seismographs.—Adolfo **Ferrari**: The crystalline structure of the fluorides of certain divalent metals. The anhydrous fluorides, FeF_2, CoF_2, NiF_2, and ZnF_2, exhibit the same tetragonal crystalline lattice, which is of the 'rutile' type.—V. **Caglioti**: A new example of anomalous mixed crystals.—P. **Comucci**: Notes on wulfeenit and vanadinite from Oudida (Morocco).—Cramela **Ruiz**: Barytes from the Giona mine (Racalmuto).—Enoch **Peserico**: Variation in the electrical resistance of the submaxillary gland during functional activity.—C. **Iucci**: Capacity for parthogenesis of the egg of the second generation of the bivoltine race of silkworms.

SYDNEY.

Linnean Society of New South Wales, March 31.—H. J. **Carter**: Entomology—past and present (presidential address). The scientific conception of entomology is modern. The seven orders into which Linnæus divided insects are, with one exception, surprisingly near the modern classification. Historical entomological records show the close interweaving of observation with pure fable characteristic of natural history literature, and great dependence on 'authority' and on superficial evidence. The great importance of the study of entomology and its increasing penetration into practical politics is also discussed. The immense number of insects, their complexity of form and development, their close interrelation, and their vast geological age give them a peculiar value to students of evolution and genetics. Australia, in particular, with its huge area of lightly differentiated regions—so far as defined zoogeographic barriers are concerned—affords a good field for the study of variation. The economic aspect of entomology is becoming more important. Reference is made to the attempts to control such pests in North America as the gipsy moth, the European corn borer, and the Japanese beetle, and in Australia the prickly pear, the cattle tick, and the sheep blow-fly. Satisfaction is expressed at the increasing number of Australian entomologists entering various fields. Among the advantages of having the systematic work done by Australians are: (1) The work is done largely by men who combine field observation with literary knowledge of the subject, and (2) the types remain in Australia for reference.—J. R. **Malloch**: Notes on Australian Diptera (No. viii.). Descriptions and notes on further Australian and Tasmanian species of Sapromyzidæ, Clusioididæ and Muscidæ; one genus and twenty-eight species are described as new.—R. J. **Tillyard**: Upper Permian insects of New South Wales. Part I. Introduction and the order Hemiptera. The upper Permian insect fauna found at Belmont, Warner's Bay, Merewether Beach, and Newcastle, N.S.W., is by far the most highly specialised Palæozoic insect fauna known, and consists of only small to medium-sized species belonging to the orders Hemiptera, Coleoptera, Mecoptera and Neuroptera, together with the two extinct orders, Paramecoptera and Protocoleoptera. All these were holometabolous or ancestral to holometabolous forms, except only the Hemiptera, which are only represented by the sub-order Homoptera. In the Homoptera five families (all now extinct) are represented, with fifteen genera and twenty-eight species, twenty-four of which are described as new. The fauna thus ranks next in importance in number of genera and species to that of the Ipswich Upper Triassic in Queensland; as regards the Sternorrhyncha, it is the richest fauna yet discovered.—C. H. **Curran** and E. H. **Bryan**, Jr.: The Australian Syrphidæ in the Bishop Museum (Diptera). The apparent abundance of species of Psilota is noteworthy as this genus is poorly represented in other parts of the world. Five species (two of Psilota, one Chrysogaster, one Microdon, and one Cerioides) are described as new.—G. H. **Cunningham**: Gasteromycetes of Australasia (iv.). Species of the genus Geaster.

WASHINGTON.

National Academy of Sciences (Proc. vol. 12, No. 4, April).—Carl **Barus**: Mutually counteracting pinhole probes.—Frank C. **Hoyt**: Transition probabilities and principal quantum numbers. Using the 'classical' form of the quantum theory, the transition probabilities are calculated from the term values of the stationary states of an atom alone, and the corresponding amplitudes can also be found. No justification is offered for the method of averaging used.—W. H. **McCurdy**: Absorption and resonance radiation in excited helium and the structure of the 3889 line. See NATURE, January 23, p. 122. The line 3889 Å.U. has a weak component 0·044 Å.U. to the short wave-length side of the main component.—B. **Bruzs**: Thermodynamic derivation of a black body radiation isotherm. A number of processes of the form $A \rightarrow B - Q$, where Q is connected with the absorption of heat, are considered. An 'ideal' substance is used and Q is assumed to be independent of temperature.—Enos E. **Witmer**: Critical potentials and the heat of dissociation of hydrogen as determined from its ultra-violet band spectrum. Lyman found that in the presence of a large proportion of argon, helium emits groups of lines between λλ 1063 and 1670. Working on these results, the heat of dissociation of the hydrogen molecule is considered to be equal to the vibrational energy for that value of the vibrational quantum number at which the frequency is zero. The probable value is 4·34 volts or 100,100 calories. The higher resonance potentials and the ionisation potentials of the hydrogen molecule are calculated.—G. Y. **Rainich**: Curved space-time and radiation. The suggestion is put forward that radiation is concentrated in singular lines, when intensity becomes a statistical conception similar to that of modern conceptions of the mass of a body. This points to a reconciliation of the wave theory of light with the emission theory.—Friedrich G. **Brieger** and A. J. **Mangelsdorf**: Linkage between a flower colour factor and self-sterility factors. Three allelomorphic sterility factors are recognised in Nicotiana. The factor for ivory flower colour and the sterility factors segregate independently; white flower colour is linked with them.—Clyde E. **Keeler**: On the occurrence in the house mouse of a Mendelising structural defect of the retina producing blindness. The defect is characterised by complete absence of rods and external molecular layer and reduction of the external nuclear layer, resulting in total blindness. It affects both sexes, behaves as a Mendelian recessive, carries no lethal action, and appears after birth.—Raymond **Pearl**: Vital statistics of the National Academy of Sciences. (5) The growth of the Academy. The numbers of living members on December 31 of each year are used. In the years 1863–76 the Academy doubled its membership; from 1867–90 it maintained a membership of about a hundred, decreasing afterwards until 1898. Since then it has steadily grown, and at the end of 1925 had reached 230.—Einar **Hille**: On Laguerre's series. (1) The formal Laguerre's series of a certain class of functions can be shown to be summable Abel. Expansions of zero are obtained and a summation theorem for Hermitian series is given. (2) The summation theorem of (1) can be utilised in the convergence theory of Laguerre's series.—G. A. Miller: Groups containing a relatively small number of Sylow subgroups.

Diary of Societies.

SATURDAY, June 5.

Royal Society of Medicine (Otology Section), at 10.30 A.M.—Dr. W. H. Hartridge: The Fundamental Experiments on which the Resonance Theory is based.

North of England Institute of Mining and Mechanical Engineers (Associates' and Students' Section) (at Newcastle-on-Tyne), at 3.—P. S. Lea: Notes on Safety Lamps abstracted from Recent Reports.

Royal Institution of Great Britain, at 3.—Sir Walford Davies: The Triad and the Perfect Fourth; their Uses from Hucbald to the Present Day. (With Musical Illustrations.)

MONDAY, June 7.

Royal Society of Edinburgh, at 4.30.—Prof. F. H. Edgeworth: On the Development of the Cranial Muscles in Protopterus and Lepidosiren.—Dr. G. W. Tyrrell and Dr. M. A. Peacock: The Petrology of Iceland. Part 1—The Basic Tuffs.—MM. Prawochenski and Kaczkowski: Observations on the Fragment of a Horse Skull from Interglacial Deposits near Pulawy, Poland.—Y. Tamura and Dr. F. A. E. Crew: On the Effects of Vasectomy and of Epididymo-Deferentectomy in the Mouse.

Institute of Actuaries, at 5.

Royal Institution of Great Britain, at 5.—General Meeting.

Aristotelian Society (at University of London Club), at 8.—Dr. C. Delisle Burns: The Activity of Mind.

Royal Society of Medicine (Social Evening), at 9.30.—F. T. G. Hobday: Our Animal Friends as Patients (Address).

TUESDAY, June 8.

Royal Anthropological Institute (Exhibition of Tardenoisian and Pigmy Types of Stone Implements), at 2.30 (continued until June 22).

Manchester Geological and Mining Society, at 4.

Royal Institution of Great Britain, at 5.15.—Brig.-Gen. Sir Percy Sykes: Chinese Turkestan and the Pamirs.

Quekett Microscopical Club, at 7.30.—E. Heron-Allen and A. Earland: Selective Building in the Shells of the Foraminifera.

Röntgen Society (Annual General Meeting) (at British Institute of Radiology), at 8.15.—A. E. Speight: Abstracts from Apparatus and Technique for Radiography of the Accessory Sinuses.—Dr. L. A. Levy and D. W. West: A New Method of Dosage for Use in Actinotherapy.

Royal Anthropological Institute (at London School of Economics), at 8.30.—M. Terry: Some Little Studied Aborigines encountered during Travels in Northern Australia.

WEDNESDAY, June 9.

Royal Institution of Great Britain, at 5.15.—Prof. J. Barcroft: Organs of Multiple Function (4). Lungs.

Geological Society of London, at 5.30.—Dr. W. D. Lang: *Nas pagoda* (Salter): the Type of a New Genus of Silurian Corals.—J. F. Jackson: The Junction-Bed of the Middle and Upper Lias on the Dorset Coast.—Prof. P. G. H. Boswell: A Contribution to the Geology of the Eastern Part of the Denbighshire Moors.

Radio Society of Great Britain (Informal Meeting) (at Institution of Electrical Engineers), at 6.

Institute of Water Engineers (at Manchester) (continued on June 10, 11, and 12).

THURSDAY, June 10

Royal Society, at 4.30.—Dr. A. V. Hill: The Viscous-Elastic Properties of Smooth Muscle.—A. S. Parkes: (a) Observations on the Œstrous Cycle of the Albino Mouse; (b) On the Occurrence of the Œstrous Cycle after X-Ray Sterilisation.—Isabella Gordon: The Development of the Calcareous Test of *Echinocardium cordatum*.—J. Walton: Contributions to the Knowledge of Lower Carboniferous Plants.—Prof. J. H. Priestley and E. Rhodes: On the Macro-Chemistry of the Endodermis.—D. Keilin: A Comparative Study of Turacin and Hæmatin and its Bearing on Cytochrome.—E. Ponder: The Equations applicable to simple Hæmolytic Reactions.—J. P. Hoet and Phyllis Kerridge: Observations on the Muscles of Normal and Moulting Crustacea.—C. H. Best and H. P. Marks: Additional Note on the Effect of Insulin on the Lactacidogen Content of the Skeletal Muscles.

Institute of Pathology and Research (St. Mary's Hospital, Paddington), at 5.—Dr. J. Freeman: The Pathological Mechanism of the Asthma Syndrome.

Linnean Society of London, at 5.

London Mathematical Society (at Royal Astronomical Society), at 5.—

Royal Institution of Great Britain, at 5.15.—Dr. J. Newton Friend: Science in Antiquity (2).

Optical Society (at Imperial College of Science and Technology), at 7.30.—Dr. L. C. Martin: The Distribution of Light in Elementary Optical Images.—T. Smith: (a) Note on the Criterion for the Best Position of Focus; (b) The Stationary Position of Axially Symmetric Functions.

FRIDAY, June 11.

Royal Society of Arts (Indian Meeting), at 4.30.—Capt. B. K. Featherstone: Exploration in the Karakoram Mountains.

Royal Astronomical Society, at 5.—A. N. Brown: Observations of V Cassiopeiæ (Ch. 8534) in 1921-26.—Dr. J. H. Jeans: Stellar Opacity and the Atomic Weight of Stellar Matter.—Dr. W. J. S. Lockyer: The Spectrum of the Bright-Hydrogen-Line Star H.D.C. 20336 in Camelopardalis (Sp. Type B3 pe).—L. J. Comrie: The Standard Equinox of 1950.0.

Physical Society of London (at Imperial College of Science and Technology), at 5.—J. H. Awbery and Dr. Ezer Griffiths: The Latent Heat of Fusion of some Metals.—D. W. Dye: The Piezo-electric Quartz Resonator and its Equivalent Electric Circuit.—E. J. Evans: The Characteristics of Electrostatic Machines on Non-inductive Loads and on the Coolidge Tube.

Malacological Society of London (at Linnean Society), at 6.

Royal Society of Medicine (Ophthalmology Section) (Annual General Meeting), at 8.30.—R. Pickard: The Visual Field in Atheroma of the Retinal Vessels.

Royal Institution of Great Britain, at 9.—Prof. J. C. McLennan: The Spectrum of the Aurora.

CONGRESS.

June 9 to 12.

South-Eastern Union of Scientific Societies (at Colchester).

June 9.—R. A. Smith: Essex in Pre-Saxon Times (Presidential Address).

June 10.—R. Paulson: The Beechwood; its Canopy and Carpet; Dr. E. J. Salisbury: The Plant Communities of the Seashore; C. E. Benham: Dr. Wm. Gilberd of Colchester, author of "De Magnete"; Alderman W. G. Benham: The Borough Arms at Colchester.

June 11.—E. C. Stuart Baker: Some Curious Aspects of Evolution; Alderman W. G. Benham: The Colchester Oyster Fishery; S. Hazzledine Warren: The Correlation of the Lower Palæolithic; E. A. Martin: Break-Names in Geological History.

June 12.—A. Farquharson: The Social Constitution of a County; G. E. Hutchings: The Choice of Maps for Regional Surveys; Dr. C. Tierney: Some of Nature's Secrets.

CONVENTION.

June 7 to 12.

Photographic Convention of the United Kingdom (at Edinburgh).

PUBLIC LECTURES.

MONDAY, June 7.

Royal College of Science, at 5.30.—H. E. Wimperis: The Relationship of Physics to Aeronautical Research. (Institute of Physics Lectures on "Physics in Industry.")

WEDNESDAY, June 9.

King's College, at 5.30.—Prof. S. Radhakrishnan: The Philosophic Basis of Hinduism. (Succeeding Lectures, under auspices of British Institute of Philosophical Studies, on June 16 and 23.)

SATURDAY, JUNE 12, 1926.

Technical and Intellectual Values.

VERY frequently we hear the complaint that, in connexion with certain of our activities, there are too many conferences and too little achievement. Specialists gather to discuss their own aspirations and grievances; they deliver their criticisms and indicate how society is refusing the positive reconstruction which would result from the realisation of the aspirations, the removal of the grievances, and the careful examination of the criticisms: but definite suggestions which shall be understood by the plain man are said to be rare. The complaint may be justified particularly where the specialists are concerned with teaching and with the implications of scientific developments. In both cases, results, so far as they affect the life of the plain man, are not immediately apparent, and he is therefore apt to glance at conference reports with some impatience and hasten back to his more 'practical' pursuits.

It is to be expected, therefore, that he will pass over certain resolutions passed by the Conference of Teachers in Technical Institutions which was held in London on May 22–25. He may not be alarmed by the statement that, just as the results of the Board of Education's Circular 1371 and Memo. 44 would have been a reduction of the standard of educational efficiency, so will be the result of the introduction of the same underlying principles in the Economy Act. He will not be moved by the opinion of the Conference that courses in junior technical schools should be as wide as, though differing in character from, those in secondary schools, since his general acquiescence to "secondary education for all" is usually accompanied by a happy ignorance of the multitudinous definitions and of the varying branches of education to which so many labels are being attached. It is certainly very doubtful whether he would be very enthusiastic concerning the Conference's declaration in favour of the principle of internal examinations in all grouped courses, or share the Conference's alarm at the increasing number of external examinations which are being organised by various unions of education authorities—an alarm great enough to spur the Conference to call for a representative meeting of local education authorities and teachers in technical institutions in order to consider the best method of obtaining a system of examinations for those groups of subjects in which National Certificates are not in being or in process of formation.

Arising out of the Conference (if not, in each case, specifically indicated on its public programme), however, were three matters which will commend themselves both to the plain man and the specialists concerned

The new president of the Association, Mr. A. E. Evans, of the Battersea Polytechnic, delivered an address which has already received considerable comment in the general press. "It is high time," he said, "that we abolished the intellectual snobbery and make-believe that regards Art, Literature, Music and the Classics as members of an aristocratic family with Science as a sort of distant cousin, whilst Technology and Commerce are spurned as illegitimates." Whether or not the image be overdrawn matters very little if its presentation will do something towards speeding up the great family reconciliation which, doubtless as a result of the efforts of Mr. Evans's Association and its allied bodies, is slowly taking place. Mr. Evans's purpose was to remind those who pay the ideas much lip-service (but do little towards their practical realisation) that one might as well try to separate the two poles of a magnet as try to divide education into two parts—cultural and vocational; that the good citizen is not one who avoids breaking laws, but one who deliberately *does* something for his day and generation; that engineering, chemistry, commerce, and the like have as great a humanitarian value if taught in the right way as any of those branches of learning beloved by the pedants, since subjects taught on the 'vocational' side of technical institutions teem with examples of how service to humanity has been rendered by their help.

The second important matter was raised by the Mayor of Marylebone, who accorded the Association a civic welcome. On entering public life, he said, men who have been used to one aspect of industry or commerce are faced with entirely new conditions. They have to deal with all sorts of matters from education to electricity proposals and the removal of refuse. They have not merely, as in their business, to be convinced themselves as to the value and necessity of administrative measures, but also to accumulate sufficient knowledge and persuasion to convince their colleagues. The growth and ramifications of public administration are continually increasing. A technical education vitally linked to immediate human needs is therefore imperative for public men. There are large fields of research and study connected with public administration which should be explored by *young* men who will later have the destiny of their fellows in their hands.

The Mayor's point is one of great interest, especially if one reflect on the position occupied by a Medical Officer of Health who, supported by a definite science, presents proposals to his committees, and that of the Director of Education, who has also to formulate proposals for his committees. Both contribute to public welfare, but the Director, lacking a recognised science, sometimes occupies an unenviable position when he is faced by contrary 'opinions' gathered frequently without close examination and research.

The final matter discussed at the Conference may ultimately be proved to be one of the most important of its activities. It was foreshadowed in a speech at the Association's annual dinner. There can be no doubt that some voluntary (and other) educational bodies have tended to regard technical education as concerned almost wholly with the quick preparation of shorthand-writers, plumbers, etc., and it is not to be wondered at that the plain and earnest man may distrust that which he thinks does little more than flood the labour market at public expense. On the other hand, the Association denies this and insists not only on the vital need of its work, but also on its humanitarian value. The position should be made clear not only to teachers but also to the plain man. Technical education has a philosophy which, it is claimed, will commend itself to all. Has it yet been written and published in clear terms? It is not a matter which can be left entirely to university professors of education. Will the Association of Teachers in Technical Institutions supply the deficiency? If it will do so, the reconciliation of the educational family to which Mr. Evans referred will be greatly hastened, and the family itself will discover friends of which, hitherto, it has been quite unaware.

The Centenary of the Athenæum.

History of the Athenæum, 1824–1925. By Humphry Ward. Pp. xii + 370 + 32 plates. (London: Printed for the Club, 1926.)

NO other Club vies with the Athenæum in its interest to scientific men. Faraday was its first secretary, Humphry Davy and Thomas Young were on its first committee; Darwin and Huxley have their portraits on its walls. To four generations of men of science it has been almost a matter of course to belong to it; the young and ambitious have peeped in at its door, and the old have found consolation in looking out of the window. Moreover, scientific men neither monopolise it nor even predominate in it; they share the Club, vastly to their own advantage, with men of letters and affairs, with statesmen, bishops, judges, artists, scholars; with most of those who, for better or for worse, represent the learning of our time and country.

The Athenæum has reached and passed its hundredth birthday, and an old and distinguished member has written the history of its hundred years. A hundred years seems a great while ago, especially to the young but looked at properly, as the old regard it, it is not much after all. When we add to the years which we ourselves remember those penumbral (or half-shadowy) years of which our fathers and grandfathers have told us, we seem to carry our recollections easily back across a hundred years, and perhaps a trifle more. Waterloo seems ever so much the nearer because of the beribboned coach which brought the news to my grandfather's village; I seem to have known Sir Astley Cooper and Mr. Brande pretty well, even the great Sir Humphry in the days when he let Mr. Faraday lecture for him now and then. It is not difficult to keep in touch with a short century ago.

Some time before these hundred years began a great house stood at the foot of Regent Street; the First Gentleman in Europe lived in it, and Nash's great white street (which has lately dissolved away before our eyes, after we had found out its beauty) stretched from the Great Personage's doorstep to the Park on which he had graciously bestowed his name. The critics of the day found fault with Prince and street and everything; "we had hoped," says one, "that that tissue of cast iron and whitewash which reaches from Pall Mall to Portland Place would, at one end at least, have had a redeeming spot to balance the absurdity standing at the other." The house was so big that when they pulled it down the United Service Club was built on one wing of it and ours upon the other, and its doorstep stretched far across the space between. The billiard-room of the Athenæum is said to stand where the Prince Regent had his dining-room; where Herbert Spencer played his game was possibly, nay more was probably, the dreadful spot where the bell had once been rung for Mr. Brummel's carriage.

The Great War (as our grandfathers called it) had left a deal of money in England, and it was spent reely; travel had enlarged men's ideas, and the First Gentleman set no example of economy. He had ecently become a greater personage than ever, and Carlton House was no longer big enough for him; but when he moved into Buckingham Palace his old house was too big for anybody else, and they pulled it down with as little concern as they had shown to the foul lleys round St. James's Market. What had contented nd delighted the eighteenth century did not satisfy the nineteenth; taverns and coffee-houses were good enough for Dryden and for Addison, and Dr. Johnson ound nothing so productive of happiness among all he contrivances of men; but the Waterloo generation outgrew the Mitre and the King's Head. The Guards had their Club after Waterloo; after the Peace, Castlereagh founded the Travellers', for visitors from abroad and for noblemen and gentlemen who had made the Grand Tour, travelling not less than five hundred miles from London; the Oriental (Jos Sedley's Club and Jan Bahawder's) followed soon afterwards. In short, a movement had begun which soon turned the sweet shady side of Pall Mall into a street of palaces, and utterly transformed the social life of London. About the same time a hospitable person called Crockford entertained very handsomely in St. James's, and built a big house at the top of the street at the very time the Athenæum was a-building. White's and Boodle's and Arthur's belonged to a much older lot; they had grown out of the chocolate houses where country gentlemen and men of fashion met, and made it worth the landlord's while to keep out the common people. But apart from these, Clubland as we know it to-day came into being a hundred years ago, as near as may be—in a time of great expansion and prosperity.

The idea is said to have first started in John Murray's house in Albemarle Street (see how near we keep to the present day!) that "literary men and artists required a place of rendezvous," now that the old coffee-houses were superseded and many of them destroyed; and a remarkable man was the first to make the suggestion. John Wilson Croker was the Mr. Pepys of his time; he was Secretary to the Admiralty, like Pepys, he was a fellow of the Royal Society, like Pepys again; he knew everything and everybody; his correspondence was immense, and his diary has helped to keep him famous. Macaulay detested him; Disraeli and Thackeray drew him in ugly colours and unpleasant company. But Disraeli, who was elected to the Athenæum in 1866, might have got in thirty years before had the omnipotent 'Rigby' shown him a helping hand; and the other two had grievances of their own. After all, if Croker did not find in young Disraeli the sort of man he wanted for his club, one need scarcely wonder; it is easier to admire the old Dizzy than the young. Croker had his faults as he had his enemies; but we now think of him as a shrewd, an honourable and a sociable man.

Croker was a bosom friend of Sir Humphry Davy's, who was president of the Royal Society at the time; and in letters to Davy he discussed the character and the constitution of his proposed Club in great detail:

> "In order to keep our Club what it is intended to be, a club of literary men and artists, we must lay down clearly and positively, as our first rule, that no one shall be eligible into it except Gentlemen who have either published some literary or professional work, or a paper in the Philosophical Transactions—Members of the Royal Academy—Trustees (not officials) of the British Museum—Hereditary and Life Governors of the British Institution. The latter will open our doors to the Patrons of the Arts; I do not see any other classes which could be admitted, unless Bishops and Judges, who are *par état* literary men although they have not published any literary work."

There are subtle points in this letter; there is a liberal spirit not entirely emancipated from the social prejudice of the times. I like the notion of "literary men *par état*"—who have written nothing.

The first list of "persons of acknowledged eminence" was filled up easily and handsomely. Sir Walter Scott and Tom Moore, Campbell and Samuel Rogers, represented the literary men of the day. Sir Thomas Lawrence and Chantrey stood for art, together with Robert Smirke the younger, architect of the British Museum and the College of Physicians, a man remembered with respect and praise when he is remembered at all. In science there were the great names of Davy and Thomas Young, to which Faraday's was presently to be added in the humbler rôle of secretary. Among the noble patrons of the arts were Lord Palmerston and Lord Aberdeen, the Lord Lansdowne who filled Bowood with its greatest treasures, Lord Ashburnham the picture-collector, and Lord Spenser of the Althorp Library. There were so many other notable names on the original committee that one may begin by admiring the skill with which Croker and Davy chose their men, and end by wondering at the numerous crowd of distinguished personalities in George IV.'s London.

There was Sir Henry Halford, the Court Physician, a great figure in society; Richard Heber, greatest of bookhunters, who needed three copies of every book, and left eight houses full; Sir George Beaumont, an old man, a friend of Sir Joshua's and a benefactor of Wordsworth—a true patron of the arts; Davies Giddy or Gilbert, the Cornishman, another elderly man, who had discovered young Humphry Davy and (together with his friend Dr. Beddoes) had helped to start him on his illustrious career. There was Thomas Linton Parker, a county magnate in Lancashire, intimate friend of Gainsborough's and learned antiquary; also another scholarly squire, Aylmer Lambert of Boyton in Wiltshire, whose treasures of art were famous in his day and who wrote and published a "Description of the genus *Pinus*," a beautiful and costly book; Henry Thomas Colebrooke, the first Englishman to study Sanskrit; William Stewart Rose, a friend of Sir Walter's and translator of Ariosto; Edward Locker, father of Frederick Locker-Lampson, Secretary to Greenwich Hospital and founder of the gallery of naval portraits in the Painted Hall,—these and two or three more completed the committee. The list is a remarkable one; there is a fine, friendly, gentlemanly air about it; it gives us a glimpse of conditions different from our own, under which the men of professional eminence were fewer, the dilettanti much more numerous and distinguished, and whole classes of men, important and influential to-day, are conspicuous by their absence.

The Club opened its doors in February 1824, in the house in Waterloo Palce now occupied by the Italian State Railways. Croker saw to everything; he engaged the servants, seven men, five women, and three boys, at a total wage of 550*l*. a year; he ordered the coals, he bought the liveries (at 4*l*. 15*s*. per suit, or 10*s*. additional if the committee should prefer plush to velveteen), and the beds and bedsteads, "those for the three upper servants of rather a better kind." He purchased some 500 ounces of beautiful table-silver (still as good as ever) at 7*s*. 6*d*. an ounce; and he laid in "a Pipe of Port, another of Madeira, and a Butt of Sherry, and twenty dozen of Claret for present use." The port cost from about 50*s*. to 64*s*. a dozen, the claret from 80*s*. or 90*s*. to 120*s*.; as in Mr. Spectator's day, "the plaguy French claret cost more money, and did less good."

By midsummer the Club had more than five hundred members. The Prime Minister, Lord Liverpool, and seven future Prime Ministers—Canning, Goderich, Wellington, Peel, Russell, Aberdeen, and Palmerston—were all in the first list. Five of these five hundred, including the celebrated Captain (Sir Edward) Sabine and Decimus Burton, the architect of the Club, were still members fifty-four years after; and the last survivor, Mr. John Lettsom Elliot, died in 1898, after seventy-four years of membership. The limit of numbers was very soon increased to 1000, and the rush of would-be members grew beyond all anticipation. The ballot became a severe ordeal, black-balls being so common that Mr. Humphry Ward finds it "difficul to understand how the Club managed to survive an prosper when such a nipping wind was prevalent i the years of its infancy." Men canvassed openly o their friends' behalf—a thing undreamed of now! W find Southey, for example, begging a fellow-member' vote and influence for "an old friend of mine—Kenyo is his name—one of the best and pleasantest men who I have ever known." This was Mr. John Kenyon, wh looked like Mr. Pickwick according to some, or like Benedictine monk according to others; and wa immensely popular "both in life and death," leaving great fortune to a large number of friends, among who Robert Browning's share came to 10,000*l*. In 183 very soon after the Club came into its own house, th celebrated Rule II. was passed, giving the committe power to elect nine eminent persons annually withou ballot. The first object of the rule was merely to sav a certain number of meritorious candidates from th risk and anxiety of the ballot; but it became a honourable distinction, and has given the bulk of i most distinguished members to the Club.

Decimus Burton, son of a prosperous London build (a rival of Cubitt's), was the remarkable man chosen, course by Croker, to be the architect of the new Clu

He was only twenty-four years old in 1824; but helped and protected by Nash he had already built the 'Colosseum' in Albany Street and several of the large houses in Regent's Park; and before he began to build the Athenæum (in 1827) he had built the Archway at Hyde Park Corner, the Wellington Arch on Constitution Hill, and other severely classical structures. Within three years, that is to say by 1830, the Club was built, at a total cost of about 43,000*l.*; it is vastly less than it would cost to-day, it is scarcely as much as the Club is obliged to spend on structural improvements on the renewal of its lease; but it seems a deal of money for men of science and letters and the arts to have spent upon their house a hundred years ago. The building looked just as it does to-day (and long may it remain so), save that it lacked the upper story, which was added some seventy years later. Croker conceived the idea of adorning the Club with its frieze from the Elgin Marbles; and he is said to have spent money on this embellishment which had been ear-marked for an ice-house. "I'm John Wilson Croker, I do as I please. . . . You ask for an ice-house, I give you a *Frieze*," is a well-known epigram by Joseph Jekyll, the wit of the first committee.

Mr. Humphry Ward's book falls into two parts. In the first part he describes the Club and sketches its history in a very charming fashion, with plenty of anecdotes and gossip and reminiscence, such as the theme invites and suggests abundantly; acknowledging his debt for much historical material, and repaying it handsomely, to the late secretary of the Club, Henry Richard Tedder. Tedder, who by the way had been a close friend and an executor of Herbert Spencer's, served the Club for more than forty years; the Club held him in the greatest possible respect, and a life-like portrait on the wall keeps him in its remembrance.

The second part of the book, which is all Mr. Humphry Ward's own, contains a list, with brief but telling annotations, of the members elected under Rule II. from the year 1831 until last year. It seems a little hard to exclude from commemoration *all* those who came in by the broad road of the ballot, who cannot all deserve neglect and oblivion; but the limitation set is at least a soundly conservative one, and the list as it stands is a wonderful catalogue of well-known names. The book opens in my hand, at random, at the year 1878. In that year came in Lister, and Rayleigh, and Frederick Harrison, and James Bryce; two great Anglo-Indians, Sir Alfred Lyall and Sir William Muir, both of them scholars and one of them a wit; Sir Robert Morier, "le grand ambassadeur qui a roulé Bismarck"; and last, but by no means least, Allen Thomson, the eldest of them all, a great anatomist and famous teacher, whose son still reminds us of him in the Club. Next year brought in Burne-Jones and Henry Sidgwick, and Stubbs the historian, and Stanley Jevons, and Huggins the great astronomer; also Lord Crawford, who succeeded Sir William in the chair of the Astronomical Society and was a true patron, if ever there was one, of science and of art; his son too is a member of the Club. In the following year we have Michael Foster and John Addington Symonds, and Salmon the Provost of Trinity, theologian, mathematician, and chess-player; also Lewis Morris and Orchardson, and Aldis Wright the great Shakespearian and learned Hebraist. Opening the book at another page we find that just fifty years before, Charles Darwin and Charles Dickens, Macready the actor, George Cattermole the painter, George Grote and Arthur Stanley, all entered the Club together in one special election by the committee. Mr. Humphry Ward's catalogue is well-nigh 250 pages long; the names cannot all be illustrious, but they are all more than respectable; they are the familiar names of the men who have made the world we live in, among whom have been our teachers and our friends.

Let us take a look within the Club, following, but not following too closely, Mr. Humphry Ward's description. The house is planned quite differently from the big house over the way. In the 'Senior' you look and look again for the stairs; but the great staircase of the Athenæum is the feature of the house. The pillars of the entrance-hall are copied from those of the Temple of the Winds; they are golden-yellow, on bronze bases, and the very sofas between them are of classical design. The floor is of a mosaic pattern; the recessed and panelled ceiling is enriched with delicate Pompeiian designs. The design and colouring are Alma Tadema's, who, together with Sir E. J. Poynter and Mr. A. Lucas, undertook the re-decoration of the Club in the early 'nineties. It is not in the taste of to-day, but it suits the architecture of the house to perfection; and it helps usefully to remind us that some things in Victorian art were exceedingly beautiful. On the Pall Mall side of the Hall is a pleasant morning-room. Time has ripened and softened a somewhat gorgeous ceiling, a rich Japanese wall-paper, and wood-work of a peculiar brown, of which last the club's earthenware teapots are said to have suggested the *motif*. There were some interesting pictures here until they were moved elsewhere not long ago. A portrait of Dr. Johnson by Opie was the gift (if I remember rightly) of Mr. Humphry Ward himself; it is as fine a thing as Opie ever painted, it reminds one of what he mixed his colours with, it shows Johnson as we would keep him in our mind's eye for evermore. Alas, it now hangs neglected on an unlighted wall; and its own place is filled by things incomparably inferior to it.

On the other side of the hall is the long dining-room, with a row of windows looking out upon the garden. The ceiling and mural decorations, by Sir E. J. Poynter, are curious but withal beautiful, and it seems an æsthetic solecism to hang modern portraits on the Pompeiian panelling of its walls. One knows where among the many tables one's friends are likely to be found—where men of science mostly sit, or where the artists or the critics; or the august corner where statesmen consort together, and eat and drink like common men. There are nooks and corners still associated by tradition with certain famous clubmen. Abraham Hayward, more than fifty years a member, friend of Sydney Smith and of Macaulay, translator of "Faust," story-teller, whist player and bon-vivant, sat in the corner by the door; was it not called "Abraham's bosom" even unto yesterday? In the same corner before Hayward's day sat Theodore Hook, drinking what (belittling it) he called 'toast-and-water,' and making up stories about bishops; and in the corner opposite, far-off in the south-west, J. M. W. Turner used to dine, and dine alone, and drink his bottle of port in semi-darkness after bidding the candles to be taken away. Charles Dickens is said to have used the same corner-table in after years. To go back for a moment to Hayward, he has very little to say about the Club in his published "Letters"; but curiously enough, it is from him we learn that Thackeray was blackballed in 1850, to be elected by the committee as soon after as possible, in the following year. Can it have been some old friend, or friends, of "Wenham" who did this thing?

As we turn to go upstairs we shall, perhaps, be shown just where Dickens and Thackeray made it up, after a long and bitter quarrel; Edmund Yates had satirised the satirist, and Dickens had taken sides with Yates. We shall be shown also where poor Dicky Doyle lay down and died—Dicky, who drew the immortal title-page of *Punch*, and signed it with his dicky-bird effigy. The great drawing-room, a Library (to the southward) and a Writing-room, all full of books, occupy the first floor. A fine bust of Croker, by Chantrey, is one of the ornaments of the drawing-room; Lord Rosebery and Mr. John Murray are said to have discovered it, and the committee had the good fortune to buy it for a small sum. In the South Library there is a big table in the middle of the room where Thackeray dictated Esmond (or parts thereof) to his friend Eyre Crowe; and Richard Burton sat afterwards at the same table, with his snuff-box beside him, translating the "Thousand and One Nights." In a corner of the same room was a favourite seat of Macaulay's, used afterwards by a line of scholars, by Hallam and Matthew Arnold, by Mark Pattison and by Lord Acton.

The Library (which Mr. Humphry Ward lingers over with obvious predilection) has been a feature of the Club from the beginning; books are here, there, and everywhere—in gloomy store-rooms, in basement passages, in dizzy galleries where few members are young or bold enough to venture life and limb. For sheer want of space accessions to the Library have been comparatively few in recent years; but books which no gentleman's library should be without are very plentiful, the older editions of the classics are all there, and there is a famous lot of the great illustrated folios once vastly admired by all persons of taste and fashion. Splendidly bound and enshrined in fine cabinets we find here such things as that monument of the Naples Bourbons, the great "Case e monumenti di Pompeii," or Graevius' "Thesaurus," or Hoare's "Wiltshire," or Gould's bird-books, or Temminck's still more beautiful "Planches coloriées"; or Brockedon's "Passes of the Alps," or Rossellini, or Stuart and Revett, and very many more. It was one of the chief objects and ambitions of the Library Committee when Henry Hallam was a member of it, about the middle of last century, to "purchase such works in the fine arts, in natural history and antiquities, as, though eminently instructive or interesting, are too costly or bulky for the majority of private persons." Many of us are old enough to remember the days when men (when we ourselves) loved and coveted such books as these, of which this strenuous, anxious generation takes no account at all; and are there not one or two (such as Sibthorp's "Flora Graeca") which we desire and covet still?

We might pass on from room to room finding associations everywhere and memories without end. We have not yet seen Faraday's wheeled chair, still standing as he left it; nor yet another and more famous 'Empty Chair'; nor Thackeray's terra-cotta statuette nor the Owls of Athene (several of them); nor the stone horse-block outside which was put there on purpose for the Duke of Wellington to mount at the door. But it is high time we took our leave of the Club, and of Mr. Humphry Ward's book. In doing so we may heartily declare that the book could not have been better done; it is light in touch, copious in anecdote, sympathetic in allusion, gentle in criticism. The Athenæum may well be proud of this history, and of the fellow-member who has put his heart into the writing of it.

And now what has been said in praise of the book becomes all of a sudden a tribute to its author's memory; for since these last words were written Humphry Ward's long life has drawn gently to its close.

D. W. T.

Popular Astronomy.

The Earth and the Stars. By Dr. C. G. Abbot. Pp. xi + 264 + 33 plates. (New York: D. Van Nostrand Co.; London: Chapman and Hall, Ltd., 1925.) 15*s.* net.

THE appearance of a popular work on astronomy, particularly one by so experienced a worker as Dr. Abbot, is an event of much interest to those who believe that science has a message for the general public, for there is no science which bears more closely than does astronomy on the intellectual problems that face all educated men. It is probably true also that no science can claim so copious a literature of the popular kind, but the rapidity and revolutionary character of recent advances has left the great bulk of astronomical treatises hopelessly behind the times. A book of the type of Dr. Abbot's is therefore anything but superfluous, and the reader will find in it information which even the publications of a year ago were too early to supply.

The general plan of the book is drawn, in the main, on conventional lines. Following a brief survey of the heavenly bodies and a chapter on "Some Famous Astronomers and Famous Instruments," the reader is given some idea of the order of magnitude of the electron and the stellar system, and the principle of the spectroscope is briefly described. It is doubtful whether the account of the processes of emission and absorption of light is sufficiently definite to be intelligible to the uninitiated reader. The earth, moon, and the sun's family then come under consideration, after which three chapters are devoted to the sun. Despite the title of the book, the sun claims more space than any other individual body—as, indeed, we should expect in a book by Dr. Abbot. He considers in some detail the possibilities of direct mechanical utilisation of solar energy, and is of the opinion that "there is, perhaps, no field where investigation is more needed, or more apt to produce useful results for mankind." A chapter on "The Calendar, Star Places, Navigation," is succeeded by some stories of the constellations, and the last four chapters are devoted to the system of stars and the stellar universe. These contain an outline of the chief facts which have been gleaned with regard to the stars and nebulæ, individually and collectively, concluding with a summary of the work of Jeans on the evolution of stars from spiral nebulæ and that of Eddington on the interiors of stars and the source of stellar energy.

The book concludes with six short appendices, giving notes on the solar eclipse of January 1925, and the tides, tables of data concerning the solar system and the first magnitude stars, a list of the constellations, and a comprehensive, non-technical dictionary of astronomical terms. The numerous figures and diagrams are mostly excellent, but one or two of the latter (*e.g.* Fig. 40, p. 196) are capable of considerable improvement.

The book is very interesting, and in spite of some digressions Dr. Abbot has managed to include a large amount of material in a well-arranged form. The information given is up-to-date, and has the general character and freedom from technical details which are desirable in a work of the popular class. There can be no hesitation in saying that the author has succeeded in his aim of producing a book helpful "to those who wish to acquire by easy reading a general survey of the universe they dwell in." A considerable number of pertinent anecdotes are included, and one or two the relevance of which is not so clear. The style is conversational—an excellent method of presenting a subject popularly, but one which, as here, may be followed too slavishly.

Conversation has, indeed, the advantage over the formal written statement in that it is alive, and holds the reader's attention more firmly, but it has defects which can and should be removed on revision. On p. 195, for example, we read: "We shall mention a little further on, perhaps, one or two other special parallax methods." The word "perhaps" here is excusable when spoken, for the fulfilment of the promise may depend on time or some such limitation, but it is surely superfluous on the printed page. Another preservation of the defects of conversation is to be found in the frequent repetitions of turns of phraseology or playful asides. Thus on p. 92 we read, *à propos* of the sun: "No star could have obeyed better the spirit of the advice of Robinson Crusoe's father to stick to the middle class as the happiest," and on p. 226 the same comment occurs again. So common, indeed, are such repetitions that we soon learn, on encountering an illustrative saying of this kind, to await its recurrence with a confidence which is rarely unjustified. Nor is it only such phrases as these that are reproduced; the same lack of critical revision is evident with respect to plain statements of fact, *e.g.* Kepler's laws, which are thrice set out on pp. 9, 13, and 68. The several occurrences of the same statement do not always agree; as, for example, the definition of the precession of the equinoxes, which on pp. 14, 20 and 55 and in the glossary is rightly given as a westward movement, and on p. 7 as an eastward movement; or the three accounts of the distribution of novæ in the sky on pp. 182, 212, 223. This feature of the book is much to be regretted, inasmuch as a very little care would have removed it and brought about a vast improvement.

A few slips occur, of varying degrees of importance.

Spectrum lines from the sun's western limb are said to be displaced to the violet instead of to the red (p. 73). On p. 94 we read: "Eddington has shown it to be probable that . . . light pressure . . . actually prevents the existence of any stars of masses more than five times the sun's mass." In another connexion, however, the existence of more massive stars is referred to. We are surprised also to find the discovery that flame, arc and spark spectra of the same element are different in character attributed to Gale and Adams (p. 101); surely Lockyer's work can no longer be ignored.

There is one other point which it is important to mention. In two or three places occur statements which, considering the character of the book, we think too dogmatic. Thus we are told on p. 85 that Clerk-Maxwell *proved* (instead of *predicted*) theoretically that light exerts a pressure on small particles. No physicist, of course, would misunderstand this, but the man in the street is entirely dependent on the statements of specialists, and the word "proved" is for him final. He would be surprised to learn that on the same principles it could be "proved" that the atom is unstable and the universe cannot exist for a day. Again, on p. 214 it is stated definitely that Cepheids are not double stars, and on p. 222, spiral nebulæ are described without qualification as "island universes."

It is regrettable, though necessary, to direct attention to so many blemishes in a book which has given us great pleasure. The faults are mostly of a trivial character, but taken together become of considerable importance. Fundamentally the book is excellent, both in matter and in form; what it suffers from is lack of a final revision. It is greatly to be hoped that this will be supplied in the next edition. H. D.

Comparative Morphology of Fungi.

Vergleichende Morphologie der Pilze. Von Ernst Gäumann. Pp. x+626. (Jena: Gustav Fischer, 1926.) 28 gold marks.

THE need for a good and well-balanced treatise on the morphology of the fungi, incorporating the results of modern work, is one that has, no doubt, been felt by many botanists in recent years, and the present book comes nearer to meeting it than any that has hitherto appeared. One may, perhaps, regret that so much space is given to cytological details, but this is inherent in the author's expressed object, namely, to apply the data obtained from cytological studies to the interpretation of the problems of comparative morphology in the fungi. This method of treatment leaves comparatively little room for the consideration of the fungi as living organisms, adapted to their surroundings: physiology is not touched on; and life-histories are scarcely described except as incidentals to the cytological story. As a result, the imperfect forms of fructification are relegated to the background and the Fungi Imperfecti as a whole are dismissed in four pages. These, however, are the author's self-imposed limitations and are not open to criticism, however much they may be regretted.

The book is divided into a short opening section on the vegetative and reproductive organs of the fungi, and a main part, in which a detailed account is given of the morphology of the four classes, Archimycetes, Phycomycetes, Ascomycetes, and Basidiomycetes. The heterogeneous class of the Archimycetes, containing the Olpidiaceæ, Synchytriaceæ, Plasmodiophoraceæ, and Woroninaceæ, is derived from various roots in the Sporozoa-Flagellate-Myxomycete alliance, while the rest of the fungi are regarded as a single phylum, originating, in all probability, from the green algæ. The Oomycetes diverged early to a blind end, the Chytridiaceæ progressed through the Zygomycetes (Endogone-like forms) to the Ascomycetes and Basidiomycetes.

The Hemiasci are considered to form the connecting link between the Zygomycetes and Ascomycetes proper and are divided into two orders, the Endomycetales (including the yeasts) and the Exoascales in which are grouped the two isolated and not completely understood families of the Protomycetaceæ and Exoascaceæ. The gradual reduction of sexuality in the Ascomycetes affects chiefly the male gametes, which become functionless and disappear, their place being taken by secondary spores or by cells of the female organ; with the loss of the latter, conjugation between two vegetative hyphæ may be all that is left of the sexual act.

Where the author's views diverge from those of others who have concerned themselves with the phylogeny and comparative morphology of the fungi, he has indicated and explained the differences in their points of view, while the copious literature references have been selected especially to include those in which detailed bibliographical accounts of earlier work may be found. In such matters as the derivation of the Oomycetes from the algæ, he takes only the balance of probabilities as he sees them, and there is a refreshing absence of dogmatism throughout the work. It is stiff reading, owing to the very full documentation and the great extent of the literature covered, but the arguments are clear and the descriptions of the forms selected to represent the different families are concise and admirably illustrated. The author is to be congratulated on his excellent presentation of a most difficult subject.

Letters to the Editor.

Electrical Constitution of the Upper Atmosphere.

RECENTLY considerable interest has been evinced in the nature and constitution of the upper atmosphere (NATURE, March 13), and it has been suggested that wireless methods are perhaps the most effective in exploring this region.

In this connexion the following facts, and possible explanations, may be of interest. In a recent paper in the *Philosophical Magazine* (June 1925) the writer suggested that a certain type of atmospheric disturbance which is semi-musical in nature, *i.e.* consisting of a musical note the pitch of which falls to a limiting frequency n_0, may throw some light on the electrical constitution of the upper atmosphere. The interpretation suggested was that these disturbances owed their musical nature to the dispersive action of the medium, which was assumed to consist of an assembly of electrons in a rarefied atmosphere. Such a medium will have the effect of transmitting different frequencies with different velocities, with the result that the spectrum of frequencies comprising an impulse is drawn out into a musical note of varying frequency.

It was shown that the lowest pitch of the disturbance is determined by the relation

$$n_0^2 = \frac{Ne^2}{\pi m},$$

where N is the number of ions per c.c., e is the charge on an ion, and m the mass of an ion. This is what I call the characteristic frequency of the medium.

In some experiments about a year and a half ago I found the prevailing characteristic frequency to be from 300 to 500 a second. In making some recent tests I noticed that the prevailing characteristic frequency had risen two or three times, suggesting a four to tenfold increase in the ionic density. Associated with these changes there has recently been an increase in sunspot activity, magnetic storms and an auroral display so far south as London, and a noticeable falling off of the strength of short-wave signals from America. There seems little doubt that these are all associated with the approach of the period of sunspot maximum in 1928, especially in view of the theoretical deduction that such an increase in ionic density must necessarily increase the attenuation for night transmission if the constitution of the layer is as assumed above, provided the time period of the waves is short compared with the mean time between electronic collisions with molecules. Further evidence in confirmation of these views is afforded by measurements of trans-Atlantic telephony signals on a wave-length of 5270 m., published in the *Bell System Technical Journal*, July 1925. It is there shown that the average night strength of signals is largely decreased during magnetically disturbed days, a fact which is in accord with the foregoing theory, and confirms the hypothesis that the recent reduction of short-wave signal intensity is due to the sunspot activity.

It seems also probable that the explanation of the musical atmospheric disturbances given by the writer is substantially correct, and that observations of these will provide additional data for determining the electrical constitution of the upper atmosphere.

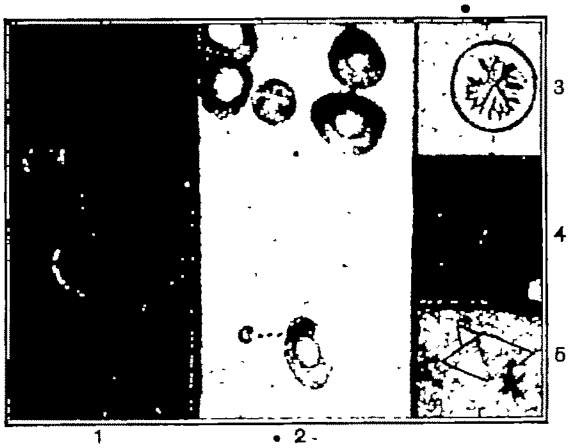
Hydrolysis of Starch Grains by Light Polarised by Small Particles.

DURING the last three winters I have been engaged in an experiment, which throws additional light on the work described in a former paper (Baly and Semmens, *Proc. Roy. Soc.* B, 97, 250), and as the effects took place in a small flask, disposes of the 'accidental pressure' hypothesis of critics.

The well-known scattering and polarising effect of colloidal particles suggested the use of a suspension of diastase as a polarising agent, and the experiment was thus arranged: About 10 cc. of a suspension of well-washed potato starch in distilled water was placed in a small thin-walled flask (A), and this was immersed in a beaker containing a strong colloidal solution of taka-diastase. As control, an equal quantity of the starch suspension was used, contained in a flask (B), which was lightly waxed, to depolarise any reflected light. The outer vessel in this case contained tap-water. The necks of both flasks were plugged with cotton-wool dipped in toluene, and the vessels were exposed for several days in a window at the top of a tall building, to catch the horizontal rays of the morning and evening sun.



Potato starch grains in distilled water after exposure to polarised light.

1. Exposure two days; examined and photographed immediately after bright afternoons.
2. After less intense exposure; on partial drying, change inside grain is shown, canals (c) to exterior forming.
3. Exposure four days; crystals forming inside grain. (× 300)
4. Exudation from holes in coat beginning to crystallise. (× 200.)
5. Bunch of crystals from single grain—with crystal plates.

The light polarised by the particles of diastase was thus reflected vertically upward and irradiated the starch grains lying at the bottom of the inner vessel (A). The control received direct light through a cleared space in the waxed surface of B. The results were tested at intervals of two or three days by examination on a microscope slide and were as follows:

(1) Immediately after a bright sunrise or sunset, many of the grains in flask A were found to be rapidly breaking (Fig. 1) while in flask B they were practically intact.

(2) If the weather were dull or the examination delayed, the grains merely showed a transparent streak in the centre, which gradually extended and formed little canals to the exterior (Fig. 2) through which the contents exuded, leaving the shrivelled skeleton or coat.

(3) When some of the liquid was mounted on a microscope slide with cover glass and left to dry in the dark, a film was formed showing diffraction fringes and crystals slowly formed in the liquid.

(4) Occasionally the hydrolysed-contents crystallised within the grain (Fig. 3) or exuded from it, leaving the tiny shell in the centre as in Fig. 4.

(5) After prolonged exposure the empty shells or coats break down to a fatty substance (giving black or brown with osmic acid and red with Sudan III.), and rhomboidal or hexagonal plates are left near the crystallised grain-content (Fig. 5). These plates are often very thin, and in this case the outline in the photograph was slightly darkened for reproduction in print. On boiling with Fehling solution, the contents of flask A gave a distinct change of colour, which was not visible in B. Specks of cuprous oxide were also seen within the partially hydrolysed grains from A.

It would be premature to discuss the theoretical significance of these results, but they seem to indicate that in the action of certain enzymes, beside the quantum factor in energy absorption, there is also an orientation factor. As physiological reactions take place at surfaces, there must be some correlation between the orientation of the vibration and the molecular arrangement at the surface.

I wish to express my indebtedness to Sir James Irvine for valuable suggestions and criticisms, and, as always, to Prof. E. C. C. Baly for his continued help and encouragement.

Upper Air Temperatures and Thunderstorms.

IN NATURE of November 14, 1925, p. 709, I directed attention to the method of plotting upper air temperature readings by the use of temperature and log. potential temperature as co-ordinates, the curves being designated tephigrams by their inventor, Sir Napier Shaw. It may be recalled that, by the use of these curves, the energy available from a mass of air rising under unstable conditions is shown directly as an area on the graph. Opportunity has now been taken to study these diagrams in connexion with thunderstorms in the south-east of England during the three months June, July, and August of last year, and the results obtained are of interest.

Aeroplane ascents are made daily (Sundays excepted) by the Meteorological Flight at the Royal Air Force Station at Duxford, near Cambridge, on which dry and wet bulb temperatures are read at each 50 mb step of pressure from 1000 or 950 mb up to the highest point reached. This is generally in the neighbourhood of the 500 mb. isobaric surface (18,000-20,000 feet height). From these readings the humidity of the air is calculated Unfortunately the wet bulb thermometer becomes useless soon after the aeroplane passes through the 32° F. isothermal surface, owing to the impossibility of keeping the bulb moistened, but it does not appear that humidities above this level are of very much importance in the formation of thunderstorms, so that the drawback is not a serious one for the present inquiry. To obtain a quantitative measure of the energy available from a mass of ascending air, it is necessary to know the temperature conditions existing in the atmosphere up to the point where the rising air loses its buoyancy and comes to rest, and this point is generally in cases of marked instability above the level to which areoplanes can fly as a matter of day-to-day routine. The investigation has therefore had to be on a qualitative rather than a quantitative basis, but from the data studied it appears that this is sufficient to give results of great value.

In the three months, 71 days were available on which an aeroplane ascent was made, such ascent normally taking place at about 8.30 A.M. in the morning. In a few cases where no morning ascent was available an afternoon one was utilised, but as the inquiry was mainly directed to the utility of the method for the forecasting in the early morning of thunderstorms during the coming day, the morning readings were primarily used. The three months varied in character; June had only one day of thunder, while July was thundery with 12 days, and August took an intermediate position with 9 days. The method of plotting humidity on tephigrams was discussed in my previous communication, and the proposal there put forward has been followed and has proved very satisfactory. It is clear that on a day of instability the air in each layer of the atmosphere will, in rising to its equilibrium position, develop its own amount of energy, and some one layer will on each occasion show maximum potential energy. This energy is very closely dependent upon its humidity and the heat liberated by condensation. It is easy on tephigrams to see which layer gives this maximum energy without plotting the relative humidity of every layer, and for each ascent the humidity has only been plotted at the layer which shows maximum energy on days of instability or the nearest approach to a development of energy on days when stable conditions prevailed. In this way the diagram is kept free from complication and the degree of energy available is seen at a glance.

The 71 days were divided into days of no thunder and days of thunder, the latter division containing all days on which thunder was reported from one or more of the stations contributing to the Daily Weather Report in the south-east of England, broadly defined in this case as the area south and east of Birmingham. The thunderstorm must thus have occurred within a radius of about 100 miles of Duxford. A cursory glance at the tephigrams indicated the closeness of the connexion between energy available and thunderstorms, and a more detailed study showed that the 71 days might be divided into three classes, only 7 cases remaining which did not fall readily into one of these classes

Class A *No energy and no thunder*. This contained those cases where there was no thunder, and either no energy was shown or there was energy only in a shallow layer below a layer of marked stability (36 cases).

Class B. *Energy high up generally without thunder.* In these cases energy was available, but not below the 700 mb. isobaric surface (say 10,000 feet) (13 cases). In 10 of these cases there was no thunder. In the remaining 3 cases there was thunder, but in 2 of these an evening ascent showed that later in the day energy was available at a lower level (below 700 mb.), so that the days might have been put into Class C below.

Class C. *Energy with thunder*. In this type energy was available below 700 mb., and was associated with subsequent thunder (15 cases).

These classes thus cover 64 out of the 71 cases and indicate a very close connexion between the energy shown on the tephigram and the subsequent development or non-development of thunder. The 7 cases not included in the above three classes represent only

10 per cent. of the whole, and it is not necessary to discuss them here in detail. They consist of—(1), 3 days when energy was available below the 700 mb. level, though thunder was not reported, and (2), 4 days with thunder, though little or no energy was shown. As regards (1) it must be remembered that thunder may occur but escape the network of Daily Weather Report stations; and as regards (2), Duxford will not always be typical of the air over the south-east of England for the remainder of the day.

As regards Class B, it is scarcely surprising to find that energy developed above the 700 mb. level is ineffective in producing thunderstorms, when it is remembered that the moisture content of saturated air above this level is comparatively small.

The close association between energy and thunderstorms shown by these ascents is most encouraging for the forecasting of thunderstorms and gives further proof, if such were needed, of the importance of regular aeroplane ascents to a modern forecast service. J. S. DINES.

Air Ministry, May 13.

New Experimental Results concerning the Doublet $K\beta_1$.

IN a communication under this title in NATURE of April 17, p. 554, N. Seljakow and A. Krasnikow have inferred from measurements on the lines $K\beta_1$ and $K\beta'$ in the Röntgen spectrum of manganese, that they form a relativity doublet characterised by the energy difference $M_{II} - M_{III}$. Now with molybdenum the corresponding difference is about 0·8 $\frac{\nu}{R}$ units, whereas with elements of lower atomic number similar measurements have so far not been published. The very small value found for molybdenum makes it reasonable to suppose that, for the elements between calcium and zinc in the periodic system, the corresponding energy difference would not give rise to any separable lines. For even if we assume the appearance of 3_3-orbits, which begin with scandium, to cause a disturbance in the M-level, so that the 3_3-orbits are unequally screened for this and the next element, it still follows from an approximate calculation that this effect cannot possibly give rise to a larger difference than about one-third of that actually measured. On the other hand, the broadening of the $K\alpha$-doublet of iron found by Siegbahn and Ray (*Ark. Mat., Astr. Fysik*, vol. 18, No 19) and recently studied by Thoraeus (*Phil. Mag.* (7), vol. i. p. 312, 1926), which represents a much smaller value of the energy difference, may well be attributed to such a screening effect of the 3_3-orbits, as this would, of course, be equivalent to a slight increase of the nuclear charge.

With the $K\beta$-lines, the interpretation of the doublet as due to a relativity effect would doubtless require a more detailed explanation. The intensity ratio $\beta_1 . \beta' = 2 : 1$, which supports this interpretation, appears so far to have been definitely established only with manganese (N. Seljakow and A. Krasnikow, *Zs. f. Physik*, 33, 601, 1925). Investigations by the writer carried out in this Institute seem to prove that with iron in compounds the intensity ratio (estimated) has also approximately the same value, *i.e.* 2 : 1. With titanium and vanadium, however, a value considerably larger than 2 : 1 was found.

Seljakow and Krasnikow also state that the intensity ratio $\beta_1 : \beta'$ is not sensibly affected by passing the rays through foils of the same element. A similar observation on the satellite lines in the L-series of the rare earths has been described by D. Coster (*Zs. f. Physik*, 25, p. 98, 1924). This fact supports the view that the K- or L-electron is completely removed from the atom in the absorption process. Moreover, the explanation suggested by G. Wentzel (*Ann. der Physik*, 66, p. 458, 1921), who attributes the satellites to supernumerary excess electrons in the M-level, does not appear to be refutable on this basis.

Another point should be noticed in this connexion. The elements of the rare earths offer many analogies to those between calcium and zinc. A 4_4-orbit occurs for the first time with cerium, where also the β_{14} and γ_9 lines have been found by D. Coster to accompany the β_2 and γ_1 lines, as satellites of lower frequency. The increase in intensity of these satellites with increasing atomic number appears to be closely analogous to that of the β'-satellite for the elements next to iron. On the other hand, a cursory examination of the energy levels of the rare earths seems to exclude a relativity explanation of the satellites in the case of cerium and the following elements.

The interpretation of the $K\beta_1\beta'$ lines as a relativity doublet, offered by the Leningrad physicists, appears therefore scarcely admissible, whereas the hypothesis of Wentzel seems to be in better agreement with the experimental facts. If we try to estimate the effect of the supernumerary electrons involved by this hypothesis, we are led to the conclusion that such electrons cannot be limited in number to only one, otherwise we must assume rearrangements of the electron groups to occur. Especially the fact that the β'-line appears sensibly broadened seems to exclude a normal energy level as the origin of this line, and to support the view that several kinds of radiating atoms may co-exist, these differing from each other in the number or arrangement of their electrons within the M-level G. ORTNER.

Institut fur Radiumforschung,
Wien, May 10.

Wasteful Research?

THE issue of NATURE of May 1 contains a letter by Messrs. Morgan and Holmes from the new government "Chemical Research Laboratory, Teddington," describing results of their study of certain fatty materials. I venture to ask directly and plainly: Why is such work being done in a State laboratory? Years ago there was much heartburning among consulting chemists because the National Physical Laboratory was taking the bread out of their mouths. Is it now to be the turn of the universities and technical schools to suffer from the State poacher? The work described is purely academic, such that any intelligent fourth-year student could do.

To-day the chemical schools are in large part engaged in so-called research which is of no consequence and often detrimental as training—clearly because they are led by men without practical outlook. These need even to have practical subjects of study forced upon them, which will afford their students training in laboratory methods. With scarcely an exception, the real work that is being done in chemistry is with materials of natural origin. Fats are among them. A special technical professorship to deal with these has only recently been established in Liverpool, and is in specially able, experienced hands. Another of the professors in that University, only a month or two ago, made known the results of several years' close study of perhaps the most remarkable fat yet examined—that from shark's liver. The inquiry is probably the most finished and meritorious piece of work of the day. Sir William Bragg's school has scored its chief triumph off fats. Sheffield studies them rather than iron. Last, not least, one very expensive organisation of the Department of Industrial and Scientific Research has fats specially under its charge. It has a habit of putting its work out, and some has already been placed with the University of Manchester. So it is clear that even the university may be trusted with fat. Why, then, further workers and new buildings in a field already so fully occupied?

Every halfpenny spent thus wastefully by State agencies out of the grant from the State is money withdrawn from the schools of experimental science, to which the grant was primarily made, to enable them to prosecute original inquiry and train a research force for the service of the State. The future of higher scientific inquiry is being gravely imperilled by the bureaucratic machinery which is fast closing its clutches upon our scientific liberties. We are false to the trust that is imposed on us if we further countenance a system which not a few of us regard as indefensible. The nation cannot afford to waste money in any quarter to-day, nor should it be led into thinking that it is getting special service from a Department which is showing that it is technically unfitted for the work it has undertaken. I may instance particularly fuel research, upon which half a million sterling seems to have been spent without result, mainly because practical needs have never been taken into account and existing knowledge and experience put aside.

HENRY E. ARMSTRONG.

May 2.

The Anomalous Flocculation of Clay.

IN NATURE of May 1, p. 624, there appears a letter from Dr. A. F. Joseph and Mr. H. B. Oakley regarding the so-called anomalous flocculation of clay. We should like to point out, however, that it is doubtful whether the experiments referred to in the first part of the letter could be expected to show anomalous flocculation as ordinarily understood. In the first place, it has been suggested by Comber (*Journ. Agric. Sci.*, 1920, 10, 432; *loc. cit.*, 1921, 11, 460 *et seq.*; and *Trans. Faraday Soc.*, 1922, 17, 349) that the phenomenon referred to is dependent on the presence of colloidal silica in the outer surface of the particles, and the "highly purified clay" used by Dr. Joseph and Mr. Oakley might well have lost this coating. Further, the phenomenon is shown, not so much by differences in the minimum amount of ion required for flocculation, as by an increased rate of sedimentation when a sufficiency of the ion is present. It would be interesting to know whether the particular clay used would show the phenomenon of anomalous precipitation at higher concentrations of salts either alone or after the addition of colloidal silica.

It may be mentioned that with suspensions of kaolin we have obtained very marked anomalous precipitation in alkaline solution by calcium ions after the addition of small quantities of colloidal silica, although these suspensions did not exhibit this phenomenon when silica was not present. We have also observed a similar effect with cæsium chloride, although in this case the phenomenon, under certain conditions, may be delayed for approximately 24 hours. Ammonium and potassium salts give similar results after still longer delays. The effect seems to be related to the precipitating action of the cations of these salts on colloidal solutions of silica at *p*H greater than 7,—a phenomenon which appears first to have been described by Pappadà (*Gazzetta Chim. Ital.*, 1903, 33, (ii.), 272). The nature of the precipitate in this anomalous flocculation is quite different from that obtained at other concentrations of the ions and other reactions of the medium. For example, in the case of calcium chloride a voluminous and highly flocculent sediment separates in the first two or three minutes at concentrations exceeding 39×10^{-4} *N* and at *p*H 8–9. At the end of such periods there is practically no flocculation apparent at corresponding concentrations of the salt in neutral or acid medium, or at any reaction or concentration of salt when silica is not present.

Edinburgh.

Major-General William Roy.

REFERENCE was made in NATURE of May 1, p. 630, to the life and work of Major-General William Roy. It is stated in the note in question that Roy entered the army at twenty years of age; his own statement is that a "body of infantry was encamped at Fort Augustus in 1747," when he was twenty-one, and that "as Assistant Quarter-Master it fell to my lot to begin . . . the execution of that map." It appears that he held a minor position in the Post Office at Edinburgh until 1747. As to the date of his joining the army, Mr. George Macdonald, in his valuable study "General William Roy and his Military Antiquities of the Romans in North Britain," published by the Society of Antiquaries in 1917, states that it is quite possible that Roy was not in the army at all during the construction of the map of Scotland. All that we know for certain on this point is that Roy was appointed Practitioner Engineer on December 23, 1755.

No mention is made in the note of Roy's archæological work. As a fact, throughout the whole of his life he was deeply interested in the history of the past, and he is probably nearly as well known as the author of the "Military Antiquities" as he is as the founder of the Ordnance Survey. It may interest readers of NATURE to know that the terminals of the base which he measured on Hounslow Heath in 1784 were replaced by guns buried vertically, muzzles upward, in 1791, and that these guns still remain in position.

Coytbury, Winchester, May 25.

Hydrogen as Anion.

WE are all so much entertained by Prof. H. E. Armstrong's broadside attacks that those of us who happen to come within his range must not complain; but I feel that I must protest against his criticism (NATURE, April 17, p. 553) of the beautiful experiment of Bardwell which proved that hydrogen is an anion in metallic hydrides (*J. Am. Chem. Soc.*, 44, 2499 (1922)). If Prof. Armstrong would read carefully Dr Bardwell's paper he would see what pains were taken to separate the anode and cathode chambers, and since hydrogen was evolved quantitatively at the anode it could scarcely be due to liberated alkali metal unless this also were set free at the anode—which even a thorough-going opponent of physical chemistry would scarcely assume. This being so, it is perhaps unnecessary to mention the bald chemical fact that the alkali metals do not in any case react with metallic hydrides to set free hydrogen.

GILBERT N. LEWIS.

The Steel Industry.[1]

By Sir William Peter Rylands.

As there are now indications that the world has made some definite progress towards a return to normality, this occasion is not inappropriate for presenting a picture of the past history of the steel industry, so that it may help in forming some reasoned judgment as to future prospects. For this purpose, with the assistance of Mr. Lloyd, I have prepared a chart (Fig. 1), and in this connexion I desire also to express my thanks to Sir William Larke for the valuable information he has placed at my disposal. In this chart I have set out four main curves, one representing the total of the world's production of steel, and the other three the respective annual productions of the United States, the Continent of Europe, and of Great Britain. I had expected to find a steady development in the world's consumption of steel, but I must admit to a feeling of some amazement when the curves were finally plotted out.

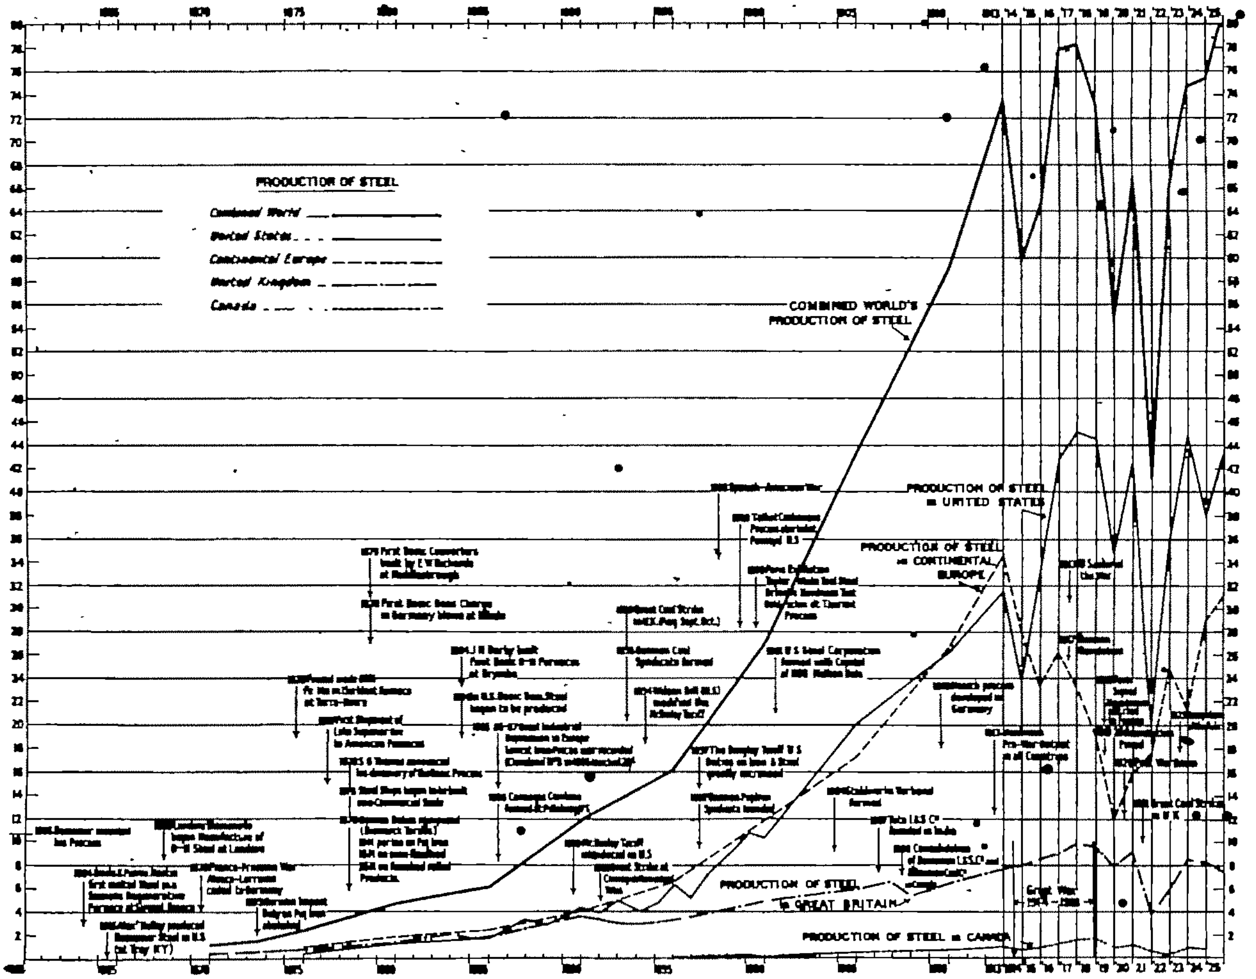

Fig. 1.—The world's production of steel, 1870–1926.

Measured in terms of present consumption, the total production of steel was almost insignificant up to forty years ago, and the year 1885 may be taken as marking the commencement of what may fairly be described as the 'Steel Age,' for which the discovery and development of the basic process was so largely responsible.

The most striking feature in the curve of the world's production of steel is the extraordinary uniformity in the rate of increase. Periodical fluctuations which must have taken place are entirely obscured in the curve plotted as a bold line, and up to 1914, instead of any inclination for the rate of increase to diminish, the curve tended continually to become more steep. It is difficult to avoid the conclusion that had the normal development of the world not been interrupted by the War, the world's consumption of steel would have continued to increase at a rate not dissimilar from that previously experienced, and might to-day have exceeded 100 million tons per annum.

In addition to certain subsidiary points of interest from which useful deductions may possibly be drawn, the curves bring to the eye three other main features. The first is the disturbing effect of the War, as illustrated by the curve movement between 1913 and the present time; secondly, the extraordinary similarity of the total production of the United States and the Continent of Europe respectively during the pre-War period; and thirdly—a matter with which Great Britain is peculiarly concerned—the failure of Great Britain to maintain her position in relation to the United States and the Continent. Until the year 1890 the respective productions of Great Britain, and United States, and the Continent of Europe were approximately the same. Thereafter, the production of steel in the United States and on the Continent grew with amazing rapidity, while the production of Great Britain, although increasing, increased at a rate in no way comparable with the general increase in the world's demand.

---

[1] From the presidential address to the Iron and Steel Institute, delivered at the annual meeting on June 3.

In spite of the unsatisfactory condition of the steel industry during the past few years, the curve seems to suggest that the pre-War rate of expansion of the world's consumption has been approximately restored, and encourages the hope that in the next ten years an expansion even to the extent of thirty million tons a year is not beyond the bounds of possibility, or indeed of reasonable anticipation—an expansion which would go far to solve many of the troubles from which the industry is suffering. Unfortunately, ten years is a long time, and British steel-makers, at all events, are much concerned to know what proportion of that estimated increase will fall to their lot, and how soon they can hope for a demand for British steel equal to British capacity to produce.

Many, if not all, the difficulties of basic industries are to be attributed to an arrest for practically ten years of the normal growth in the world's demand, an arrest which, unfortunately, was not accompanied by an arrest in the rate of increase in instruments of production. In the case of the steel trade, and other industries vitally concerned with the supply of munitions, there was in many countries a direct stimulus to an increase in plant, and an improvement can scarcely be expected until that increased capacity is absorbed.

The curve of the United States production indicates that the capacity of that country both to produce and consume continued to grow during the period of the War at approximately the pre-War rate, and the market in the United States being such a large factor in the world's demand for steel, it is manifest that the total world's demand must be greatly increased before there is any surplus demand available for the benefit of the European manufacturers.

Production on the Continent, after sinking to the depths of the post-War depression, has steadily risen, and in 1925 was but little short of the aggregate production of 1913. There is, however, a large amount of plant on the Continent still lying idle, of an estimated capacity of ten to fifteen million tons per annum, which can only be brought into operation by a corresponding increase in the world's demand.

The production of the United States in 1925 exceeded the highest level reached before the War by more than ten million tons, and to absorb this increase and to occupy the idle European plant and provide for a normal increment in the steel requirements of the United States, there must be an increase in the world's demand of at least thirty million tons, or, say, ten years' increment at the remarkable rate of increase experienced prior to the War.

It is difficult to avoid the conclusion that the pressure of competition from the Continent during the next ten years must continue to be very severe. In this connexion we must bear in mind that there are many new developments in steel manufacture in other countries of the world, and this increase in local production must diminish the share of the world's demand available to the old steel-producing nations.

Up to this point we have discussed the prospects of the steel industry, particularly from the point of view of the United States and the Continent of Europe, but we here are more intimately concerned with the well-being and future prosperity of the industry in Great Britain.

I have already directed attention to the regrettable feature in the curves showing that from 1890 onwards Great Britain secured a negligible share in the increase of the world's steel trade. Another regrettable feature is indicated in the closing years covered by the chart. While the world's demand, the production of the United States, and the production on the Continent showed during those two years a healthy and encouraging improvement, the production of Great Britain steadily fell, and if the suggestion is well founded that we cannot reasonably hope that the world's demand will, in less than ten years, overtake the world's capacity to produce, the present trend of British production must give rise to feelings of profound anxiety.

It is no doubt true that, owing to the depreciation of the Continental exchanges, and the lag in internal values, as compared with world values, the Continental manufacturers have enjoyed an artificial advantage in competing with Great Britain, both in the British home market and in the markets of the world, and that we may hope that, in the course of a year or two, this lag will disappear and Great Britain will no longer suffer from that peculiar handicap. Unfortunately, pre-War experience does not encourage us to anticipate that even under pre-War conditions—if these are to be regarded as the conditions of normality—British steel manufacturers will be able to compete with that success which present circumstances would seem to demand.

Prior to the War the heavy competitive trade passed largely into the hands of the manufacturers on the Continent and in the United States, while such increase as was, in fact, secured by the British steel industry, was rather in the direction of special lines and special qualities, and with the assistance of special conditions. Even for the home requirements of billets and sheet bars a large proportion was imported from abroad.

Clearly, with the great increase in British steel-making plant, it is now essential that the British steel manufacturers endeavour to secure a greater share of the heavy competitive trade, since it is doubtful whether any increase in the world's demand which can be anticipated during the next ten years will be accompanied by a sufficient increase in the special trades where Great Britain enjoys some peculiar advantage. Otherwise, without a serious reduction in productive capacity, the conditions of the British steel industry may be difficult for a considerable number of years to come.

These reflections invite consideration as to the reason why Great Britain failed to maintain its share in the general expansion of the world's trade, and after maintaining its position for twenty years up to 1890, thereafter was left behind in the race.

Great Britain was the cradle of the steel industry. Some of the most revolutionary advances in technique originated in Great Britain. There were bountiful supplies of cheap coal, and although the Minette ore fields were of great assistance to the German industry, much of their steel was made from ore derived from other sources, presenting no particular advantage.

No doubt the United States derived great advantage from their immense and expanding home market, but it is a notable feature that the increase in production on the Continent kept pace step by step with the corresponding increase in the United States, and it is not easy to appreciate the exact advantage enjoyed by the Continent of Europe over those who conduct the industry in Great Britain.

Examining once more the history of the steel industry, it will be noted that its early development following on the introduction of the basic process was accompanied by a serious trade depression—a depression experienced not only in Great Britain, but also shared by the United States and the Continent. Between the years 1885 and 1887 the price of Cleveland iron reached the lowest figure ever recorded.

Two important factors developed both in the United States and on the Continent approximately at that time: the first was the definite adoption by both the United States and Germany of a tariff policy designed to protect the home market; the second, arising without doubt out of the depressed condition of the industry, was the development of a high degree of internal organisation of the trade in both those countries. At the depth of the depression the Carnegie Group was formed in the United States, followed later by the United States Steel Corporation, while in Germany syndicates were created for controlling the coal, pig iron, and finally steel, by means of the Stahlwerks Verband. It would not be appropriate to lay any stress upon the desirability of an import duty, or to draw any deduction as to the advantage which accrued from that policy to the industry in the United States and in Germany. This is a matter of political controversy. We are on safer ground if we argue that organisation was the responsible and dominant factor.

In few, if any, other industries are the costs of production so profoundly affected by large scale output and continuous operation as in the industries of steel and coal, and I am strongly convinced that the remarkable success of Germany and the United States in securing the lion's share of the increasing world's demand for steel is to be attributed to organisation directly aimed at securing that result.

As an illustration, on a visit to Germany in 1912, I was informed that the cost of producing mild steel billets in Westphalia exceeded 80 marks per ton, approximating very closely to the cost of manufacture in Great Britain. Those same billets were delivered to buyers in England at a delivered price of less than 4*l.* per ton, and having regard to the cost of carriage, it was manifestly impossible for the British manufacturers to compete.

No doubt the pursuit of special qualities is not entirely compatible with the policy of large and standardised production, and so long as the capacity of Great Britain can be satisfied by special business of this kind, and the manufacturers concerned are content, a valuable and important industry can be maintained; but if, as appears now to be essential, Great Britain is to secure a greater share of the world's steel trade, a different policy is imperatively demanded.

The commercial greatness of Great Britain was largely founded upon its production of coal and steel, and if that industrial position is to be maintained, the problem should be approached from the broadest point of view in the interests of the country as a whole. Some national responsibility attaches to the steel-makers. It is not enough that a few steelworks should be conducted with success. It is rather a matter of great national concern that the industry should secure the greatest possible share of the world's steel trade, and give the utmost employment to the industrial workers of the country.

A further reflection, not altogether fanciful, is suggested by the amazing rate of increase in the world's consumption of steel. It is difficult to believe that a cheaper substitute for coal could ever be discovered for the manufacture of pig iron, and while we are assured that the coal resources of Great Britain may be expected to last for some hundreds of years, that is a comparatively short period when measured in terms of geological time. Even, however, if we need not concern ourselves with anxieties which lie in the dim and distant future, the cost both of coal and of ore must increase under the law of diminishing returns. Within the recollection of many of us, slack was regularly sold by collieries at 3*s.* per ton at the pit, and forty years ago the price of Cleveland pig iron was so low as 32*s.* per ton; yet in spite of improvements in technique, the real costs of both coal and pig iron have greatly increased. It would appear certain that this tendency must continue, and the real cost of steel in Great Britain, with the exhaustion of home supplies of ore and the inevitable increase in the cost of coal, will steadily rise. It is equally likely that certain other parts of the world more favourably situated in regard to ore and steel will enjoy an increasing economic advantage. Practical steel-makers will no doubt be better able to judge how far the cost of home supplies of ore will be affected during the next ten or twenty years, but taking a broad view, this reflection, so far as it is of substance, emphasises the importance of scientific organisation of the industry, both on the technical and commercial side.

The Iron and Steel Institute has done much in the past to assist in technical development, but still more intimate co-operation is now necessary. The vast world's consumption of iron and steel demands correspondingly large scale productions, the co-ordination of technical knowledge, and the most efficient application of every technical advance if a steel-producing nation is to hold its position in the race.

The manufacturers in the United States of America, and on the Continent, seemed to have realised this, and have set an example which might wisely be followed if the steel trade of Great Britain is to overcome the pressing difficulties of the next ten years and of the more remote period when we may gradually lose some of the national advantages which we at present enjoy.

Fossil Insects in Relation to Living Forms.

By Dr. R. J. TILLYARD, F.R.S., Cawthron Institute, Nelson, New Zealand.

WHEN Handlirsch completed his great work "Die Fossilen Insekten" in 1908, it was possible to take a wide survey of the problem of fossil insects. The outstanding feature of this was the great gap in our knowledge of Permian and Triassic forms. On one side it was seen that the present type of insect fauna could be traced back with little essential modification right to the English Lias, in which all the chief existing orders of insects are known except the Lepidoptera and Hymenoptera; on the other, there lay the very different Upper Carboniferous faunas of the Age of Giant Insects. The only connecting type common to both was the cockroaches, which are thus seen rightly to merit the name of aristocrats of the insect world, and, like other aristocracies, are in this democratic age a small and disappearing unit. Between these two were known only Permian cockroaches and a few Permian and Triassic types, not enough to enable us to trace a good connexion.

Three large and important insect faunas have since been opened up and carefully studied. Taken together, they almost completely fill the Permian-Triassic gap in the record, and show us in large measure the lines of evolution of the chief orders of insects. These beds are enumerated below.

(1) The Upper Triassic Beds of Ipswich, Queensland. —These were discovered many years ago by Mr. T. H. Simmonds of Brisbane, but more thoroughly explored by Mr. B. Dunstan, Chief Government Geologist of Queensland. From these about 250 specimens have been taken, yielding a complete fauna of about 120 species. Coleoptera are dominant, making 46 per cent. of the total fauna. Hemiptera (Fig. 5) come next in abundance, the sub-order Homoptera being much more strongly represented than the Heteroptera. Other orders present are the Odonata, Protorthoptera, Orthoptera (including a few Blattoidea or cockroaches), Mecoptera (scorpion-flies), Neuroptera (sub-order Planipennia or lacewings only), and a very interesting new order, Paratrichoptera, containing four-winged insects ancestral to the true Diptera. Of these last, four well-marked genera have been found.

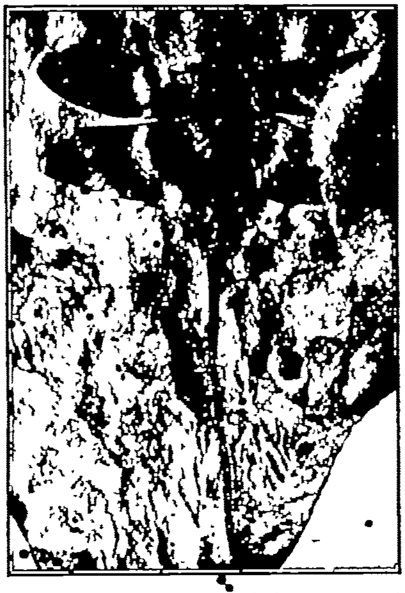

FIG. 1.—*Dunbaria fasciipennis* Till., the only known representative of the order Palæodictyoptera in the Lower Permian of Kansas. (Natural size.)

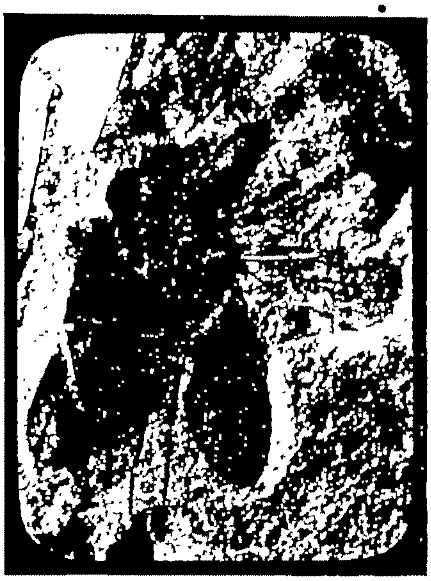

FIG. 2.—An undescribed species of Lemmatophora belonging to the new order Protoperlaria, ancestral to the stone-flies, and showing well-developed wing-flaps on the prothorax. (× 5.)

(2) The Upper Permian Beds of Belmont and Newcastle, N.S.W.—The discovery and working of these beds is due to Mr. John Mitchell, formerly head of the Newcastle Technical College, who in spite of his advanced age is still wielding his huge hammer on this hard, cherty rock, and, with the assistance of Mr. and Mrs. T. H. Pincombe of New Lambton, continues to add wonderful new types to the record. Nearly 200 specimens have been found and about fifty species so far described. These beds, originally classed by geologists as Permo-Carboniferous, have been shown to lie only about 300 feet below the bottom of the Trias, with no break hereabouts between Palæozoic and Mesozoic strata. The flora consists almost entirely of Glossopteris, and the associated insects form a highly specialised fauna of very few orders. Homoptera and Mecoptera are dominant; no Heteroptera have yet been found. With the numerous scorpion-fly remains there has been found one type allied to the anomalous recent American genus Merope, and, closely allied to that also, a type recognisable as the oldest known true lacewing (Neuroptera Planipennia). A new order, Paramecoptera, allied to the Mecoptera and evidently representing the common ancestors at that period of the three orders Diptera, Trichoptera and Lepidoptera, is found in these beds, there being two genera, Belmontia and Parabelmontia. A few true Coleoptera occur, together with a most remarkable series of larger forewings evidently allied to them and showing all gradations from a flattened, apically pointed tegmen with complete venation down

to half-formed elytra with the venation completely lost except in the anal region. These must be regarded as being remnants of the older order from which the true Coleoptera originated, and are called Protocoleoptera. As several quite distinct types occur, even in these small beds, these fossils give point to the remark frequently made by that wise old coleopterist the late Dr. D. Sharp, that the enormous order Coleoptera as we know it to-day must have had a polyphyletic origin.

(3) The Lower Permian Beds of Kansas.—A magnificent collection of fossil insects, totalling 2000 specimens, has recently been taken from this locality by the Yale University Expedition led by Dr. Carl Dunbar. The beds were originally discovered by Dr. Sellards of Yale, who also possesses an extensive collection, mostly unstudied. This fauna is the most important and best preserved of all known insect faunas, many of the specimens showing the colour-pattern and minutest hairs on veins and membrane of the wings. From its study we learn how the insects reacted to the change of climate between the Upper Carboniferous and Lower Permian. The advent of hot, arid conditions, with formation of salt lake areas, sounded the death-knell of the Age of Giant Insects, the only ones remaining in the Lower Permian being a few Protodonata and Protorthoptera and a single wonderfully preserved species of the old order Palæodictyoptera, *Dunbaria fasciipennis* Till. (Fig. 1).

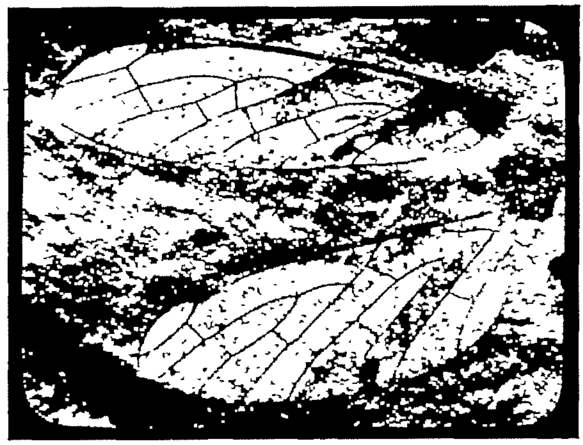

FIG. 3.—*Permohymen schucherti* Till., order Protohymenoptera, Lower Permian of Kansas. (×4)

The dominant type of insect was an aquatic type ancestral to the Perlaria or stone-flies of the present day. Some of these are preserved perfectly in every detail, and show a very unexpected character in the presence of well-formed wing-flaps with extensive venation, on the sides of the prothorax (Fig. 2). Mayflies (order Plectoptera) were also very abundant, but differed from those of the present day in having all four wings of about equal size and similar venation. Two genera of true dragonflies (order Odonata) are preserved, one showing almost a complete wing; their venation is much simpler than that of even the smallest damsel-fly of to-day, not even the closed quadrilateral cell being present. True scorpion-flies (order Mecoptera) were abundant, and all of very small size. Most of these were close allies of the existing Australian family Choristidæ, but one form was ancestral to the American genus Merope. The absence of any true lacewings, raphidians and sialids is most remarkable; the geological record of the Permian makes it almost certain that these are later specialisations from a much older mecopteroid stock. Incidentally, the scorpion-flies can be traced back to the Upper Carboniferous and are as old as any known winged insects; so that the problem of the origin of what is called holometaboly, or the formation of a true pupal or resting stage in insects, is bound up with the evolution of this little-known group of insects.

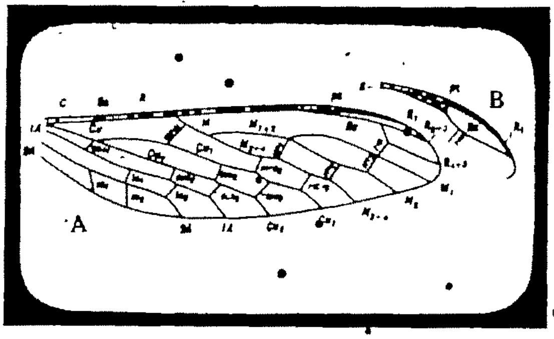

FIG. 4.—A. Diagrammatic representation of *Protohymen permianus* Till., order Protohymenoptera, forewing, from Lower Permian of Kansas. (×3.) B. Pterostigma of *Permohymen schucherti* Till. (×4)

Other orders recognisable in the Kansas beds are the Copeognatha or psocids, the Embiaria or web-spinners, and four types which can be definitely classed as Homoptera and are of exceptional interest in giving for the first time an accurate interpretation of the venation in that order. But the most wonderful find of all was a whole series of wings and some nearly complete insects belonging to the extinct order Protohymenoptera, containing the ancestors of the Hymenoptera in which fore and hind wings were of almost equal size and were not yet linked together in flight by hooklets. The astonishing simplicity of the venation in these types has quite upset the complex hypothetical explanations of Hymenopterous wing-venation due to MacGillivray and others, and at one stroke shows the true homologies of the veins and also makes it an easy matter for students to master the subject for systematic work. Of the three genera discovered, Protohymen (Fig. 4) stands right in the ancestral line of the recent order

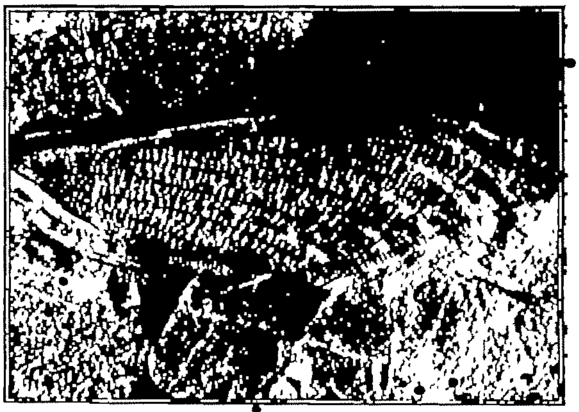

FIG. 5.—*Mesogereon superbum* Till., order Hemiptera, ancestral to the Cicadidæ, from Upper Trias of Ipswich. (×1½)

Hymenoptera, leading directly to the horntails and sawflies, while Permohymen (Fig. 3) and Asthenohymen must be regarded as specialised side branches.

The fossil evidence is now fairly strong that there were three distinct groups of holometabolous insects which evolved a pupal stage independently of one another early in the Permian period. These are (*a*) the Mecopteroid orders, namely, Mecoptera, Neuroptera, Paramecoptera, Paratrichoptera, Diptera, Trichoptera, Lepidoptera, and Siphonaptera; (*b*) the Hymenopteroid orders, Protohymenoptera and Hymenoptera; and (*c*) the Coleopteroid orders, Protocoleoptera, Coleoptera and their parasitic offshoot Strepsiptera. The only possible explanation of this appears to have been the marked change of climate which ushered in the Lower Permian. We must conceive that the pupal stage was a response to a new environment, the larva going underground and shortening the later nymphal instars into a single more complex change or metamorphosis.

In concluding this article, we must point out that the evidence as it stands at present points to a long history for winged insects before the Upper Carboniferous, though no fossils have yet been found in the Pterygota older than these. For the Apterygota, or primitive wingless insects (orders Thysanura, Protura and Collembola), an even longer geological history must be demanded, probably taking them back to the Lower Devonian. We know nothing as yet of the most primitive type of insect wing, whether it evolved from a gill or from a paranotal expansion, nor do we know anything at all about the original type of wing-venation except that it was probably a very simple one, not complex as in the highly specialised Upper Carboniferous groups. The problematical remains recently described as jaws and palpi of insects from the Rhynie Beds (Old Red Sandstone of Scotland) may well have belonged to Thysanura, but only careful study of definitely well preserved specimens could finally determine this point.

Obituary.

DR. J. T. BOTTOMLEY, F.R.S.

JAMES THOMSON BOTTOMLEY, who died in Glasgow on May 18, was born in Belfast on January 10, 1845. His father was William Bottomley, of Belfast, and his mother a sister of the late Lord Kelvin. He was educated at Queen's College, Belfast, and Trinity College, Dublin, where he had a distinguished career and was gold medallist at the degrees of B.A. and M.A. He started his scientific career by becoming assistant to Prof. Andrews at Belfast, afterwards a demonstrator of chemistry and physics in King's College, London, and in 1870 he came to the University of Glasgow to act as Arnott and Thomson demonstrator in the Department of Natural Philosophy, at the head of which was his uncle, Sir William Thomson. He held this position until 1899, when Lord Kelvin resigned from his professorship.

During these twenty-nine years Dr. Bottomley was continuously engaged in research work, and his researches covered a very extensive field, including liquefaction of gases, the use of liquid air for experiments on radiation at very low temperatures, the air thermometer, the bolometer, emissivity and conductivity of wires in vacuum, radiation from bright and black bodies, vacuum pumps, thermo-couples, modulus of elasticity, and the electrical properties of platinoid, etc. These papers were contributed mostly to the *Proceedings of the Royal Society*, and the Reports of the British Association. He published a book on theoretical mechanics in two parts, vol. 1 on dynamics, and vol. 2 on hydrostatics. But in this line he is best known as the author of "Four-Figure Mathematical Tables: Comprising Logarithmic and Trigonometric Tables, and Tables of Squares, Square Roots, and Reciprocals."

As time went on, Sir William Thomson delegated a good deal of the lecturing to students to Mr. Bottomley. He belonged to a type not uncommon in our universities, of distinguished scholars and amiable gentlemen, enthusiastic in their own department of study, and with every good desire in the world to help their students, but largely unable to impart their knowledge in the class-room. Uncle and nephew were both deficient in this respect, one being too advanced and abstruse for the average student, the other in being too ridiculously simple. He elaborated the obvious, sometimes painfully though unconsciously, wasting time striving to elucidate minor points which all understood. He did not seem able to state the salient points and pass on. Hence when he was getting on very well with his audience, often they would lose all patience with his meticulous niceties. When an emergency arose it appeared how difficult it is for the cloistered man of science to deal with a practical situation. Physics and psychology seemed to have no common ground. A sense of humour or power of repartee would heal the breach in a moment, but Dr. Bottomley was too serious for that and could not retaliate or change his mode of lecturing. Kelvin might bore the hilarious dawdlers quite as much, but they did not dare to take liberties with him.

As consulting engineer, Dr. Bottomley acted for the Scottish Asylums Board and for Nobels, Ltd. He had a regular electrical engineering consulting practice mostly concerned with lighting installations, such as Skibo Castle, Roxburgh Castle, etc. He joined the Institution of Electrical Engineers as an Associate in 1872 and was elected a member in 1889.

Dr. Bottomley became associated with the business of Kelvin, Bottomley and Baird when the firm was floated as a private limited company in 1900, and on the death of Lord Kelvin in 1907 he was appointed chairman, a position which he continued to fill until his death. In recognition of his distinction as a scientific worker and of his long and honourable connexion with the University of Glasgow, the degree of Doctor of Laws was conferred upon him in November 1904.

M. M.

MR. STEPHEN PAGET.

STEPHEN PAGET was born in Henrietta Street, Cavendish Square, London, in 1855, the fourth and youngest son of Sir James Paget, who was well known as the leading scientific surgeon of the mid-Victorian period. The tide was turning in the fortunes of his father when Stephen was born, for Sir James was writing that if he can afford that brougham his wife shall walk fewer miles in the week than she has often walked in the day. Stephen received his preliminary education at St. Marylebone and All Souls Grammar School in the Regent's Park just at the top of Baker Street. The school had been established by his maternal grandfather, the Rev. Henry North, domestic chaplain to the Duke of Kent, and received most of the doctors' sons in the neighbourhood. From this school he proceeded to Shrewsbury, where he had a good training in the classics, and from there he passed to Christ Church, Oxford, where his brother Frank was a senior student, graduating in 1878 after gaining second class honours in "Greats."

His eldest brother had been called to the Bar, the second and third had taken holy Orders, one afterwards becoming Bishop of Oxford, the other Bishop of Chester; Stephen decided to follow his father's profession. He entered as a student at St. Bartholomew's Hospital, obtained the F.R.C.S. Eng. in 1885 and was almost immediately elected assistant surgeon to the Metropolitan Hospital, whence he migrated to the West London Hospital. Here he became full surgeon until he determined to specialise, and was appointed surgeon to the Throat and Ear Department at the Middlesex Hospital. Ill-health overtook him and he was presently obliged to abandon all thought of practising his profession. He left London and settled at Limpsfield in Surrey, where he died on May 8.

Stephen Paget was ill-suited by health, temperament and education for the arduous life of a consulting surgeon, but he attempted it, failed, and by his failure was able to render services of the greatest value to physiology and pathology. Gentle in character, logical in thought, and before all things a lover of truth, he devoted the last eighteen years of his life to make known the truth about experiments upon animals and to show how the advance of medicine in every branch depends upon freedom of research. To this end he was instrumental in founding the Research Defence Society, of which he was the first secretary. The object of the Society was to fight against and expose the lies, half-truths and innuendoes of prejudiced anti-vivisectionists. Paget carried out the campaign with deadly effect against a host of fanatics and faddists. He wrote books, delivered lectures and published addresses, always courteously worded and without heat, which did much to allow an unscientific public to see the matters under discussion in their true proportion.

Paget wrote charmingly and in an easy style, which make it pleasant to read his many books. Biography perhaps interested him most. In "The Memoirs and Letters of Sir James Paget" he accomplished successfully the difficult task of a son writing the life of a distinguished father, whilst in the "Life of Sir Victor Horsley" he had to meet difficulties of an entirely different kind and he was equally successful. His lives of Ambroise Paré and John Hunter give delightful accounts of these great surgeons of a bygone age, whilst the "Confessio Medici" should be read and re-read by every student of medicine.

He married a daughter of Dr. Burd of Shrewsbury. To her and their two daughters medicine owes a debt of gratitude. Their loving care enabled him to devote all his time and energies to the great object of his life—the freedom of research.

MR. H. KIRKE SWANN.

HARRY KIRKE SWANN died on April 14 in New Barnet, near London, at the age of fifty-four years, after a short illness. He was chiefly known to ornithologists by his excellent books on the bibliography of British birds and his writings on the Accipitres or birds of prey. In 1916 appeared the "Bibliography of British Ornithology," a volume of 691 pages, which he wrote in collaboration with W. H. Mullens, and in 1919 appeared the "Geographical Bibliography of British Ornithology" in conjunction with W. H. Mullens and the Rev. F. C. R. Jourdain, in 1923 "A Bibliography of British Ornithology from the Earliest Times," by Kirke Swann alone, a chronological list of British birds, termed a supplement to the above-named bibliography.

His love of ornithology dates from Swann's boyhood; at twenty years of age he visited Nova Scotia and eastern Canada, and his zoological observations are embodied in an attractive little book, "Nature in Acadie," which appeared in 1895. In 1892 he founded in London the *Naturalist's Journal*, eventually continued by Mr. S. L. Mosley; the first two volumes were edited by him, and contained several articles by himself on British birds. Mr. Swann was always a busy man and could generally only devote his spare time to his beloved ornithology. He became a partner and later proprietor of the booksellers' firm of John Wheldon & Co., and in 1921 he joined with William Wesley & Son to form a company under the name of Wheldon & Wesley, Ltd., of which he was a director and very active member when he died. In 1913 appeared Swann's "Dictionary of English and Folk-Names of British Birds, with their History, Meaning, and First Usage; and the Folk-lore, Weather-lore, Legends, etc., relating to the More Familiar Species," a work containing a wonderful amount of information.

For a long time Mr. Swann took a special interest in the Accipitres or diurnal birds of prey, collected their eggs, and later on their skins. In 1920 there appeared his "Synoptical List of the Accipitres," followed in 1922 by a second revised edition under the title "A Synopsis of the Accipitres." These lists contained, in addition to the names, in accordance to the strictest priority, short diagnoses of the (unnecessarily numerous) genera, species and subspecies; considering the great variability of plumage, according to age, sex, and individual variation of most Accipitres, these diagnoses, though often useful to ornithologists, cannot suffice to determine the forms without more knowledge.

A few years ago Mr. Swann visited the United States, where he studied birds of prey in most of the larger museums, while in 1925 he made a collecting trip to Rumania and the Danube delta, with Mr. J. H. McNeile, and wrote an attractive little book, "Two Ornithologists on the Lower Danube."

In 1924 there appeared the first part of a large, ambitious work in quarto, called "A Monograph of the Birds of Prey," beautifully illustrated with coloured plates by Mr. H. Grönvold, of birds and eggs, and some photographs of nests, very well printed and well written. Possibly the Accipitres are not only the most attractive but also the most difficult group of birds for a systematist, and it is therefore not to be expected that Mr. Swann's work was in every case correct in the recognition and grouping of species and subspecies, but it is very regrettable that he could not finish it; so far only five parts have appeared, which is less than half the work.

SIR JAMES CANTLIE, K.B.E.

THE death on May 28 of Sir James Cantlie, at the age of seventy-five years, removes from our midst a man of originality and untiring energy, and a ready writer and speaker. In his early days he was demonstrator of anatomy and assistant surgeon and later surgeon to the Charing Cross Hospital, but most of his life work outside his practice, whether in London, Hongkong, or again in London, was devoted to teaching and pioneering in unexplored fields of medical education. A great believer in physical training and fresh air both for the young and the middle-aged for the maintenance of health, he first set out some of his views in 1885 in a remarkable paper entitled "The Degeneration of Londoners," which encountered a good deal of ridicule, but was remembered during the War when a large number of recruits for the army were placed in Class C.

Cantlie's knowledge of tropical medicine began in Egypt, when he was one of twelve young medical men sent out there to assist in combating the 1883 epidemic of cholera. His next experience was in Hongkong, where he became Dean of the Chinese Medical College, and in conjunction with Sir Patrick Manson carried on a large practice. In Hongkong he did some good work in helping to check the local outbreak of plague in 1894, though the measures were not successful in preventing the disease from being carried by infected ships to the ports of other countries. In close association with Yersin and Kitasato, he became conversant with the most recent knowledge concerning the disease at that time, which, when he returned to London two years later, was made use of by the London County Council, which employed him as its adviser on plague.

It was Cantlie who first started the idea of the necessity of the establishment of a School of Tropical Medicine in London. He was also a founder of the Society of Tropical Medicine and Hygiene, of which Sir Patrick Manson was the first chairman, and of which, when some years later it became the Royal Society of Tropical Medicine and Hygiene, Cantlie also became president. By his influence a tropical section was added to the annual meetings of the British Medical Association.

During the War, Sir James Cantlie, with the assistance of Lady Cantlie, performed very valuable services to the country by the training of men and women for Red Cross work.

MR. JOHN STUART.

IT is with much regret that we learn from the *British Journal of Photography* of May 7 that Mr. John Stuart died quite suddenly on April 28 in his ninetieth year. He had been chairman of the well-known firm of opticians, Ross Ltd., for many years, and was the proprietor of the *British Journal of Photography*. Mr. Stuart was born at Lossiemouth, and was attracted to photography in the very early days of the collodion process, and for a few years travelled in Spain, Portugal, and Italy making a large number of wet-plate negatives, many of which were used for publication. At this time Andrew Ross, who founded the firm, was dead, and his son, Thomas Ross, had succeeded him. Mr. Stuart joined the firm in 1870, and shortly after the death of Thomas Ross he married his widow. Under Mr. Stuart's direction the firm continued to expand, and all who are interested in optical matters will call to mind the name of Francis Wenham, who was a valued colleague. Mr. Stuart was the sole proprietor of the *British Journal of Photography* for more than forty years, and the editor states that his editorial and business staff were given a completely free hand, his influence, when exercised, tending towards the restriction of the publicity in the pages of the journal of the manufactures of Messrs. Ross Ltd.

IT is announced in the *Chemiker Zeitung* that Dr. Carl J. Lintner, emeritus professor of applied chemistry at the Technische Hochschule in Munich, died on April 9 in his seventy-first year. After graduating at Munich, Lintner turned his attention to the technology of agriculture and of brewing, and after some experience at the Experimental Station for Agricultural Chemistry in Halle and at the Institute for Brewing in Berlin, he returned to Munich in 1884 and began to collaborate there with Soxhlet. In 1896 he was appointed to the chair of applied chemistry, and from 1902 until 1914 he directed the Experimental Station for Brewing at Munich. His chief researches were upon enzyme action, especially in relation to brewing.

WE regret to announce the following deaths:

Sir Thomas Elliott, Bart., K.C.B., for twenty years secretary to the Board of Agriculture and afterwards Deputy Master of the Mint, on June 4, aged seventy-one years.

Prof. Nils Gustaf von Lagerheim, professor of botany and director of the Botanical Institute of the University of Stockholm, and corresponding member since 1892 of the Pharmaceutical Society.

Lieut.-General Sir William Leishman, K.C.B., F.R.S., Director-General of the Army Medical Service, on June 2, aged sixty years.

Dr. E. S. Reynolds, emeritus professor of clinical medicine in the University of Manchester, on May 22, aged sixty-five years.

Sir Stewart Stockman, Chief Veterinary Officer and Director of Veterinary Research at the Ministry of Agriculture and Fisheries, on June 2, aged fifty-six years.

Sir John Williams, Bart., G.C.V.O., emeritus professor of midwifery at University College, London, and president of the University College of Wales in 1913 and first president of the National Library of Wales, on May 24, aged eighty-five years.

News and Views.

An interesting feature of the proceedings at the anniversary meeting of the Linnean Society on May 27 was the presentation to the Society by Sir David Prain, on behalf of the subscribers, of a portrait of the general secretary, Dr. Benjamin Daydon Jackson. The portrait, by Mr. Ernest Moore, will commemorate Dr. Jackson's long and helpful association with the Society as an officer for a period of forty-six years—a period equal to one-third of the present life of the Society, which was founded in 1788. In 1880 Dr. Jackson, who had joined the Society in 1868, was elected one of the two honorary secretaries, succeeding Mr. Frederick Currey on the botanical side, and as such he continued to serve until 1902, when on the retirement of the assistant secretary, Mr J. E. F. Harting, he was appointed to the specially created post of general secretary As general secretary Dr. Jackson has for the past twenty-four years ably administered the Society's affairs, and his knowledge and experience have been invaluable to the successive presidents, secretaries, and councils.

Though he completed his eightieth year on April 3, Dr. Daydon Jackson looks back on an almost unbroken record of attendance at the fortnightly meetings of the Linnean Society during his forty-six years' official connexion with it. Even during his earlier period of service as botanical secretary, Dr. Jackson made the Society his headquarters, and his unrivalled knowledge of the Linnean collections has been at the service of fellows or visitors. Several generations of workers retain a grateful recollection of assistance given with equal cheerfulness to the eminent visitor from abroad or the young student at home. Reference was made to Dr. Jackson's encyclopædic work; the compilation of the "Index Kewensis" was necessarily centred at Kew, but the "Glossary of Botanical Terms" is a product of leisure moments at the Linnean Society, while his "Catalogue of the Linnean Herbarium" is intimately associated with the genius of the place His reputation as our authority on the work and collections of Linnæus was recognised at the Upsala celebrations in 1908 by the conferment of honorary degrees (Ph.D. and A.M) and a royal honour (R.N.O.). Dr. Jackson will continue his association with the Linnean Society as Curator of the Linnean Collections; in this capacity his services will still be available to workers, and it is hoped that he may find ample leisure for putting on record more of his great knowledge on Linnean matters.

There is some risk that expectations not likely to be justified are being founded on the recent discovery of fresh foot-and-mouth disease carcases as a source of outbreaks of foot-and-mouth disease. All those who have had to give serious consideration to the introduction of the disease from abroad in recent years have recognised importation of entire carcases or portions of carcases of animals slaughtered while affected with the disease as a clear possibility. In spite of this, very great quantities of chilled or frozen beef are introduced from foreign countries, including Argentina, in which foot-and-mouth disease constantly exists. There was reason, however, to think that that could not be a very fruitful source, because the virus of the disease would probably have lost its vitality in the carcases by the time they arrived here.

What makes fresh, unpreserved meat from Belgium and Holland particularly liable to start an outbreak of foot-and-mouth disease is that it may arrive in Great Britain within 24 or 48 hours after the animals are killed, and would then be certainly infective. That source can be effectively stopped, but it is much to be feared that it will not prevent the recurrence of outbreaks in Great Britain so long as the disease is highly prevalent in the adjacent countries of the continent. It is an important fact that Scotland has for a period of two years been free from foot-and-mouth disease, although it is known that during that period thousands of pigs' carcases have been imported from the continent. Besides, the disease was frequently introduced before the present practice of killing pigs and dispatching their fresh carcases immediately had been begun. The real risk lies in the fact that every person or thing that has been in contact with an animal affected with foot-and-mouth disease, or in a place where diseased animals have recently been kept, becomes capable of spreading the disease for a period that may last for some days at least, and may therefore cause an outbreak on arrival in Great Britain after the comparatively short journey from Belgium and Holland.

The address delivered to the Iron and Steel Institute by Sir Peter Rylands, which appears elsewhere in this issue, is an exceedingly illuminating one, and the chart showing the facts concerning the production of steel in different parts of the world is very striking. That the fraction of the world's production contributed by Great Britain is a diminishing one is, however, inevitable in view of the vast resources of easily accessible and chemically suitable ores and fuel possessed by the United States, and of the entry of other countries, having natural resources of an extensive kind, into the field of production. It would be of interest to see a similar chart in which the value of the steel produced was shown instead of the tonnage, when perhaps the British share would prove to be somewhat larger, on account of the position occupied by Great Britain as a producer of the highest classes of steel. Sir Peter Rylands rightly emphasises the importance of organisation to the industry, and attributes much of the success of American and German undertakings to the industrial organisation which has improved efficiency. On the scientific side, the British steel industry is already responsible for the conduct of a large volume of research work, but much more thorough co-operation is required in order that the fruits of research may be made available to the industry as a whole. Nowhere is the influence of purely scientific investigations on manufacture to be more clearly seen than in the steel industry, except perhaps in the electrical industry, in which the necessity of co-ordinating scientific knowledge with practice has been recognised to the fullest extent.

IN the course of his lecture on "Iron in Antiquity," delivered at the Royal Institution on June 3, Dr. J. Newton Friend referred to some interesting historical points as to the early use of metals. Native gold was known to man at a very early date and was highly prized on account of its intrinsic beauty and resistance to tarnish. Native copper and iron were also known in certain districts, but it was centuries later before man learned to reduce those metals from their ores. Iron was manufactured in the Near East at an early date. About 1300 B.C. the Hittites were beginning to use iron weapons for military purposes, and in a letter, thought to have been addressed to Rameses II. of Egypt, the Hittite king states that he is sending with the letter an iron dagger. The Romans, in late years, were skilled metallurgists. Virgil in his "Aeneid," written about 40 B.C., describes the smithy in full work, whilst Pliny, whose work on natural history appeared in A.D. 77, shows a considerable knowledge of iron ores and of the working of the metal. He appears also to have recorded the accidental formation of cast iron. An iron ring of Roman origin, probably the remains of a ferrule, was found recently at Uriconium, and appears to have been made by bending a strip of iron into the form of a ring and soldering the ends with some copper alloy Cast iron was known in Sussex about 1350, and soon became quite a common product. It was at first used exclusively for casting purposes, and in 1588 cast-iron guns were used, as well as bronze, by the Spaniards in their Armada. When, many years later, it was found that cast iron was the most suitable starting-point for the manufacture of iron and steel, the demand for it increased enormously. In 1800 the United Kingdom produced about ¼ million tons of pig iron, a quantity that had increased by 1918 to more than 10 million tons, but fell again to just over 6 million tons in 1925.

IT is possible that the activities of the Russians in the scientific exploration of northern Siberia may be strengthened by the co-operation of Norway. It is reported in the *Times* of June 3 that a conference has been held in the Soviet Legation at Oslo under the presidency of Dr. Nansen to consider the possibility of a joint Russian and Norwegian expedition to Yakutsk. The conference was attended by representatives of the University of Oslo, the Geographical Society, and the Foreign and Commercial Departments. The Russian Academy of Sciences was represented by Dr. Wittenberg. It was stated that there are at present sixty Russian men of science engaged in investigation in Yakutsk. This area is one of special interest, particularly to the anthropologist, on account of the light which investigation of its people may throw on ethnology and racial movement in Asia. Any investigation of the people and culture of Russian territory in Asia, however, and especially the investigation of its archæological remains, is of interest to a wide circle outside Russia. Any attempt, therefore, to strengthen Russian effort by interesting scientific workers of other countries in these investigations deserves careful and, where circumstances permit, sympathetic consideration.

MANY interesting facts relating to the early manufacture of glass were mentioned by Sir Flinders Petrie in the course of an address delivered at the annual meeting of the Society of Glass Technology held at University College, London, on June 1. Glass was produced in the Euphrates region and in northern Mesopotamia so long ago as 2500 B.C., but in Egypt all glass was imported until 1500 B.C. Fifty years after the introduction of Syrian workers into that country, however, it became one of the commonest of all objects. Glass beads, the most popular use of glass, were not then made from liquid glass but from glass paste, glass-blowing not having been introduced until the Christian era. Sir Flinders, in referring to the use of glass by the ancients for the purpose of weights, said that three glass weights of the same denomination which had been found proved on testing to agree within $\frac{1}{100}$ of a grain.

AN organisation similar to Science Service of Washington, for the purpose of supplying to the press readable and accurate knowledge of scientific progress, has been formed in Paris under the title of "Office d'Information scientifique et technique," at the instigation of M. le duc de Gramont. The board of control consists of J. L. Breton, director of the National Office of Scientific and Industrial Research and Inventions; Charles Fabry, professor at the Sorbonne; Armand de Gramont, president of the council of the Institute of Optics, Paul Janet, director of the École supérieure d'Électricité, Louis Lumière, of the Academy of Sciences; Louis Mangin, director of the Muséum national d'Histoire naturelle; Émile Picard, permanent secretary of the Academy of Sciences; Georges Roger, of the Academy of Medicine; Émile Roux, director of the Pasteur Institute. The director of the office is Lieut.-Col. J. Raibaud. The new institution will co-operate with Science Service of Washington in the exchange of news of scientific and industrial progress in France and the United States.

SOME interesting side-lights were thrown on Indian religious custom and medical practice in Sir J. C. Bose's lecture on the action of cobra venom on plants which was delivered before the Royal Society of Medicine on June 2. Sir J. C. Bose found by experiment on animals and plants that a moderate dose of cobra venom produced an arrest of the pulse before death. In Indian popular belief it was thought that when a person bitten by a snake exhibited signs of death, revival was possible. For this reason the body was not cremated but was placed on a raft and allowed to float down the river. *Shuchikayan*, of which an ingredient is a minute quantity of cobra venom, has been employed in Indian medicine for a thousand years when a patient is at the point of death from heart failure. It is believed to revive the failing activity of the heart.

He had found that minute doses of cobra venom also stimulate certain nervous activities of plants.

The annual conversazione of the Royal Society to which ladies are invited will be held in the Society's rooms on Wednesday, June 16, at 8.30 P.M.

The annual visitation of the National Physical Laboratory, Teddington, will take place on Tuesday, June 22.

Sir Dugald Clerk, K.B.E., well known for his work on the development of the internal combustion engine, has been elected Prime Warden of the Goldsmiths' Company.

The Ross Institute and Hospital for Tropical Diseases, Putney Heath, London, S.W. 15, will be opened by the Prince of Wales on July 15. The Government of Nigeria has given a sum of 1000*l.* to the Institute to mark its appreciation of the services rendered by Sir Ronald Ross to residents in the tropics by his researches into the causation of malarial fever.

At the forthcoming Oxford meeting of the British Association, August 4-11, Prof. A. S. Eddington will deliver an evening discourse upon the subject of "Stars and Atoms," and Prof. H. F. Osborn one on "Discoveries in the Gobi Desert by the American Museum Expedition" Public lectures will also be given in Oxford by Sir William Bragg, Sir Dugald Clerk, Capt. Eckersley, Prof. Julian Huxley, and Prof. P. F. Kendall.

It is announced in *Science* that the Willard Gibbs Medal of the Chicago section of the American Chemical Society has been awarded this year to Sir James Colquhoun Irvine, of the University of St. Andrews. The presentation will take place at the September meeting of the Chicago section of the Society, when Dr. Irvine will be attending the Philadelphia meeting of the American Chemical Society.

The following have been elected officers of the Manchester Literary and Philosophical Society for the ensuing year: *President*, Dr. H. Levinstein; *Vice-Presidents*, Prof. W. L. Bragg, Prof. H. B. Dixon, Mr. E. A. Eason, Dr. R. S. Willows; *Secretaries*, Mr. John Allan, Prof. W. H. Lang; *Treasurer*, Mr. R. H. Clayton; *Librarians*, Mr. C. L. Barnes, Dr. Wilfrid Robinson; *Curator*, Mr. W. W. Haldane Gee.

It is expected that the *Proceedings of the Optical Convention* will be published not later than August 1 next, and that they will therefore be available during the meeting of the British Association at Oxford. Owing to the large number of papers read at the Convention, and the consequent size of the Proceedings, it has been found necessary to increase the price, which is now fixed at 30*s.*, plus 9*d.* postage, instead of 25*s.* as previously announced. Orders should be addressed to the Secretary, The Optical Convention, 1926, 1 Lowther Gardens, Exhibition Road, London, S.W 7.

An exhibition of Tardenoisian and pygmy types of stone implements is being held (June 8-22) at the Royal Anthropological Institute, 52 Upper Bedford Place. The exhibits will form a very fairly representative collection of the microlithic industry such as, we understand, has not hitherto been gathered together. Specimens will be included from Northumberland, Yorkshire, East Anglia, the south of England, Cornwall, Somersetshire, and Wales, France, the Fayum, Mesopotamia, East Africa, India, and Sydney, N.S.W. The exhibition is open to all fellows of the Institute; those who are not members may obtain admission on presentation of a visiting-card.

According to a statement of the Berlin correspondent of the *Times* in the issue of June 3, a public Marriage Advice Bureau has been opened in Berlin under municipal auspices and with the support of the Prussian Minister of Social Welfare. It will conduct free medical examination of those about to marry. Advice will be given in those cases where hereditary or acquired disease seems to make postponement or renunciation of marriage advisable. The services of the Bureau are to be available also for those already married.

The Council of the Institution of Electrical Engineers has made the following award of premiums for papers read during the session 1925–26, or accepted for publication: The Institution Premium to Mr. L. C. Grant; Ayrton Premium to Mr. S. Mavor; Fahie Premium to Messrs. B. S. Cohen, A. J. Aldridge, and W. West; John Hopkinson Premium to Mr. S. Ferguson; Kelvin Premium to Mr. P. Dunsheath; Paris Premium to Mr. T. Carter; Extra Premiums to Prof. S. P. Smith, Messrs. J. L. Thompson and H. Walmsley, Dr. A. B. Wood; Wireless Premiums to Messrs. R. A. Watson-Watt and J. F. Herd, Mr. J. Hollingworth, Dr. R. L. Smith-Rose, and Mr. R. H. Barfield.

The Wellcome Historical Medical Museum, 54A Wigmore St., London, W.1, which has been temporarily closed for alteration and reorganisation, was partially re-opened on June 1. The work of reorganisation is still proceeding, and when completed the arrangement and classification of the collections will be systematised, and the objects made more accessible for inspection and study. The Museum is open to members of the medical profession and research workers generally from 9 A.M. to 6 P.M. on week days, except Saturdays, when the Museum is closed at 1 P.M.

At the recent annual meeting of the Iron and Steel Institute, the following awards of Carnegie scholarships were announced: Mr. F. H Arnfelt (Stockholm), 100*l.*, for research on iron aluminium alloys; Mr. V. N. Krivobok (Pittsburg), 100*l*, for a study of recrystallisation of metals after cold-working; Mr. A. G. Lobley and Mr. C. L. Betts (Great Britain), 100*l.*, for an investigation on the viscosity of iron and steel at high temperatures; Mr. A. R. Page, 100*l.*, to enable him to carry out research on the hardening and tempering of high-speed steels; Mr. Tibor Ver (Budapest), 100*l.*, to study the effect of alternating stresses on the structure and mechanical properties of metals; Mr. L. B. Pfeil (Swansea), 100*l.*, to continue his investigation on the growth and properties of single iron crystals; and Mr.

J. H. Partridge (Birmingham), who received 100*l.* in 1925 in aid of a research on the electrical and magnetic properties of cast iron, a further award of 50*l.* to enable him to continue the investigation.

THE Council of the Institution of Civil Engineers has made the following awards in respect of papers read and discussed at the ordinary meetings during the session 1925–1926:—A Telford Gold Medal to Mr. O. L. Prowde (Makwar, Sudan); a Watt Gold Medal to Mr. H. R. Lupton (Leeds); Telford Premiums to Messrs. A. S. Angwin and T. Walmsley (London), V. Bayley (London), C. F. Bengough (Tewkesbury), A. Honeysett (London), J. N. Reeson (Melbourne, Victoria), and H A. Reed (Manchester); and a Crampton Prize to Colonel G. R. Hearn (Calcutta). The Council has also awarded the Coopers Hill War Memorial Prize for 1925 (consisting of a bronze medal, parchment certificate, and a sum of money) to Mr. E L. Everatt (Bombay). This prize was founded by the Coopers Hill Society in memory of Coopers Hill men who lost their lives in the War.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer and demonstrator in the department of Zoology of the East London College—The Registrar, East London College, Mile End Road, E 1 (June 16). An assistant lecturer in mathematics at King's College, Strand—The Secretary (June 23). Lecturers in physics and chemistry in the University of Durham—Head of the Department of Pure Science, South Road, Durham (June 26). An assistant for technical records work at the Building Research Station of the Department of Scientific and Industrial Research—The Director, Building Research Station, Garston, nr. Watford (June 26). A principal of the Pibwrylwyd Farm Institute of the Carmarthenshire Agricultural Committee—J. W. Nicholas, County Offices, Carmarthen (June 26). A lecturer in mathematics at University College, Southampton—The Registrar (June 29). An assistant lecturer in chemistry at the Liverpool Central Municipal Technical School—The Director of Education, 14 Sir Thomas Street, Liverpool (July 5). A keeper of the Department of Zoology of the National Museum of Wales—The Director, National Museum of Wales, Cardiff (July 9). A junior scientific assistant for Admiralty Research—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1. A woman resident lecturer in agricultural chemistry and botany at Studley College, Warwickshire—The Principal. An entomologist and research workers able to undertake independent inquiries on malaria, in the field or laboratory—The Secretary, Indian Research Fund Association, Simla, India. A teacher of mathematics and physics at the Wandsworth Technical Institute—The Principal.

Our Astronomical Column.

WOLF'S NOVA OF OCTOBER 1925.—Dr. W. H. Steavenson noted, at the meeting of the British Astronomical Association on May 26, that this object in Aquila increased slightly in brightness during the last two months of 1925, attaining mag. 8·7. Recent observations show that it is still of mag. 9, so that the decline is very slight. He suggested that the object is not a Nova but a normal star which has hitherto been hidden by a nebulous cloud from which it has just emerged. Its behaviour is so unusual that it deserves careful watching. Plates taken a few years ago show no trace of it, though they include stars of mag. 15.

COLOUR STUDIES OF VARIABLE STARS.—*Astr. Nach.* No. 5440 contains a study of certain variables by J. Hopmann; the colour index and bolometric magnitude were deduced at various stages of the light curve. Mira Ceti, when near minimum, became so red that it went beyond the limits of the comparison stars, and only estimates were possible. The last maximum of light occurred 1925, Dec. 7±2d, about 17 days later than the predicted date. The effective temperature of the star was then found to be 3470° as compared with 3780° at the maximum 11 months earlier. The star was, however, brighter last December than in the previous maximum: visual magnitude 3·20 compared with 3·61; bolometric magnitude 2·92 compared with 3·24. In the case of ζ Geminorum the range of bolometric magnitude is shown to be very much smaller than that of visual magnitude; in fact, the measures as they stand indicate an actual reversal of the curve, but this is not regarded as proved.

PARALLAX SURVEY OF KAPTEYN'S SELECTED AREAS.—Publications of Yerkes Observatory, vol. 4, part 4, contains a photographic determination of parallaxes in these areas (zone +45°) by Mr. Oliver J. Lee. The plan of wholesale photographic parallaxes was suggested by Kapteyn but has not met with general approval. The large scale of the 40-inch refractor is obviously an advantage in this research. Three hundred and ten photographic plates were used, all but nine being taken with a colour-filter; these nine were used mainly for proper motions. The parallax determinations are necessarily only relative. Ten or twenty stars were selected on each plate as standards: they were the faintest stars that had crisp, firm images (average magnitude 12·64), and a preliminary solution showed that they had very little proper motion, so they were presumably distant. The separate parallaxes and proper motions of 1041 stars are printed. The largest parallax is 0·113″ for a star of mag. 12·8 and proper motion 0·035″. About 3 per cent. of the stars have parallaxes so large as 0·06″. As one will expect, there are a large number of negative parallaxes. The effect of magnitude error is discussed and concluded to be small; a few of the plates were taken with a developed negative of the field used as a screen (a plan suggested by Kapteyn, which gives nearly equal magnitudes to all stars), but difficulties were found in working it.

The reduction of the relative parallaxes to absolute ones needs more absolute proper motions than are at present available in the region. Prof. Comstock, in a note included in the article, considers that the relative proper motions deduced need on the average a correction of about 1″ per century to reduce to the system of Boss.

Diagrams of the distribution of proper motions in the different areas are given; some of these, but not all, appear to conform to the two-drift configuration.

The author finally deduces the probable error of a proper motion as ±0·007″ and of a parallax as ±0·020″. He states that his results support the relative nearness of the galaxy in the region of R.A. 21″.

Teeth and Jaws of the Australian Aborigines —Anthropologists have long stood in need of data relating to the teeth and jaws of a primitive human race. This want has now been supplied by the publication, on the part of the University of Adelaide, of a thesis submitted to it by Dr. T. D. Campbell for the degree of Doctor of Dental Science ("Dentition and Palate of the Australian Aboriginal," The Hassell Press, 1925). Dr. Campbell's monograph is founded on a systematic examination of 630 dentitions collected from all regions of Australia, and representing every stage in the growth, eruption and wear of aboriginal teeth. The measurements of teeth and palate which are supplied by Dr. Campbell will prove of the utmost utility, and many of his observations are of high interest. In form and size of crown, in the number and arrangement of cusps, and in the development of roots, the teeth of the aborigines are "exceedingly primitive, probably more so than in any other living race and also than in some extinct races, such as Tasmanian and Neanderthal man." Large as are the dimensions of the molar teeth of Pithecanthropus (the Java man), Dr. Campbell met with examples in his series which outdid them. Particularly interesting to students of the teeth of fossil races of mankind are his observations on the filling up of the pulp cavity as a reaction to the wear of the crown—a reaction seldom seen in the teeth of civilised races. Campbell found that even amongst the aborigines the third molar teeth are the most variable, but whereas he had to examine nearly 200 skulls to find a single instance in which a third molar was absent, an English dentist would have to examine no more than five mouths to find a similar number. On the other hand, an English dentist would have to search 500 patients or more to find a fourth or supernumerary molar, whereas Dr. Campbell found seven or more instances in a similar number of Australian aborigines We have touched only on a few of the important and novel observations made by Dr. Campbell.

Neolithic Remains in Liguria.—In *Man* for May, Mrs J. W Crowfoot gives an account of some excavations carried out by her in the cave known as the Grotte de Bertrand in the Taggia Valley, near San Remo, in 1907–9. The cave proper is 33 ft long by about 12 ft with a bottle-neck entrance 8 ft 4 in. in length by 1 ft 7 in. in width and 1 ft 8 in. in height. It is 4 ft. high in the centre. The objects found included worked flints—a lunate arrow-point, and an arrow or javelin head, thick and roughly worked, with stem but no barbs—a needle-like pendant of bone, possibly made from a boar's tusk, six other bone pendants, also probably of boar's tusk, and five bone points, a number of shells of *Helix Nicaensis*, human skeletal remains of at least ten individuals, some showing primitive characters such as large teeth, heavy os calcis, perforation of the humerus, platycnemia, etc Nearly all the long bones and portions of the skulls were poked under the rock at the side of the cave and piled one upon top of the other, so that they could not be in the original position of interment Three hundred beads of five different types were found, including the winged type sometimes thought to be phallic Beads alternating grey and white were strung into a necklace identical with some in the museum at Toulouse. The human remains have been pronounced neolithic. Both Prof. Issel and Prof. Cartailhac, to whom the results were communicated, were of the opinion that the culture of the cave belonged to the late Neolithic period.

Fresh-water Amphipoda.—Hermann Spandl (*Sitzungsber Akad. der Wissensch*, Wien, Abt. I. Bd. 133, Heft 9, 1924) gives a systematic survey of the fresh-water amphipods and discusses the methods—active and passive migration—by which marine animals have entered fresh water. He refers in some detail to the amphipods of Lake Baikal, and concludes that many of the genera found there can be traced back to a small number of ancestral genera, the amphipod fauna of Lake Baikal does not represent a relict fauna but has arisen by progressive differentiation in the lake itself. In the Caspian Sea, however, the fauna can be divided into two parts, one part of marine origin and the other a fresh-water fauna, the genera in each category are given, and the relationships of this fauna with that of the Arctic Sea and of the Baltic are discussed A short account is given of the genera of amphipods found in subterranean waters and of the geographical distribution of fresh-water amphipods.

Morphology of Fishes.—Prof F. H Edgeworth (*Jour. Anat.*, vol. 60, pt iii.) gives an account of his reinvestigation of the development of certain of the branchial muscles in the Selachii. In 1911 the author concluded that the coraco-branchiales muscles were developed from the ventral ends of all the branchial muscle plates and the cucullaris muscle from the upper ends of the same plates. This conclusion was disputed by Allis Reinvestigation of the matter on new material has confirmed the author in his former conclusions In the same number of the *Journal of Anatomy*, Mr E. P. Allis contributes a paper on the homologies of the prechordal portion of the skull in the Holocephali, and concludes that the trabecular and polar cartilages of the skull are the pharyngeal elements of the mandibular and premandibular arches which have swung upwards and forwards, in connexion with the development of the mouth, into a position approximately parallel to the plane of the parachordals.

Resin Excretion in the Buds of *Alnus viridis*.—The development and micro-chemistry of the glandular hairs on the epidermis of the leaves and bud scales of Alnus have been studied by Friedrich Dormann (*Sitzungsber. Akad. der Wissensch.*, Wien, Abt I. Bd. 133, pp. 585–612, 1924). Many of these glandular hairs never share in the excretion of resin. Under examination these are found to be full of spherical droplets which, from their micro-chemical reactions, would appear to be complex terpenes. These contents, which seem similar to those in the glandular structures of Betula and Populus, are probably connected with resin formation. They occur, however, not only in the glandular hairs in Alnus, but also generally distributed in epidermal cells of the young leaves, so that the epidermis probably shares in resin secretion. Dormann concludes that the membrane of the cells shares in the work of resin excretion so that to this extent the expression 'resinogenous layer' used by Tschirch may be justified, but there is no reason for thinking that this part of the membrane is alone responsible for the complicated chemical changes involved in the production of resin

Campanula Mutants.—A large tetraploid mutation from *Campanula persicifolia* was exhibited horticulturally in 1916 under the name "Telham Beauty." It appears to be identical with a form recorded as coming from South Carolina in 1791, and must have arisen independently. It is self-fertile, while the species is self-sterile. Like similar tetraploids, Telham Beauty is stouter, has larger nuclei, and frequently more pores in the pollen grains. Its much larger flowers are, however, shallower in shape. It was crossed by Miss A. E. Gairdner (*Journal of Genetics*, vol. 16, No. 3) with *C. persicifolia* and with a dwarf form called *nitida* in which the flower has an almost superior ovary. Miss Gairdner finds that in the triploid F_1 (24 chromosomes) in diakinesis, univalent, bivalent and trivalent chromosomes occur. In the F_2 offspring various other chromosome numbers are obtained, one plant having 17, *i.e.* a single extra like many Œnotheras and Daturas, another being tetraploid (32 chromosomes). The hereditary behaviour of the latter indicates that the maternal chromosomes in the egg had been doubled. In the pollen formation of the tetraploid form, occasionally half of the heterotypic chromosomes split without separating, thus forming a tetraploid pollen nucleus.

DISCOVERY OF A DINOSAUR IN QUEENSLAND.—The remains of a large herbivorous dinosaur have been found in the Walloon series (Lower Jurassic) of Durham Downs in the Roma district of Queensland. They consist mainly of vertebræ with fragments of femur, tibia, fibula and pelvic bones, and are referred to a new genus, Rhœtosaurus, which is tentatively placed in the family Camarasauridæ of the Sauropoda. It is probable that Rhœtosaurus attained a length of more than 40 feet (H. A. Longman, *Mem. Queensland Museum*, 8, 3, 1926, p. 183, pls. 29-33).

AIR TEMPERATURE IN THE ARCTIC.—Six years in the Arctic have enabled Dr. H. U. Sverdrup to draw some valuable conclusions from his scientific observations with the Maud expedition. In an article in the *Scientific Monthly* for May on the results of the expedition, he points out that in winter the air temperature is always lower close to the ice than three hundred metres above it. The mean temperature at the ice is – 28·4° C., with a fall to about 100 metres, then a rapid rise to about 300 metres, and then a slower rise to – 20·3° C. at 1000 metres. On calm days the mean temperature at the surface averages about – 33° C. but corresponds with the mean at higher altitudes. The low surface temperatures are due to contact with the ice, which loses heat by radiation. Wind causes a mixing of the lower layers of the atmosphere on account of numerous eddies, and there is a decrease of temperature with altitude, but this clearly affects only the lower layers. At higher altitudes an inversion of temperature is the normal condition. Thus an explanation is offered of the phenomenon, previously noticed in polar regions, of a rise in temperature when the wind begins, independently of its direction. The minimum surface temperature is about – 45° C. because, though the ice loses heat by radiation, it is always gaining heat by conduction from the underlying sea, which retains a temperature of about – 1·7° C.

THE CONSTITUTION OF MALTOSE.—Irregularities in the results obtained by workers on the constitution of the polysaccharides caused considerable suspicion to fall on the formula given to maltose by Haworth and Leitch, and evidence has been published by J. C. Irvine and J. M. A. Black in the *Journal of the Chemical Society* for April 1926, which disproves Haworth's formula and substitutes two others between which no discrimination has yet been made. In the same issue of the journal a paper by C. J. A. Cooper, W. N. Haworth and S. Peat appears, confirming Irvine's work but admitting Irvine's priority. The constitution of maltose given by Haworth was based on the formation of 2:3:4 trimethyl glucose, but Irvine, by exact repetition of the experiments, has shown that this product is 2:3:6 trimethyl glucose. The revision of the structure of maltose involves the constitutional formulæ given to the other di-saccharides and poly-saccharides based on glucose.

THE CONDUCTIVITY OF PURE SODIUM HYDROXIDE SOLUTIONS.—The mobility of the hydroxyl ion has been determined by H. R. Raikes, A. F. Yorke and F. K. Ewart from conductivity measurements of sodium hydroxide in very pure water. Preparation of the carbonate-free hydroxide was carried out by electrolysis of sodium chloride solution, using a carbon anode and an iron cathode. The values, which appear in the *Journal of the Chemical Society* for March 1926, obtained from Washburn's value for the mobility of the sodium ion, are 173·8 and 144·3 at 18° and 10° C. respectively.

MAGNETIC PROPERTIES OF PERMALLOY.—From a separate copy of a paper on permalloy by Messrs. O. E. Buckley and L. W. McKeehan which appeared in the August 1925 issue of the *Physical Review*, we are able to supplement the information as to the magnetic properties of this alloy which was given in a note in our issue of January 9, p 65. Permalloy is the name given to a series of alloys of iron and nickel, containing from 45 per cent. to 80 per cent nickel. These alloys all possess high permeability for low fields and reach saturation at fields of less than 10 gauss. They have been tested in the form of wires 0.1 cm. in diameter, 60 cm. long in a solenoid nearly as long, by reversal of the field and measurement of the induction through a search coil wound over the middle of each wire and in series with a ballistic galvanometer. The 81 per cent. nickel permalloy reaches saturation at 4 gauss, when its intensity of magnetisation is a little more than 800, and at 1 gauss it has reached 700. The hysteresis loss per c.c. per cycle at induction 8300 is only 350 ergs, and is only half that amount for the permalloy with 78.5 per cent. nickel. When these wires are subjected to tension, saturation is reached within 5 per cent. for fields so low as 0·1 gauss and the hysteresis loss per c.c. per cycle reduced to 80 ergs.

TRANSMISSION FORMULA FOR RADIOTELEGRAPHY.—Mr. L. W. Austin has published in the *Journal of the Washington Academy of Sciences* for April 19 a preliminary note on proposed changes in the constants of the Austin-Cohen transmission formula used in radiotelegraphy. The formula has for the last twelve years been known to give satisfactory results for distances up to hundreds of kilometres and for rays of medium wave-length. At distances, however, of 6000 kilometres, the computed results are only about half those observed, and at 12,000 kilometres only about one-quarter of their true values. The author has made a close study of the numerous trans-Atlantic observations made by various observers during recent years. He finds it difficult to reconcile some of these observations In some cases the waves have passed over water all the way, in others they have passed over more land than water. The shortest great circle from Nauen to Washington is twenty-five per cent. land, but from India to the European stations nearly the whole path is over land. It is generally agreed that land attenuation is much greater than that over water. Nevertheless, by slightly altering the empirical factor of the formula and leaving the theoretical part due to Hertz alone, Mr. Austin obtains a formula which predicts with quite satisfactory accuracy the field intensities at distances ranging from 6000 to 12,000 kilometres. In a further paper he proposes to discuss the results the formula gives in all the available cases.

Visitation of the Royal Observatory, Greenwich.

THE annual visitation of the Royal Observatory, Greenwich, by the Board of Visitors, took place on Saturday, June 5, when the Astronomer Royal presented his report, which deals with the year ended on May 10, 1926. It commences with an allusion to the 250th anniversary of the foundation of the Observatory, which was celebrated last July; the King and Queen honoured the Observatory by their presence; the King presented a signed portrait of himself, which has been hung in the Octagon Room. Many foreign astronomers, who had come to England for the meeting of the International Astronomical Union at Cambridge, were also present.

The historic instruments in the Transit Circle Room were renovated for the occasion of the visitation, and it became possible to examine their beautiful graduation, which had been obscured for a long time. The standard sidereal clock is now kept in the cellar under the Octagon Room; this has been lined with cement, but is still damp; the clock being in an airtight case, this is not important.

The transit circle was used during the past year, as before, for observations of the sun, moon, planets and fundamental stars, also of stars brighter than mag. 8·0 in the zone from decl. +32° to +64°. The numbers of observations in right ascension and declination were about 10,000 each. The sun was observed on 136 days, the moon on 97. The corrections to Brown's "Tables of the Moon" for the years 1923, 1924, 1925 are: longitude +7·12″, +7·11″, +6·74″, latitude −0·55″, −0·76″, −0·84″. As regards the latitude, it will be remembered that Brown removed the constant term 1·00″ applied by Hansen; the observations indicate the need for a constant term of somewhat smaller size.

The division errors of the work transit circle were re-determined, the former values being confirmed. Observation is now beginning of 430 of the stars selected as comparison stars for Eros at the near approach in January 1931. Observations of fundamental stars with the altazimuth in the prime vertical have been continued. The results indicate that Boss's declinations between +11° and +50° need a nearly constant correction of +0·33″, agreeing closely with Raymond's result in *Astron. Journ.*, No. 857.

Work on double stars has been continued with the 28-inch equatorial; a catalogue of 400 stars has been prepared for press. 834 stellar parallax plates were taken with the Thompson 26-inch equatorial. 316 parallaxes have now been determined with this instrument, and a volume containing the first 266 of these has been published.

The 30-inch reflector is being used to study stellar temperatures of types B and A, by photographing spectra with a prism crossed by a grating. Stellar temperatures have also been compared with that of the positive pole of a carbon arc. A paper on the effective wave-lengths of stars between decl. +80° and +90° was published in *Mon. Not. Roy. Astron. Soc.* last November.

The astrographic equatorial is being used for the determination of proper motions, by repeating plates taken twenty-five to thirty years ago. In 700 square degrees, 194 stars have been found with centennial proper motion greater than 20″; 86 of these are fainter than the B.D. limit, 9·5 mag., 17 of the 86 have centennial proper motion greater than 30″.

The sun was photographed on 251 days, the series for the year being completed by the co-operating observatories. Solar activity was great from October until March, there being twelve naked-eye sunspot groups. The magnetic disturbances of January 26, February 23, March 5, were associated with two of these groups; that of April 14-15 occurred when a spot that had been visible to the naked eye in December, January, February was near the central meridian. Magnetic observations have been made at Greenwich for the last few years merely with the object of establishing the mean differences of the readings from those made at Abinger. The recent electrification of the New Cross—Lewisham railway line has rendered the Greenwich observations nearly valueless, and they will be discontinued when the still closer line through Greenwich and Maze Hill is electrified in July. The following table gives the magnetic elements at Greenwich in recent years, those for 1925 being provisional, also the mean difference Abinger *minus* Greenwich:

Year.	Dec. W.	Hor. Force. (c.g.s. units)	Vert. Force. (c.g.s. units)	Dip.
1921	13° 57·6′	0·18449	0·43218	66° 53·0′
1922	13 46·7	0·18447	0·43176	66 52·3
1923	13 35·1	0·18431	0·43137	66 51·9
1924	13 22·8	0·18426	0·43112	66 51·6
1925	13 10·0	0·18413	0·43081	66 51·5

Abinger *minus* Greenwich—

+12·8′	+0·00183	−0·00132	−16·2′

Magnetic disturbances at Abinger are, on the average, 2 per cent smaller than at Greenwich, while those at Stonyhurst are 20 per cent. greater.

Standardisation and certification of magnetometers has been carried out in recent years at Greenwich, but will in future be done at Abinger. A Schuster Smith magnetometer was brought into use at Abinger on May 1, and will be used to determine the horizontal force.

The following weather details refer to the year ended April 30, 1926. The mean temperature was 50·4°, which is 0·9° above the average. The extremes were 89·5° (July 22) and 16·0° (January 16). September was 3·4° below normal, February 5·8° above it. The mean daily movement of air was 275 miles, which is 9 below normal. The extremes were 741 miles (December 29) and 65 miles (October 6). The duration of bright sunshine was 1312 hours, or 29·5 per cent. of possible. The rainfall was 24·88 inches, which is 0·64 above the average. The wettest month was April, with 3·87 inches; the only wetter April was in 1878, with 4·31 inches. June and March were both absolute records for dryness, with 0·12 and 0·14 inches.

Wireless time signals from Paris (Eiffel Tower), Nauen, Bordeaux and Annapolis are recorded regularly on a syphon recorder. After applying all known corrections they are late on Greenwich by the following amounts respectively: 0·11 s., 0·05 s., 0·09 s., 0·06 s.

Mr. Davidson was absent from the Observatory from November 11 until April 1 for the observation of the total solar eclipse of January 14 in Sumatra. Very successful photographs were obtained. Mr G. Merton has continued his researches on cometary orbits; he also assists in the stellar parallax observations. Dr. W. H. Steavenson has made some observations of variable stars with the 28-inch equatorial. M M. Beljaieff and Dnieprovsky made a re-determination of the longitude Greenwich-Pulkovo. The reduction of the observations is not yet complete. Dr. Lundmark, of Upsala, assisted Mr. Melotte in drawing up a list of vacant areas in the sky, from the Franklin-Adams charts.

The short free-pendulum clock has performed very satisfactorily. The rate is increasing by 0·011 s. per day per month. A second clock of the same kind is now being erected.

The Italian Chemical Congress at Palermo and the Cannizzaro Centenary.

THE second Italian National Congress of pure and applied chemistry was held at Palermo, Sicily, on May 22-June 1, simultaneously with the centenary celebrations of the Sicilian chemist Stanislao Cannizzaro, who was born in Palermo in 1826. A monument was unveiled to his memory, and the Italian Chemical Society is publishing a book describing the main features of his life and work. Sir William Tilden, who delivered the Cannizzaro Memorial Lecture to the Chemical Society, summed up Cannizzaro's contributions to chemistry very broadly under the two following heads: "First, he laid down for all time the two principal methods by which atomic weights are determined, the one by reference to the molecular weights derived from an application of Avogadro's rule, and the other by an adoption of the principle discovered by Dulong and Petit as to the general relation of atomic weight to specific heat among the solid elements, and he showed that these two methods when applicable to the same case lead to the same results. Secondly, he placed inorganic chemistry in a new light by applying to inorganic compounds the same principles which had been applied to organic compounds, and thus finally disposed of the superstition which had hovered so long in the minds of chemists that organic chemistry was subject to laws different from those prevailing among mineral substances."

No better place could have been found than Palermo for the centenary celebrations. Not only was Cannizzaro born there, but also for ten years he held the chair of organic and inorganic chemistry at that University, refusing chairs at both Pisa and Naples in order to take it. He only left it to take the highest post in chemistry that Italy could bestow, the chair at Rome. During the Sicilian revolution in 1847 he left his studies under Piria to serve as an artillery officer in the Sicilian army, and handled his battery so well at Messina that he was sent to Taormina to oppose the Neapolitan troops. The final defeat of the Sicilian troops in 1849 made him a fugitive, and he finally made his way to Chevreul's laboratory in Paris, where he stayed until recalled to Italy in 1851 as professor at the National School at Alessandria, going four years later to Genoa, whence he published in 1858 his famous "Sunto di un Corso di Filosofia Chimica." In 1860 he again took arms, this time under Garibaldi, but without seeing any active warfare. From 1861 until 1871 he held the chair at Palermo, and from there he went to Rome, being at the same time made a Senator of the kingdom. From then until his death, in 1910, his life was full and varied, and honours, both civil and scientific, were showered on him.

Besides the reading of numerous papers in various branches of chemistry, an interesting programme of sight-seeing in Sicily had been arranged for those who attended the Congress, and a wide field of historical and scientific interest was covered, amid some of the most magnificent scenery of southern Europe. The itinerary included a visit to Mondello, near Palermo, to inspect the works of the Societa Gen. Elettrica della Sicilia on May 25; to the Arenella Chemical Works on May 26, to the sulphur mines of Cozzi Disi, near Girgenti, and the Campfranco works of the Montecatini firm on May 28; to the asphalt deposits of Ragusa on May 29; to the Magnisi salt mines on May 30; to the sulphur mines and other places of interest near Catania—including Mt. Etna—on May 31, and finally to Messina on June 1.

University and Educational Intelligence.

BIRMINGHAM.—The following gifts have recently been announced: 50*l*. towards the expenses of the new Fuel Treatment Laboratory, by the Bromford Tube Co., Ltd.; mounted illustrations for use in the Botanical Department, by Mrs Wilson King; pair of telephones, shown at the Paris Exhibition in 1878, by Mr. J. C. Vaudrey, two alternators, for use in the Electrical Engineering Laboratory, by Mr W. F. Higgs.

CAMBRIDGE.—The late Dr. J. E. Bles has left to the University an immediate gift of his scientific apparatus and books and the contents of his private library and (subject to his wife's life interest) the entire residue of his estate. The latter benefaction is expressly for the purpose of founding a professorship, preferably in animal embryology.

A readership in ethnology is being established, the present post, a personal appointment for Dr A. C. Haddon, terminating on his retirement at the end of the present term.

LEEDS.—Applications are invited, until June 19, for the open fellowship, value 200*l*., of the Institution of Gas Engineers for the prosecution of post-graduate research in gas chemistry. Particulars are obtainable from the Registrar of the University.

DR E. A. OWEN, head of the Radiology Division of the National Physical Laboratory, Teddington, has been appointed to the chair of physics at the University College of North Wales, Bangor.

LEPLAY HOUSE August Vacation Courses include this year visits to Dinant and the valley of the Meuse, Rochefort and the Belgian Ardennes, Irish Lake District; and Bagnères-de-Bigorre, in the High Pyrenees. These visits are open to all students and others interested in the study of geography, geology, plant life, history, and sociology. Particulars can be obtained from Miss Margaret E. Tatton, Leplay House, 65 Belgrave Road, Westminster, S.W. 1.

THE annual report on the work of the University of London presented on May 12 by the Principal Officer, Sir Cooper Perry, who is about to retire, shows a slight decrease, from 7603 to 7577, in the total number of admissions and an increase from 31,623 to 32,353 in the number of candidates for all examinations. Of 3819 candidates for degrees, 2301 were internal and 1518 were external students, the number of internal students increased from 9002 to 9323. Specially noteworthy among the private benefactions mentioned in the report is the gift of 20,000*l*. by Sir Daniel Stevenson for the establishment of a part-time chair of international history and for the development of a department dealing with that subject. Other private benefactions to the University amounted to about 55,000*l*. and the London School of Economics received more than 30,000*l*. from the Laura Spelman Rockefeller trustees. The progress of the movement for broadening the bases of university education is exemplified by the new regulations adding music and law as optional subjects to various examinations. The holiday course for foreigners held last summer attracted more applications for admission than any of its seventeen predecessors, and more than 200 had to be refused, which seems a pity. Those admitted numbered 256, representing 22 nationalities. The courses in journalism are increasingly sought after; the number of students increased from 53 in 1924–25 to 74 in 1925–26. The scheme of advisory service for external students introduced experimentally last year proved effective.

Contemporary Birthdays.

June 12, 1851.	Sir Oliver Joseph Lodge, F.R.S.
June 12, 1858.	Sir H. H. Johnston, G.C.M.G., K.C.B.
June 13, 1854.	Hon. Sir Charles Algernon Parsons, K.C.B., F.R.S.
June 13, 1870.	M. Jules Bordet, For. Mem. R.S.
June 14, 1857.	Prof. John Edward Marr, F.R.S.
June 15, 1851.	Prof. E. H. Griffiths, F.R.S.
June 17, 1860.	Prof. William Henry Perkin, F.R.S.
June 18, 1858.	Prof. A. R. Forsyth, F.R.S.

Sir Oliver Lodge, born at Penkhull, Staffordshire, was educated at Newport (Salop) Grammar School, and University College, London. From 1900 to 1919 he was principal of the University of Birmingham. In 1898 he was awarded the Royal Society's Rumford medal, and it was remarked then that in dealing with Hertz's discovery of electro-magnetic radiation it was requisite to recall the work done previously, or simultaneously, by Lodge on the surging or oscillatory character of the transmission of electric discharges along wires. Sir Oliver was president of the Society for Psychical Research, 1901–4.

Sir Charles Parsons, inventor of the steam turbine, a son of the third Earl of Rosse (president of the Royal Society from 1848 until 1854), was born in London. Following private tuition, he graduated at St John's College, Cambridge. An apprentice for a number of years in Armstrong's Elswick Works, he afterwards served on the experimental staff of Messrs. Kitson and Co., Leeds, leaving to enter into partnership (lasting from 1884 to 1889) with Messrs Clarke, Chapman, and Co., Gateshead Sir Charles has been for many years actively concerned with various electrical and engineering undertakings; among these should be mentioned the onerous post of chairman (since 1908) of the Parsons Marine Steam Turbine Co., Ltd. Awarded, in 1902, the Royal Society's Rumford medal for his success in the application of the steam turbine to industrial purposes, and to navigational uses, Sir Charles received, later, in similar recognition, the Albert medal of the Royal Society of Arts. Sir Charles was president of the British Association at the Bournemouth meeting, held in 1919. Guided by a native discretionary sense, many worthy scientific schemes have received encouragement from time to time through his beneficence.

M. Jules Bordet, foreign member of the Royal Society, was born at Soignies, Belgium. Attached to the Pasteur Institute, Paris, from 1894 to 1901, he left to become director of the Pasteur Institute, Brussels, whilst from 1907 he has been professor of bacteriology in the university of Brussels Prof. Bordet was Nobel laureate in 1919 in the physiology and medicine section.

Prof. Perkin, born at Sudbury, was educated at the City of London School and various foreign universities Awarded the Royal Society's Davy medal in 1904, for his "masterly and fruitful researches in the domain of synthetic organic chemistry," this was followed last year by the distinction of a Royal medal, in recognition of his more recent contributions to chemical science.

Prof. Forsyth is a native of Glasgow He was educated at Liverpool College and Trinity College, Cambridge, where he was senior wrangler and first Smith's prizeman Formerly Sadleirian professor of pure mathematics in the University of Cambridge, he was, until recently, chief professor of mathematics in the Imperial College of Science and Technology, South Kensington. Prof. Forsyth is a Royal medallist of the Royal Society

Societies and Academies.

London

Royal Society, June 3.—**A. E. H. Tutton**: The alkali perchlorates, and a new principle concerning the measurement of space-lattice cells. The crystallographic character and optical properties of the perchlorates of potassium, rubidium, cæsium and ammonium have been investigated. The crystal angles and goniometrical constants are progressive in the order of the atomic numbers of the alkali metals, the average change for the replacement of potassium by cæsium being double as much as occurs when rubidium replaces potassium Optical properties and the sizes, both relative and absolute, of the unit-cells of the space-lattice also show the progression with atomic number of alkali metal very clearly. The absolute dimensions of the cells have been found by a new principle. In an isomorphous series based on similar structure, if one member crystallises well and can be thoroughly investigated by X-rays and the cell dimensions determined in Ångström units, the cell dimensions of all the other members can be calculated. The case of the perchlorates and barytes group affords the first, and an excellent, example The structure and cell-dimensions of barytes are known with certitude. The cell-dimensions of the minute crystals of the isomorphous perchlorates of the alkalies have been calculated from their topic axial ratios and the barytes data In one case a critical test has been possible, that of potassium perchlorate, X-ray analysis of which has been just adequate to afford the cell-dimensions; and these have proved to be practically identical with those calculated on the new principle.—**T. E. Stanton**: On the flow of gases at high speeds. An experimental investigation was undertaken on the nature of the flow of a gas through orifices and nozzles at speeds in the neighbourhood of and exceeding the velocity of sound The prediction of Osborne Reynolds that a minimum section of the jet would exist at that point in it at which the theoretical critical pressure p_c obtains has been fully verified. The magnitude of the minimum section and its position relative to the throat of the orifice or nozzle depend on the value of the receiver pressure. The conditions for dynamical similarity in jets from geometrically similar nozzles and orifices at speeds above the velocity of sound depend on the viscosity of the gas and not solely on the ratio of the speed to that of sound. A reliable method of measuring the velocity at a point in a jet moving at speeds above the velocity of sound has been developed from the relation, determined by the late Lord Rayleigh, between the pressure in front of a fixed obstacle in the jet and the pressure of the jet The flow throughout the jet except in the neighbourhood of the walls of the nozzle is sensibly adiabatic.—**G. I. Taylor** and **W. S. Farran**: The distortion of crystals of aluminium under compression (Pt. I.) A disc cut from a crystal of aluminium can be compressed in such a way that the distortion is uniform throughout the material In these circumstances the distortion is of the same nature as that which occurs when a uniform single-crystal bar of aluminium is stretched, *i.e.* it is due to slipping parallel to a certain crystal plane and in a certain crystallographic direction The sign of the component of force normal to the plane of slip appears to make no difference to the nature of the slip.—**E. V. Appleton**, **R. A. Watson Watt** and **J. F. Herd**. On the nature of atmospherics (II.) The method now involves the use of a cathode ray oscillograph with a time-base, which is both uniform in scale and unambiguous as to time-sense Statistical analyses of approximately 8000 individual drawings of atmospheric wave forms show that sensibly aperiodic discharges were three times as numerous as were quasiperiodics; predominantly positive discharges were one and a half times as numerous as were negatives. The mean quasiperiodic had a peak field strength of 0·159 *V/m*, the aperiodic 0·075 *V/m*. The negative discharges of both types were stronger by 20 per cent. to 30 per cent. than the positives. The mean quasiperiodic had a duration 3125 μs, 30 per cent. greater than that of the mean aperiodic. The most frequently occurring form of atmospheric was a symmetrical rounded positive aperiodic, forming 14 per cent. of the whole distribution. The most frequent quasiperiodic, forming 7½ per cent. of the distribution, had a peaked positive half-cycle followed by a single rounded negative half-cycle. The experiments on atmospheric waveforms have been supplemented by observations on the net changes of the earth's electric field, resulting from lightning discharges. These observations at Aldershot, Cambridge, Helwan and Khartoum show that, at distances greater than 50 km. from the discharge channel, negative changes of field are at least 1·6 times as frequent as are positive changes. Since the field-changes at such distances may be taken as indicative of the sign of the thundercloud moment destroyed by the flash, it is concluded that lightning flashes resulting in the destruction of positive electric moments are at least 1·6 times as frequent as are those of opposite character.—C. H. **Lees**: On the determination of the specific heats of gases at constant pressure and at constant volume, and their ratio by adiabatic expansion. The specific heats of gases or the ratio of them cannot be determined to an accuracy of 1 part in 2000 or in 15,000 respectively unless either the temperature is determined to less than 0·01° C. or the adiabatic fall of temperature is increased above the 6° or 7° C. now used. If the latter course is adopted, the effect of the change of specific heat with temperature may be rendered negligible by taking the result calculated from the observations holding at the geometric mean of the initial and final temperatures of the expansion. Neglect of the deviation of the gas used from the perfect gas equation $pv = RT$ introduces an error of 1 part in 2000 in the value of the specific heat, calculated from observations at atmospheric temperatures with the usual expansion, if the deviation is only about one-fifteenth of that of carbon dioxide. The choice of characteristic equation for the gas introduces differences of the order 1 part in 400 in the value of the ratio of the specific heats calculated.—T. G. **Room**: A general configuration in space of any number of dimensions analogous to the double-six of lines in ordinary space. In space of three dimensions, it is possible to have two sixes of lines, of which every line of one six meets all but one line of the other six. Thirty-six such double sixes can be chosen from the lines existing on a general cubic surface. In space of n dimensions it is possible to have a set of $\frac{1}{2}n(n+1)$ lines, and a set of the same number of $(n-2)$ folds, corresponding to the lines in a like manner, as regards their intersections. It is now shown that in space of n dimensions it is possible, for any value of r less than n, to have a number of r-folds, and an equal number of $(n-r-1)$ folds, with the like property of intersection of corresponding elements. In the case of the double six of lines in ordinary space, there exists a quadric in regard to which the lines of one six are the polars of the lines of the other six. It is now shown that, except for the case when one set of elements consists of points, there exists no such reciprocating quadric in space of more than three dimensions. The existence of such a double set of corresponding elements is, however, not limited to the case when these are of dual character, such as a point and an $(n-1)$-fold, a line and an $(n-2)$-fold, and so on. In this paper a much more general theorem, establishing a double figure of elements with a like property of intersection, is obtained.—C. N. **Hinshelwood** and W. K. **Hutchison**: A comparison between unimolecular and bimolecular gaseous reactions. The thermal decomposition of gaseous acetaldehyde. The thermal decomposition of acetaldehyde in the gaseous state has been investigated over the temperature range 430°-592° C. The reaction is bimolecular, and under the conditions of the experiments, practically entirely homogeneous. The rate of reaction can be calculated from the equation

$$k = 5\cdot5 \times 10^{10}\sqrt{T}\,.\,e^{-45,500/RT},$$

k being expressed in gram molecules per litre per second. The contrast between this reaction and the chemically very similar decomposition of acetone is illuminating. The latter reaction, being unimolecular, is not necessarily dependent on collisions, and the number of molecules transformed in unit time is 10^{5} times greater than the number which could receive the heat of activation from collisions. In the bimolecular decomposition of acetaldehyde there is almost the exact relation between heat of activation, number of collisions, and rate of reaction, which the simplest theory predicts.—P. A. M. **Dirac**: (1) The elimination of the nodes in quantum mechanics. (2) Relativity quantum mechanics, with an application to Compton scattering. The quantum mechanics of Heisenberg are generalised to agree with relativity kinematics and dynamics. Each step in the generalisation is obtained by putting its classical analogue into a form that can be interpreted immediately on the quantum theory. The relativity quantum theory thus obtained requires that an atomic system shall recoil when it emits radiation in agreement with the light-quantum theory. Applied to the scattering of radiation by a free electron, the frequency of the scattered radiation and the recoil momentum of the electron are the same as those given by Compton's light-quantum theory, although the present theory is entirely a wave theory. The intensity of the scattered radiation is equal to its classical value reduced by the cube of the ratio by which the frequency is reduced, which is in good agreement with experiment.—A. **Fage** and L. J. **Jones**: On the drag of an aerofoil for two-dimensional flow. Prof. G. I. Taylor has shown, from considerations of momentum, that it should be possible to determine the drag of an aerofoil from the integral of the total-head losses in the wake at some distance behind the aerofoil. For two-dimensional flow this method gives satisfactory experimental results. In the neighbourhood of minimum drag the normal components of pressure around the aerofoil account for about 80 per cent. of the total drag; the contribution of the surface tractions is therefore about 20 per cent. The Prandtl method of predicting two-dimensional drag from force measurements on an aerofoil of finite span (span = 6 chords) is fairly trustworthy. Observations of pressure and velocity taken at some distance behind the aerofoil indicate that most of the total-head losses in the wake arise from the slowing-up of the air, and that the pressure does not differ appreciably from that in the surrounding stream.—F. W. **Carter**: On the action of a locomotive driving wheel. The relation between the tractive effort of a locomotive driving wheel and the surface strains in wheel and rail at points just ahead of the area of contact—a matter affecting the running qualities of the locomotive—is investigated. In general, the area of contact between wheel and rail is divisible into two portions, characterised by distinct conditions, namely, a certain initial portion in which there is no slipping between contiguous wheel and rail surfaces, and a final portion in which the surfaces slip as the strains tend towards the values existing behind the contact. Treating the problem as two-dimensional, the conditions to be satisfied in the two portions of the contact area are indicated, and a solution obtained.

Geological Society, May 19.—Jane **Longstaff** (*née* **Donald**): A revision of the British Carboniferous Murchisoniidæ; with notes on their distribution, and descriptions of some new species. Six new species and one variety are figured and described, as well as five species recorded by L. G. De Koninck in Belgium, which, with one exception, had not been previously noted in the British Isles. Altogether fifty-two species and one variety have been recorded, which are referable to five other genera and sub-genera besides Murchisonia *sensu stricto*, the greater number belong to the genus Hypergonia. Seventeen species are common to Belgium, all of which are Viséan except three, two being Tournaisian and one Waulsortian. Scotland has the most species; and so far twenty appear to be peculiar to that country, nine to England and one to Ireland. The greater number of British species are of Dibunophyllum age, only eight being from lower and two from higher zones.—T. N. **George**: The Carboniferous Limestone (Avonian) succession of a portion of the North Crop of the South Wales Coalfield. A description is given of the lithological and faunal succession of the Avonian along some thirty miles of the North Crop between Kidwelly and Penwyllt (Tawe Valley). The Main Limestone is much attenuated, when compared with other areas, being about 500 to 600 feet thick. The Middle Dibunophyllum zone is represented by two facies, deposited in more or less separate areas. That seen near the Kidwelly district consists of standard limestones yielding a normal fauna, and is comparable with beds of the same horizon in Gower, Pembrokeshire, Bristol, etc. The other consists of impure sandy and cherty limestones, with some calcite-mudstones, and a fauna chiefly composed of molluscs and Productids. As this facies is traced eastwards towards Llandebie it becomes more normal. It is evident that throughout Avonian times the area was subject to periodic earth-movements.

PARIS.

Academy of Sciences, May 3.—S. **Winogradsky**: The diagnosis of the aptitude of the soil for fixing nitrogen. Two factors intervene in this diagnosis: the number of nitrifying organisms present and the fertility of the soil as measured by the growth of these organisms. The method of spontaneous cultures measures the latter, and the silico-gel plate method measures the concentration of the organisms. Full details of the method proposed for applying these two tests is given.—Jean **Tilho**: An aggravation of the danger of capture by the Niger of the principal affluents of the Tchad. It is known that the existence of Lake Tchad is threatened by the possibility of the capture of the Logone-Chari hydrographic system, its principal tributary, by the Benone, which flows into the Niger. This danger has been increased by the construction of a canal between Ham and Pogo. It is pointed out that if the Tchad area became dry, some 200,000 square kilometres of soil now producing cotton, maize, tobacco, etc., would become sterile. Precautionary measures for preventing this disaster are suggested.—Enea **Bortolotti**: The envelopment of surfaces and the transport of directions along a curve.—André **Weil**: Surfaces with negative curvature.—**Tzitzeica**: A new class of congruences.—Paul **Mentré**: Surfaces of which the network of projective deformation is a conjugated network of Kœnigs.—J. **Ser**: An expression of the function $\xi(s)$ of Riemann.—B. **Finzi**: Energy proof of the paradox of d'Alembert in viscous liquids.—R. **Moineau**: Aeroplane with turning wing system.—A. **Zimmern**: A new method of production of herepathite. A method of preparing large crystals of iodoquinine sulphate.—A. **Dauvillier**: Extension of the Röntgen ray spectrum towards the ultra-violet; the *K* spectrum of carbon. The grating was composed of a preparation of melissic acid on lead, which was found to give pure spectra with a reticular distance of 87 Å.U. Difficulties were met with in separating the soft X-rays from the light diffused by the anode and reflected from the grating, and details are given of the manner in which these difficulties were overcome. With a graphite cathode there was obtained an intense line 45·3 Å.U.: this is the $K\alpha_1$ line of carbon and constitutes the unique *K* radiation of this element.—P. **Lebeau** and P. **Marmasse**: The estimation of small quantities of hydrogen in gaseous mixtures. The gas mixture is passed over a silica gel maintained at −190° C., which has been found to retain nitrogen, methane, carbon monoxide, oxygen and argon. The accuracy of the separation is shown by analyses of synthetic gas mixtures, the absence of hydrogen in two natural gases (marsh gas from a pool and gas from borings at Pechelbronn) has been proved by this method.—A. **Travers**: The oxidation of manganese to permanganic acid and its consequences in the application to the estimation of manganese.—Marcel **Guillot**: Researches on the complex salts arising from the action of α-picoline on the alkaline iridohexachlorides.—Mme. Ida **Vaillant-Couturier-Treat**: Note on the marine Permian of Madagascar.—C. **Dauzère**: The formation of the 'atmospheric vase' and of the 'sea of clouds'.—E. **Miège**: The appearance of *Triticum durum* in the descendants of hybrids of two *Triticum vulgare*.—L. **Mercier** and J. **Villeneuve**: Second contribution to the study of the anatomy of the head of the cycloraph Diptera; the lunula and its sensorial organs.—A. **Vandel**: Geographical spanandry (scarcity of males) in the Myriapod *Polyxenus lagurus*.—Gilbert **Ranson**: Nutrition in aquatic animals.

CALCUTTA.

Asiatic Society of Bengal, May 3.—Harit Krishna **Deb**: (1) When Kurus fought Pandavas. It would seem that the Kurus fought the Pandavas in the fifteenth century B.C. (2) The five-yearly yuga and the Saptarshi cycle. It is highly probable that about 1400 B.C. Garga enunciated the Saptarshi cycle in order to account for the apparent movement of the nakshatras in a direction retrogade to their daily motion, which was due, in reality, to an inherent small error in the lunar period of the five-yearly yuga, a yuga which, we know, was adopted by Garga.—R. B. Seymour **Sewell**: Maritime meteorology in Indian seas. Seasonal variation in the air-temperature over the open waters of Indian seas, the coastal region of the Andaman Sea, is recorded. Variations of other meteorological data are also discussed.—Sunder Lal **Hora**: Note on a hermaphrodite loach. An example of teratological hermaphroditism in *Nemachilus montanus* (McClelland).

ROME.

Pontificia Accademia delle Scienze (Nuovi Lincei), April 18.— — **Terkan**: New method of determining the luminosity and temperature of celestial bodies.—**Luigioni**: Two anomalies encountered in two coleoptera, *Timarcha Schenklingi* and *Dendarus tristis*.—**Gianfranceschi**: Law of distribution of the energy in the black body spectrum. The theoretical values furnished by the author's new formula are compared with the observations made on the solar spectrum.—Pagnini: The hypotheses on which the undulatory theory is based.—Giorgi: Reference is made to Miller's recent experiments, and also to those of Wataghin, who has subjected the ballistic theory of light to further test.—Zanon: The biology of *Thrips tabaci*. The last generation of this insect was found in the gall caused by *Schizomya pimpinellae* on wild fennel in the Roman Campagna.

Telegraphic Address: PHUSIS, WESTRAND, LONDON.

The Universities and International Peace.

THE third Congress of the Universities of the British Empire, which is to be held at Cambridge next month, is an event of more than academic interest and significance. It proves that universities differing widely from one another in origin, traditions, constitution, organisation, and even the mother-tongues of the majority of their members, and some with the thick of the earth between them, are capable of friendly co-operative effort, sustained over a period extending now to fourteen years, in pursuit of common aims. Further, it shows that such co-operation is possible without external stimulus, pressure, or aid; above all, and in this it is characteristic of the forces which hold the British Empire together, in absolute independence of State inspiration, guidance, or subvention. The question suggests itself whether universities of other countries, outside the British Commonwealth of Nations, might not similarly co-operate internationally and thereby contribute more effectively than they do at present to international peace.

There is a peace that passeth all understanding, and when it shall prevail generally in the hearts of mankind, and especially in the hearts of politicians, high financiers, trade union leaders, and newspaper proprietors, humanity will have finally emerged from the jungle, and war will be a thing of the past. But peace in our time is largely conditioned by understanding, and whither should we look for help in the promotion of understanding if not to those foci of intellectual light—the universities? These do already, beyond question, give such help, but by independent and, to a great extent, unco-ordinated effort rather than by concerted action.

At Gex last August was held the fourth annual conference of the "Entr'aide Universitaire" (World Federation of Christian Student Associations). In the course of the proceedings a striking address was given by Dr. A. E. Zimmern on "The Contribution of the Universities to International Comprehension and, thereby, to International Peace." The League of Nations, Dr. Zimmern pointed out, was created to introduce more intelligence into international relations. What divides the nations at the present time is not hatred but ignorance, folly, and intellectual sloth. International relations are no longer confined to diplomatists and great financial and mercantile houses, but exist also between multitudes of ignorant people whom the progress of science in its applications to means of transport and communication have brought close together as in no previous period of the world's history. This approximation and this multiplication of points of contact implies increasing potential causes of friction. Hence an urgent need of promoting by all available means the development of a true citizenship of the world, such as can be brought about, not by travellers' tales, novels, and plays designed to gratify an idle curiosity, not by trade or by missionary enterprise, not even by collaboration of specialists—the internationalism of science, so highly developed and esteemed in the nineteenth century—but by full and frank and generous interchange of ideas between personalities determined to comprehend each other's attitudes and points of view and the modes of working of each other's minds. What, then, should be the contribution of the universities?

Universities have two aims; namely, the fullest and finest development of the national character, and the search for truth. In the pursuit of these they contribute to international peace, first, by providing a *milieu* most suitable for enabling a foreigner to learn to understand the national character, and, second, by research in the field of international problems and the bearing thereon of national temperaments and attitudes. Dr. Zimmern does not believe in the idea of an "International University," and holds that no good can come of diluting distinctive national characteristics with an insipid cosmopolitanism. On the subject of international university congresses he offers no opinion. Within a limited field, including such questions as co-operation in scientific research and facilities for visits by university professors and lecturers and advanced students of one country to universities in other countries, such congresses, suitably organised, might afford opportunities for just that personal intercourse, that full and frank and generous interchange of ideas of people determined and competent to comprehend each other, which are so urgently necessary. A handbook of international organisations, compiled by the League of Nations, gives particulars of some 350. Several of these, such as the International Research Council and the International Academic Union, are indeed closely concerned with university activities, and others, such as the International Federation of University Women, bring together students and graduates of universities of different countries, but universities themselves are conspicuous by their absence. Groups represented by 350 organisations have thought it worth while to devise machinery for cultivating international relationship, but the universities of the world have not thought it worth while or, if they have, lack the energy to embody the thought.

The subject will no doubt be explored by the Section of University Relations of the International Institute of Intellectual Co-operation recently established by the League of Nations at Paris. It may be surmised that in any further development in this direction that may take place due weight will be assigned to a principle the importance of which has been proved by the experience of one of the most effective of international organisations, namely, the Comité Maritime International. This is the principle of continuity of the *personnel* of the delegations: "The leading persons who attend the Conferences," says a report by Sir Leslie Scott, the senior British delegate, in the *Times* of April 16, 1926, "are to a great extent the same. But for the mutual confidence engendered through personal contact with the same men, it would never have been possible to reconcile many apparently irreconcilable differences. A spirit of trust and friendship has grown up, which continual changes of *personnel* would have prevented. . . . There is no better preventive of misunderstandings [than this plan of personal continuity in representation], and in order to overcome the inherent difficulties of different language, temperament, and outlook, it is perhaps an essential condition of successful progress."

In 1918, on the invitation of the Government of the United States, the universities of the British Isles sent a representative mission to America, and in the following year similar university missions were sent to France and Belgium. Much good feeling was generated by these friendly official visits, but the precedents thus set have not been followed. The Atlantic no doubt presents a formidable obstacle, but it is not clear why such missions should not be undertaken from time to time as between countries comparatively near to one another. The visits paid on such occasions as the celebration of a jubilee or a centenary commemoration of the founding of a university, valuable as they undoubtedly are, are generally very brief and ceremonious, and the hosts and guests have not much time or opportunity for exchange of ideas. On the initiative of the University of Basle in 1922, the universities of Great Britain and Switzerland experimented with another kind of international intercourse. Delegates met together at Basle as the guests of the university, and discussed in sessions extending over several days a number of subjects of common interest. This venture, like the missions to America, France, and Belgium, appeared to meet with the approbation of all concerned, but likewise has not, so far, been imitated.

The younger generation is in this matter giving a lead to those responsible for university policy. The Confédération Internationale des Étudiants, founded at Strasbourg in 1919, has now affiliated national unions of university students in almost every country of Europe and several countries in other parts of the world. Regional groups of students in the United

States are being organised with the view of affiliation. "The time has come," says a leaflet issued by the National Union of Students of England and Wales, "for the young men and women of the universities to undertake to a much greater extent than before the organisation of activities among themselves, linking up the life of each university much more closely with that of other universities, and providing facilities for themselves (such as tours, congresses, etc.) which will give them that wider experience so essential to the education of those who are to become the leaders of to-morrow. Such activities by no means impair the quality of academic work; rather they enrich and supplement it. For example, the N.U.S. arranges for its members faculty tours. . . . Each year medical, agricultural, engineering, theological, and art students visit the leading hospitals, laboratories, farms, factories, art galleries, etc., of the different countries of Europe." In the past it has been customary to look upon university student organisations only as appertaining to particular universities, and not as having national or international activities. In the changed conditions of to-day it behoves the universities to consider whether it is wise to leave the cultivation of the international field so largely to their undergraduate and youthful graduate members and, it may be added, university women, whose International Federation, though not rivalling the Confédération Internationale des Étudiants in membership, is rapidly extending its influence.

More effective than such missions or conferences are, perhaps, academic institutes in foreign countries, a subject which was discussed at length at the annual conference of universities of Great Britain and Ireland in 1925. In this direction the Office National des Universités et Écoles Françaises has been very active, and there are now French Institutes in London, Florence, Naples, Madrid, Barcelona, Prague, Sofia, and Buenos Aires. The United States has, since the War, undertaken a peaceful penetration of universities on the eastern side of the Atlantic by means of the American University Union in Europe, with divisions at Paris and London. The establishment of branches of the Union in Rome, Berlin, and Vienna has been suggested, an American Institute has been founded at Prague, and there are at Geneva an International Educational Institute and an International Students' Union, both financed from America, whilst an American committee of the Geneva Institute of International Relations maintains an office for the reception of English-speaking visitors who come to Geneva to study international co-operation. This office was visited during the summer of 1925 by about 5000 Americans. The newly constituted Comité d'Administration of the European centre of the Carnegie Foundation for International Peace contemplates the formation of American Institutes at Berlin, Warsaw, Madrid, Rome, and in the Balkans as well as in the Far East, South America, and Mexico. All these American enterprises differ from the French Institutes in that they are entirely independent of State control. The same applies to the only comparable British Institute—that at Florence—but not to the Pan-American Union, which, through its Educational Section, keeps the Latin American universities in touch with one another.

Among other institutions through which universities exert an important influence on international relations by promoting international comprehension are university fellowships tenable in foreign countries for advanced study and research, and university vacation courses for foreigners. But, after all, the greatest contribution the universities can make to the cause of international peace is one which Dr. Zimmern seems to have overlooked. As Mr. Stanley Baldwin explained with admirable force and lucidity in his address entitled "Truth and Politics" on his inauguration as Lord Rector of the University of Edinburgh, the most important task of a university student is to learn to think clearly, to learn habits of precision in statement, honesty in handling evidence, fairness in presenting a cause—in a word, to be true in word and deed, and it is truth and the habit of truth alone that will "destroy the face of the covering cast over all people, and the veil that is spread over all nations" (Isaiah xxv. 7).

Science and the Modern World.

Science and the Modern World: Lowell Lectures, 1925. By Prof. Alfred North Whitehead. Pp. xi+296. (Cambridge: At the University Press, 1926.) 12s. 6d. net.

IT is fortunate that in the twentieth century, science and philosophy are beginning to be united in the same person as they were in the seventeenth century before their fatal divorce occurred. Prof. Whitehead's latest book cries out to be read and re-read and meditated upon (and to that end if possible possessed) by every man of science who is not content to live merely in his own special 'groove of routine' and is concerned in the trend and tendency of science as a whole; and by every philosopher who desires, as he must, to keep himself in contact with the thoughts of science. It is a work not only of the first importance but also of great beauty. Apart from the vivid writing, the reader's delight arises from two sources: in the first place, from the rapid characterisation of the various epochs into which Prof. Whitehead divides the history of modern scientific thought; and secondly, from his method of pointing out in each epoch just how the central thought of the epoch bears, in the way of contribution or of defect, upon the central thought of the present as the author conceives it. The poet prefiguring him wrote: 'and as he works, the industrious bee computes *his* time as well as we.' One result of this procedure is that while the bulk of each historical chapter is simple and luminous reading, each chapter contains a few pages which demand the closest attention, but work with cumulative preparation towards the dramatic outcome.

The plan of the book is to begin with the origins of modern science out of the Middle Ages, and then after a sketch of the history and nature of mathematics, to take in succession the outstanding movements of thought—the seventeenth century, which Prof. Whitehead calls the century of genius, the eighteenth century, the romantic reaction of the earlier nineteenth century, and then the nineteenth-century science, which is followed by an account of the theory of relativity and the quantum theory. Certain chapters follow, to which I shall return presently. The historical surveys—if I may call them so—are distinguished not so much by any learning which would cause surprise in reading an author whose wide cultivation and breadth of human interest are so well known, as by the freshness and originality with which the salient features are seized. With all its rebellion against the rationalism of the Middle Ages and its appeal to Nature as the fountainhead of knowledge, and submission to "irreducible and stubborn facts" (as he quotes from William James), modern science owes to the medieval rationalism its belief in natural order; and to its insistence on 'the rationality of God conceived as with the energy of Jehovah and with the rationality of a Greek philosopher,' its 'belief in the connexion of every occurrence with its antecedents in a perfectly definite manner, exemplifying general principles.'

The service of Bacon to the new learning is acknowledged with a cordiality and discrimination which contrast refreshingly with the recent meagre and grudging commemoration of his anniversary, in an age which forgets his scientific inspiration because he was a disagreeable person and exaggerated the reach of his inductive methods, though even there it might be remembered that he taught the importance of negative instances. Berkeley is singled out as perhaps the most fruitful mind of the eighteenth century, though he affected little the course of science. The chapter on the Romantic Reaction contains a striking study of Wordsworth and Shelley as supplying, one in antagonism to science, the other, Shelley (as he urges in a very interesting passage), in full sympathy with science, the feeling for the æsthetic concreteness of Nature, as a whole and in its parts, which the 'materialism' of science lacked. (In interpreting 'the light that never was on sea or land' as the eternal objects of philosophy, Prof. Whitehead has overlooked Sir Walter Raleigh's exposure of that general misunderstanding, "Wordsworth," pp. 107 ff.) The greatest invention of the nineteenth century he declares was 'the invention of the method of invention.' But these chapters are packed with illuminating aphorisms.

The greater part of the book consists of Lowell Lectures given at Boston, and is, therefore, a hemi-semi-popular version of Prof. Whitehead's philosophy of Nature as approached from the history of science. It has thus the advantage of insinuating into the scientific reader's mind by a study of science itself the conceptions already reached. But it does much more. It presents the main drift of the author's former work with a clearness not before exhibited and perhaps not before completely attained; and it makes new and important additions. Prof. Whitehead's chief interest is to substitute for the hitherto prevailing 'scientific materialism,' as he calls it, or 'mechanism,' with its underlying conception of individual bits of matter in motion, the conception of 'organism.'

The first conception became fixed in thought with Descartes Its immense service for science Prof. Whitehead does not, of course, deny, but it is an abstraction which has broken down in the history of science itself. Through the influence of biology and physiology, and now of psychology, the notion is imposing itself that the enduring things are organisms, and the present condition of physics itself he compares to the condition of astronomy when people began to help themselves with the introduction of epicycles—a sure sign of the need for change. He puts the difference this way (p. 81): On the current theory a bit of matter has *simple location*, that is 'in expressing its spatio-temporal relations it is adequate to state that it is where it is, in a definite region of space, and throughout a definite duration of time, apart from any essential reference of that bit of matter to other regions of space and to other durations of time. The organic theory asserts not only internal relatedness within the enduring thing, but interaction between all things.' He goes so far as to deny that even spatio-temporal relations between things, generally regarded as external, are so (p. 174). When it is more fully analysed, this means that each thing in Nature mirrors all the rest, or is what he calls a 'prehension' of them; a modification of Leibnitz's doctrine (in which he agrees with writers like James Ward and others), by which the entities in relation are not windowless but are in communication with all others, as it were by tubes of force.

This thoroughgoing interrelatedness of events is part and parcel of Prof. Whitehead's concrete treatment of

Nature, only he has never expressed it so explicitly as in this book. Space-time is for him no mere framework into which things fit; but Nature, which is essentially passage or transition, consists of events, and events are slabs or 'durations' (or portions of such) in this passage presented in sense, in which what he calls 'objects' (or what others have called 'universals') are 'ingredient' and have 'situation.' In this book there are introduced at least two new conceptions, that of 'endurance' or 'reiteration,' and that of 'value.' Enduring objects are the persisting patterns in which complex eternal objects (like yellow, hard, soluble in nitric acid, etc.) are actualised in union—not necessarily unchanging patterns, but it may be a pattern which is realised in succession like that of a musical melody.

The other notion of 'value' is that which is yielded by the suggestion of the romantic poets. Value is the intrinsic reality of an event, and realisation is in itself the attainment of value. It is, in other words, what an event counts for in the whole and therefore varies in degree. But always the wholeness or concreteness of events is given fact, and an 'æsthetic attainment is interwoven in the texture of realisation' (pp. 131-2). (I do not know if this meaning of value coincides with the ordinary use of value in speaking of goodness, truth, and beauty as values; but I incline to think it does.)

Finally, going beyond Prof. Whitehead's previous work into what must be supposed to underlie Nature as a whole and its parts, we have the notion of an eternal activity, which takes the place on this theory of Spinoza's 'Substance' (a notion tainted, of course, with the static conception of the seventeenth century), which realises itself in a hierarchy of emerging entities, themselves 'structures of activity' which are evolved, whereas on the mechanistic theory there is but material which endures.

These necessarily brief and condensed outlines might gave the impression that the book largely moves among attenuated conceptions. The reverse is the fact; it is always a man of science using philosophy as a critic of abstractions. The physicist in particular may find discussions of pending physical problems in the highly suggestive interpretation in Chap. ii. of the strange discontinuity in the paths of electrons within the atom, so that they occupy a series of isolated dots rather than a continuous line; and in the treatment in Chap. viii. of the quantum theory on the lines of the organic conception. These suggestions I must content myself barely to refer to.

The most difficult part of the book concerns Prof. Whitehead's differences from the orthodox treatment of relativity and in particular his conception of time. Time is distinguished from duration. In a duration we have measurable or, as Prof. Bergson says spatialised, time. Time itself is denied to be extensive (and indeed it is fairly clear that as a dimension of the spatio-temporal nature time cannot be of the same sort as the dimensions of space). But we are then met with the doctrine that time is a sheer or atomic succession of 'epochal durations'; the time within the duration being needed to secure the realisation of the enduring objects. These are stiff considerations, and I confess that I have not yet been able to get inside them completely. In other words, I cannot at present find room for any time except what is implied in the spatio-temporal process. All the more reason for myself and others to penetrate them, for they are an essential part of Prof. Whitehead's speculations. They are intimately related with some other features of the doctrine, the suggestion (p. 131) of a wider evolution beyond Nature itself, and within which Nature is but a limited mode, the hint here and in earlier work of a transition from Nature to what is left unexplained under the designation of 'mind' (for when Prof. Whitehead speaks of perceiving or a percipient event, this is but a bodily event, the functioning of which is consciouness, and he very forcibly observes *à propos* of some interpretations of relativity as an affair of the mind, that what we are concerned with is not the observer's mind but his body); finally, the whole relation between the world of eternal objects and the actual world.

As to the rest of the book, I can barely mention the last two chapters, one on religion and science which is quite admirably done, and the last on requisites for social progress, which largely turns on the correction of our specialised education by the cultivation of sense for concrete organic wholes, that is in the widest sense of 'art.'

Two other chapters, x. and xi., on 'Abstraction' and 'God' do not belong to the original Lowell lectures, and though they are a completion of the conception of the book and necessary to Prof. Whitehead's thought, and from the philosopher's point of view the most important novelty of the book, do, to some extent, interfere with the artistic unity of the work. They are an exquisite piece of metaphysical work, as if one were hearing a new Plato expound the relation of 'forms' (ideas) to actual reality, and the intercommunion of 'forms.' But they are too condensed to bear reproduction, and they will be of less interest to the purely scientific reader. For the same reason I omit any attempt to affiliate Prof. Whitehead with other, living or recent, philosophers—a subject of great interest. We may hope that we shall not have to wait long for fuller exposition of these matters and more light upon some of those difficulties to which I have referred. Meantime we must be thankful for the present book, which is without any exaggeration one of immense significance.

Against a second edition I note a few trifling misprints: p. 20, line 10; p. 101, line 13; p. 105, line 10; p. 160, line 7; p. 177, line 9 from foot; and add a query as to whether there is not some mistake in the second 'impassible' (p. 11). A misprint on p. 117, 'thoughts too deep for terms,' is too poignant for tears.

S. ALEXANDER.

The History of Electrical Communication.

Board of Education. Catalogue of the Collections in the Science Museum, South Kensington; with Descriptive and Historical Notes and Illustrations. Electrical Communication. 1: Line Telegraphy and Telephony. Compiled by R. P. G. Denman. Pp. 55+12 plates. (London: H.M. Stationery Office, 1926.) 9*d*. net.

TO derive the full educational benefit from a science museum, it is necessary to read a good descriptive and historical catalogue of the exhibits before visiting it. This section of the catalogue of the Science Museum, South Kensington, describing line telegraphy and telephony excellently fulfils this purpose. As the exhibits described are typical of the various stages of the development of the art, it will prove very helpful to every student of applied electricity, whatever his age may be.

In the introduction the earliest attempts at electric signalling are described. It is related how in 1730 Stephen Gray demonstrated by means of frictional electricity that a down feather could be moved at a distance of 800 feet. A few years later the Abbé Nollet formed a ring of Carthusian monks, 1800 yards in length, holding on to iron wires which connected them in series. He then discharged a battery of Leyden jars round the loop. The simultaneous leap made by each monk proved the rapidity of the discharge, and that its intensity was practically the same at all points. Desaguliers repeated some of Stephen Gray's experiments in 1738. It is interesting to remember that the Royal Society gave the first Copley medal to Gray and the second to Desaguliers. The latter received no less than three Copley medals, thus beating Faraday, who only received two. Cawthorn, in his "Vanity of Human Enjoyments," thus relates his end.

"Can Britain . . .
. . . permit the weeping muse to tell
How poor, neglected Desaguliers fell?
How he, who taught two gracious kings to view
All Boyle ennobled, and all Bacon knew,
Died in a cell, without a friend to save,
Without a guinea and without a grave."

The last of the frictional electricity systems was developed by Sir Francis Ronalds in 1816. After this, inventors turned their attention to the much more convenient voltaic systems. Wheatstone and Cooke took out their first patent in 1837 for a method for giving signals by means of electric currents. A few years later a telegraph was working between Paddington and Slough, a distance of 18 miles. In 1843, with funds granted by Congress, Prof. Morse constructed a line between Washington and Baltimore. The armature on the receiving instrument moved backwards and forwards printing zigzag lines on a moving strip of paper. This instrument was later supplanted by the 'sounder,' operators finding it easier to listen to the clicks of the armature against the upper and lower stops than to read the slips. Messages with this instrument can be sent at the rate of 40 words a minute. Cooke and Wheatstone's revolving disc telegraph of 1840 reminds one of some of the apparatus used in modern automatic telephony. Hughes's type printing telegraph still survives.

Exhibit No. 2 shows Ronalds's 1816 telegraph and gives a vivid picture of science at that date. The invention was brought to the notice of the Admiralty, who thought it "wholly unnecessary." Ronalds therefore never proceeded with it. No. 7 shows Cooke's original electric alarum. Finding that this instrument did not work satisfactorily, Cooke consulted Wheatstone. This resulted in one of Wheatstone's greatest inventions—the relay—developments of which are in use in practically all modern telegraph systems. Wheatstone's five needle instrument (exhibit No. 9), made in 1837, consisting practically of five galvanometers, shows some of his methods of overcoming difficulties. No. 30 shows the Fullerphone, an instrument used extensively in the War. By means of this instrument both telegraph and telephone services can be worked simultaneously over the same wire.

There is an excellent exhibit of Murray automatic printing telegraph apparatus, a system which may be extensively used in the future. The submarine cable exhibits are very interesting. A specimen of the first cable laid between Dover and Calais in 1850 is shown. We always understood, however, that it was the anchor of a French fishing smack that broke the cable and not the action of the tides. One of the first mirror galvanometers, designed in 1858 by Lord Kelvin, then Prof. W. Thomson, is shown (No. 60). Then we have the siphon recorder and specimens of early Atlantic cables.

Varley's carbon lightning protector (No. 88), patented so far back as 1866 by the brothers Varley, consists of two copper points nearly touching one another in a small box filled with powdered carbon. It is supposed to be a non-conductor up to a definite voltage and a conductor for a higher voltage. Something similar to this was invented by the French electrician Thury some years ago for use on his high-tension direct-current system. It seems to the writer that if something thoroughly trustworthy of this nature were invented it would perform admirably the functions of an electrical safety valve and a lightning protector.

There is a good exhibit of telephone transmitters and receivers. The Strowger automatic telephone sets and the working model of the automatic telephone system for the London area will interest many. The model is probably for its size the most complex mechanism extant. Six exchange switching centres are represented; access to these can be obtained by a number of automatic telephones included in the exhibit. Visitors may make test calls with these instruments and trace the progress of their call through the successive pieces of apparatus. They can also see how the call proceeds from one automatic exchange to another or a manually operated exchange. The telephone call meter (No. 136), which registers the number of effective calls made by a subscriber, is of general interest.

An interesting exhibition of telephotographs (No. 140), presented by the International Western Electric Co., shows the degree of technical excellence to which the transmission of pictures over long telephone lines has now been carried. This application of science has been rendered possible by the grouping of many modern inventions together. The thermionic valve, the carrier current transmission system, and the photoelectric cell are all used in the system. The method is a trustworthy one. A positive transparency prepared by any photographer can be sent, even although still wet, over telephone lines of any length in a few minutes, and after the usual photographic development of the received picture it can be produced in a newspaper.

A. R.

Nitrogenous Derivatives of the Sugars.

Hexosamines and Mucoproteins. By P. A. Levene. (Monographs on Biochemistry.) Pp. x + 163. (London: Longmans, Green and Co., 1925.) 10*s.* 6*d.* net.

DR. LEVENE'S monograph deals with an important group of natural compounds, closely related to the simple sugars. Some of the properties of the parent-compounds are described briefly in the first chapter, in which the existence of ring-systems of different size is referred to; but Haworth's proof that even glucose itself contains a 6-atom instead of a 5-atom ring calls for a further revision of formulæ which have been accepted for a generation without any foundation of experimental proof. The remarks of the author, in reference to chitosamine, that "much of the chemical structure of the sugar was formulated correctly rather by instinct than by experimental evidence," appears to be capable of a much wider application, but with a reservation as to the necessary correctness of the 'instinctive' formulæ.

The following chapters of the book deal with the hexosamines and their derivatives, with the hexosaminic and aminoheptonic acids and with the anhydrohexoses. Important sections are devoted to the configuration of these sugar-derivatives, and the study of this problem has led the author inevitably to the problem of the Walden inversion in the sugar series, on which he is now undertaking experimental work with the view of determining whether a change in polarity of a group attached to an asymmetric carbon atom does or does not change the direction of rotation.

The later part of the book deals with mucoproteins. These are complex proteins, in which the protein part varies widely from tissue to tissue and from species to species, whilst the carbohydrate group is always linked with sulphuric acid, the group being built up from equimolecular proportions of sulphuric acid, acetic acid, hexosamine, and glucuronic acid. These complex compounds have been made the subject of an intensive chemical investigation, in the course of which new ground has been broken in the preparation of sulphuric esters of simple carbohydrates. The field for investigation is a very wide one, and there are many difficulties to be overcome; but the author has given an admirable review of the present position. His chapters on 'Methods' describe the basic chemical operations which must precede any further investigations in this direction.

Bird Life and Natural Selection.

Indian Bird Life: or the Struggle for Existence of Birds in India. By Douglas Dewar. Pp. xv+276. (London: John Lane, The Bodley Head, Ltd., 1925.) 7*s.* 6*d.* net.

WE congratulate Mr. Dewar in having written the best of the very numerous books which he has brought out. In his introduction he rather frightens us when he hints that he is going to show us to what extent Darwin was right or the reverse in his theories. As we read, however, we find that this apparently is not his object, and that all he intends to do is to quote examples of how natural selection may be influenced by environment or, in some cases, how neither natural selection nor environment can, in his opinion, account for what happens. The author's quotations are well selected but his theories are quaint. There are but few scientific workers who will agree with Mr. Dewar's theory that much of what occurs in life is due to 'luck.' On p. 260 he remarks, "the struggle for existence of birds results in the weeding out of the unlucky rather than the less fit." We hope that when Mr. Dewar has again perused his own work and the excellent examples given therein of the survival of the fittest, he will feel in a position to change his mind. The book consists of a compilation of facts and statements recorded by others, but Mr. Dewar has done an excellent piece of work in bringing these same facts and statements together and in arranging them in so readable and interesting a form. The reader can draw his own conclusions from what is written, and, even if these conclusions do not agree with those of the author, he will be none the less indebted to him.

Mr. Dewar's observations on the extraordinary mortality amongst young birds and upon the small percentage of eggs which ever hatch are most interesting although very far from complete. The chapter on competition for nesting sites is not so good, for we have more of the author's deductions and fewer facts from other people, whilst in some places he undoubtedly goes astray both in his facts and in his conclusions. This is especially the case when he dilates on the life history of some of the parasitic cuckoos, for he has apparently not read certain recent papers in the *Proc. Zool. Soc.* showing how over-production of the eggs of cuckoos, where these birds become too common, works out their own destruction.

We think Mr. Dewar will also have some difficulty in convincing his readers that his conclusions as to breeding behaviour are correct. Thus we notice that he considers lapwings and other birds which try to draw intruders from the vicinity of their eggs or young by feigning injury, are merely the victims of unbalanced minds. Those who have seen birds behaving in this manner and not merely read articles referring to them, know well that such birds show most conclusively in many ways that they are acting for the definite purpose of saving their property. Whether, however, we agree with Mr. Dewar's conclusions or not, every one interested in the question of evolution and environment should read his book, and we may end as we began by congratulating him on having compiled a work which is a desideratum for all naturalists.

Our Bookshelf.

Health and Environment. By Leonard Hill and Argyll Campbell. Pp. xix + 208 + 8 plates. (London: Edward Arnold and Co., 1925.) 12*s.* 6*d.* net.

THIS handbook deals in the space of two hundred pages with subjects of so personal and intimate a character that there is not a single individual who could fail to be interested by a very large portion of it, especially as it contains a good deal of straight talk on clothes, food, light, and open air. The subject matter, though presented in non-technical language, is based on sound scientific investigations which may be examined more fully in the Medical Research Council's Special Report Series, Nos. 32 and 52 dealing with "The Science of Ventilation and Open-air Treatment," Parts I. and II., and No. 73 "The Kata-thermometer in Studies of Body-heat and Efficiency," written by Prof. Leonard Hill. These two authors have rendered a social service in presenting to the individual a rational method of 'keeping fit' and in laying down the guiding principles for the heating, lighting, and ventilation of factories, schools, public and other buildings where large numbers of people congregate. In this connexion the book is of especial value to employers of labour and public health bodies.

Our daily papers have recently shown the only too frequent outbreaks of fire in country houses. Here we see the installation of modern systems of lighting and heating in old structures, never intended for them, followed by a very obvious and expected result. Results not quite so obvious must accrue from the present-day practice of designing of houses by architect's draughtsmen without the co-operation of sanitary engineers from the outset; the latter are called in only when new houses are nearing completion. The book establishes a plea for the designing of suitable systems of heating and ventilation before the foundations of buildings are laid.

One of the present authors was the first to stress the importance of the tonic effect of moving-air upon the human body, and it is in the correlation of this with a sense of comfort and general well-being that the kata-thermometer designed by Prof. Hill has been of such great use. Diagrams illustrating the use of this instrument and the results obtained with it are given. These are very clear, with the exception of Fig. 13, which has suffered in reproduction.

Employers of labour will be specially interested in the inexpensive improvements suggested in their trades, whereby the comfort and efficiency of the worker are enhanced and the output consequently increased.

To physicists, the description of the kata-thermometer designed by Prof. Hill and its recording pattern evolved by E. Schuster may not be new, but the results of its applications are likely to prove interesting. A detailed account of these instruments is given at the end of the book specially for the information of ventilating engineers.

Insulated Electric Cables. By C. J. Beaver. In Two Parts. Part I. Materials and Design. Pp. 264. (London: Ernest Benn, Ltd., 1926.) 36*s.* net.

ALTHOUGH the manufacture of electric cables is a comparatively recent industry, the progress that has been made in their design and method of manufacture is most satisfactory. In the early days of electric lighting it was common to use bare conductors laid in pipes filled with oil, the wrappings of the conductors being used simply as spacing materials. In the Edison system, for example, the conductors consisted simply of copper rods wound over with jute rope and drawn into iron pipes. The Crompton system also, which consisted of bare strip conductors in a culvert, was extensively used in the early days, and some of it is in use to-day after thirty years' service. The great improvements that have recently been made in cables are mainly due to the great encouragement given by the manufacturers to mathematical and physical research. In this volume Mr. Beaver discusses the materials used in the manufacture and the design of electric cables. An excellent résumé is given of the latest practice and the most modern theories which are used in design.

So far as conductors are concerned, aluminium seems to be coming to the front. A very careful comparison is made of the relative properties of conductors. It is pointed out that for conductors of equal resistance, aluminium conductors are only half the weight of copper conductors. Hence as the price of aluminium per pound is less than double the price of copper, aluminium conductors are indicated for many purposes. During the War, Germany was very short of these metals and so invented a method of producing zinc in the form of a ductile wire, but its low melting-point renders the soldering of joints with this material a very difficult operation. The increasing use of high pressures has made very elaborate researches on the properties of dielectrics necessary. The author describes many of these problems. Reference is made to the use of vulcanised bitumen as an 'ozone-proof' covering for rubber dielectrics. We can recommend this book.

Rambles in Vedânta. By B. R. Rajam Aiyar. Being a Collection of his Contributions to the *Prabuddha Bhârata*, 1896–98. Pp. xlvi + 888. (London: George Allen and Unwin, Ltd., 1925.) 12*s.* 6*d.* net.

RAJAM AIYAR, scholar, poet, and philosopher, was born in 1872 at Batlagundai, a village in the Madura district. He entered the Christian College, Madras, in 1887, graduating in 1889, and attended the Law College for three years. He then devoted himself for a time to letters, but later turned to philosophy and religion. After a period of preparation he took up what can only be described as the rôle of an evangelist. He founded a monthly magazine, *Prabuddha Bhârata*, which ran for two years with some success, but was brought to an end by his premature decease at the age of twenty-eight years. This brief sketch of his career is necessary for a just appreciation of this reprint of some of his work. In "Rambles in Vedânta" we have a number of the articles, poems, aphorisms, essays, and tales which he contributed to the magazine, both under his own name and under various pseudonyms. He himself describes them as an exposition of the principles of the ideals of the Vedânta which he aimed at presenting in their purest and simplest form, removing the misconceptions and mysticism which had gathered round them. He had studied arduously the Upanishads, the Gita, and the work of Sankara to this end. But his interpretation was peculiar and individual; and his work shows that he had been strongly influenced by his reading in English literature, of which he had a real and keen but critical appreciation. If, therefore, his guidance in Hindu philosophy and religion can be accepted only with some reserve, the book is none the less valuable to Western readers as affording an insight into a personality which could perhaps have been produced nowhere but in the India of the end of the nineteenth century.

The Pathology of Tumours. By Prof. E. H. Kettle. Second edition. Pp. viii + 285 + 4 plates. (London: H. K. Lewis and Co., Ltd., 1925.) 12*s.* 6*d.* net.

THE second edition of Prof. Kettle's book is arranged on the plan of the first, with the addition of many new diagrams and some revision of the text, particularly in the section on the general biology of tumours. The substitution of drawings for many of the photographs contained in the previous edition is a welcome improvement, since to the student entering on the study of pathology photographs are rarely satisfactory. The inclusion of a chapter on treatment is unusual in a volume of this type, but it is not altogether out-of-place, and a correlation of pathology and therapeutics enables the student more readily to grasp the general principles of both these branches of medicine.

Prof. Kettle's brief summary of the experimental study of cancer is excellent. He recognises fully the value of research work on the tumours of fowls and animals, considering it proved that the criteria by which we recognise a malignant tumour in mankind hold good in the mouse and other creatures. The work of W. E. Gye raises questions of the first moment, and "the parasitic nature of, at any rate, one form of malignant growth would seem to be proved."

The book is very well illustrated and indexed, and for medical students is ideal as an introduction to the subject of neoplasms and to the study of pathology in general.

A Text-Book of Inorganic Chemistry. Edited by Dr. J. Newton Friend. Vol. 3, Part 1: The Alkaline Earth Metals. By Dr. May Sybil Burr (*née* Leslie). (Griffin's Scientific Text-Books.) Pp. xxvi + 346. (London: C. Griffin and Co., Ltd., 1925.) 20*s.* net.

THIS part of Dr. Friend's "Inorganic Chemistry" deals with the triad of alkaline earth metals (calcium, strontium, barium) and with radium and its compounds. It contains an immense amount of detail, as is indicated by the fact that the footnotes include on the average at least one reference for every three or four lines in the text; but for this very reason the book is much more suitable for use as a work of reference than for continuous reading. In accordance with general policy, illustrations have been restricted to half-a-dozen equilibrium diagrams, and no figures are given of the plant used to manufacture products such as calcium carbide, cement, or glass. Special attention has been paid to agricultural questions arising out of the use of calcium cyanamide and of calcium phosphates as fertilisers.

La lumière et les radiations invisibles. Par Prof. A. Boutaric. (Bibliothèque de philosophie scientifique.) Pp. 284. (Paris: Ernest Flammarion, 1925.) 10 francs.

THIS book gives a somewhat popular and non-mathematical survey of the theories of light and the phenomena of radiation. It embraces a very wide range of phenomena, including, for example, the colour of the night sky, the pressure of light and its cosmic importance, and the behaviour of a ray of light passing through a gravitational field. The final chapter deals with the ether and is very well written; the more difficult experiments associated with the ether are described in an appendix.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On Prof. Miller's Ether Drift Experiment.

SOME time ago I was told (I think by Prof. R. W. Wood) that the late Prof. Morley had expressed himself as anxious about the immense superstructure that had been built on the null result obtained by Prof. Michelson and himself during a comparatively few very careful experiments. He was anxious that the experiment should be repeated under different conditions and the result confirmed. We now know that such repetition has been undertaken, at first in connexion with Prof. Morley, by Prof. D. C. Miller of Cleveland, for whose zeal, enthusiasm, and enterprise we must feel high admiration. Not six or a dozen repetitions, but thousands of them, have now been made, on the tops of mountains, on plains, with frames of different materials, and with a sufficient length of light path to give a result of 1 part in 1000 million. The undoubted result of these repetitions has been to confirm the null result of Michelson and Morley, so far as regards the orbital motion of the earth, and thereby establish one of the foundations on which the theory of relativity was at first based, up to what at that date had seemed to be the probable errors of experiment.

Whether there is anything more to be deduced from Prof. Miller's results (he clearly thinks there is) is a matter which is manifestly *sub judice*. His first *reported* claim, that the result on the top of a mountain was much greater than on a plain, could scarcely be accepted. If that had been true, the ideas involved would have been extremely difficult and revolutionary. It is a relief to know that that, at any rate, is no longer urged. The place at which the experiment is performed seems to matter not at all; and that is a great simplification, for it enables us to open our minds to see whether there is anything that can be admitted in his present claim. Prof. Miller has studied and plotted all his results in an admirable manner; and the only question is whether the outcome should be considered as practically zero, or whether (as he believes) there is a real residual effect which has to be accounted for.

What Prof. Miller now claims to have detected is a drift of the solar system in a direction approximately normal to the plane of the ecliptic, a drift which could not have been observed under the conditions of the early experiments. But the pressing question is whether such a drift has been observed now. That it is contrary to the main postulate of the theory of relativity, namely, that no effect due to motion through the ether can ever be observed, or, in other words, that everything goes on as if the ether did not exist, cannot be cited in opposition. For that is just the postulate which is under examination, and it has never been finally proven; though it has been made plausible by the verification of deductions made by its aid.

The argument of Prof. Miller, as I understand it, is that there is a slight residual effect due even to the earth's orbital motion, but so small that it comes within the limits of what is possible to observe. The effect is by no means of the full magnitude, but is, as it were, diluted down to (say) one-fifth of its theoretical value by some unknown cause, which he conjectures may be the FitzGerald-Lorentz contraction. It seems just possible that the FitzGerald contraction, though shown by Lorentz to compensate, does not compensate completely. Whether the compensation is complete or not, however, is a theoretical matter of some difficulty, which has not yet been thoroughly gone into, so far as I know, though reference may be made to a short paper by Sir Joseph Larmor in the *Phil. Mag.* for June 1904. If any good reason can be adduced for an outstanding discrepancy, that would strengthen Prof. Miller's position enormously; but until such reason is forthcoming the discrepancy must be doubted.

Assuming for the moment that the orbital motion does show a very slight and imperceptible or barely perceptible residual effect, Prof. Miller claims a larger effect, even ten times as large, which, plotted in accordance with sidereal time, could be accounted for by a cosmic drift of considerable magnitude if that too were diluted down by the same unknown cause and in the same ratio. He does not claim that the main drift of the solar system is observed, but only a residual fraction of it; and unless some reason can be given why there should be this residual fraction, and why the compensation should not be complete, it is dangerous to accept the result as certain, in spite of the skill with which Prof. Miller disentangles it from his multitude of observations and presents it as a small but recognisable and definite result.

The great importance of such a result, if it can be established, must make us very wary in accepting evidence for it, especially in view of the many disturbing causes. Hitherto the observations have been plotted with the view of displaying the reality of this supposed ether drift. But suppose they were plotted with some other object in view. For example, suppose they were plotted on the hypothesis that the south side of the housing of the instrument was slightly warmer than the north side. How would the average curve agree with that? An interferometer with so long a length of light path is a terribly sensitive instrument. The heat of the source of light, the warmth of the body of the observer, the exposure to radiation from the sun on one side and into space on the other, have all to be carefully considered. It is rather surprising that the readings were made by a peripatetic observer, with the instrument in constant and not very slow rotation. Under those conditions even the rotation of the earth might have a gyrostatic influence, and one would have thought that a stoppage of the frame and a reading of the fringes by a seated observer in many azimuths, would have been more satisfactory. It must be admitted as unlikely that an ether drift has been discovered by optical means; but the unlikely is not the impossible.

Assuming that the operations have been made with the cold-blooded and skilled accuracy of a Greenwich observer without regard to any theory whatever, and that the residual effect is genuine, then some result ought to be deduced; whether it be the important one claimed by Prof. Miller, or some more commonplace explanation. Meanwhile, one undoubted result does emerge from all this labour, namely, that the certain motion of the earth in its orbit fails to give any but a minute residual and doubtful effect—which is just the conclusion put forward by Michelson and Morley, a conclusion hitherto accepted by the scientific world. Beyond that there remains a residual effect to be discussed, and either established or negatived. The history of science has constantly shown that small residual effects *may* contain the germ of important discoveries. I hope that it may turn out so in the present instance, though I cannot say that I hope it with any confidence.

OLIVER LODGE.

Photograms of Auroræ in Southern Norway.

SINCE 1911 photograms of aurora have been taken systematically from my stations in southern Norway, and many hundred photograms and ordinary photographs have been measured and calculated in order to find the height and situation of aurora in space. A detailed report of the results from 1911 to 1922 has recently been presented to the Academy of Science in Oslo, and it is to be hoped that the publication will not be very long delayed. During the years 1923, 1924, 1925, and 1926 the work has been continued, with six stations at work, and more than 250 successful photograms have been taken, and several hundred photographs. This material, which has not yet been completely measured and calculated, will be a very valuable supplement to that mentioned above.

Especially this spring, during the splendid auroras of January 26 and March 5 and 9, a long series of interesting photograms has been taken. On January 26 I first saw the aurora from my house at Bygdø near Oslo, at 17 h. 40 m. Greenwich time, as a green-yellow arc under the Great Bear. Some minutes later a reddish to violet coloration appeared in the north-west, which had a quite diffuse character without visible rays. I took a series of photographs of it, and on the plates ***thin small rays are visible which could not be detected visually.***[1] (Plates Sonja E.-W., Herzog, Bremen.) About 18 h. 30 m. the aurora was splendid. Two arcs stretched over the heavens, from west to east; the northern was red and the southern was green. I am sorry to say that I did not get photograms of these arcs; visual observations from Denmark and from central Norway show that the red arc had an altitude much greater than the green one. About 19 h. the red arc had dissolved into long red rays which formed a beautiful corona. Of this I succeeded in taking a series of photographs which showed that the point of radiation had a somewhat abnormal situation: height above the horizon 72°, azimuth ÷3° to ÷4° (mean from 61 photographs during the period 1911 to 1922, are 70° and ÷9·7° respectively).

Soon afterwards the first period of activity ended, and it was not until about 21 h. that a new period of great activity began. The red coloration was sometimes exceedingly intense, in spite of the full moon, especially in the north-east. About 22 h. 30 m. the aurora was again quiet, but the third period of activity occurred about midnight to 1 h. in the morning, when the observations ceased. As the long series of photograms (about twenty) have not yet been calculated, we will content ourselves with this short report.

On February 24 the aurora appeared again with fine yellowish-green curtains at 18 h. 15 m. to 18 h. 50 m. in the north up to the polar star, and I saw the green aurora line in the zenith and to the south. But clouds all over the sky rendered photographic work impossible.

The next great aurora appeared on March 5. Long rays on the northern sky and in the zenith were observed already at 18 h. At 18 h. 30 m. I got into telephonic connexion between my station at Bygdø and my station at Tømte (48 km. to the N.N.W. of Bygdø), where the Antarctic explorer Carsten Borchgrevink took photographs simultaneously by instructions through the telephone. We succeeded in taking about 48 photograms, 30 of which were successful. One of these is reproduced in Figs. 1 and 2.

The measurements and calculation of this photogram showed that the altitude of the lower border was unusually high; four points at the feet of the rays gave the altitudes of 135, 132, 131, and 137 km. above the earth. The summits of the rays reached at least 350 km. Of this interesting curtain we took a series of photograms which showed that the lower border was continually descending and increasing in brilliancy, but the detailed computations have not yet been made.

The first period of activity ended about 20 h. 10 m. A new one began at about 21 h. 10 m. with a diffuse arc in the north. This grew successively stronger, and changed at about 21 h. 27 m. into rays and curtains which lasted until about 22 h. In the meantime the station in Kongsberg had been ready for work and five interesting photographs were taken simultaneously from the stations Bygdø, Tømte, and Kongsberg (mutual distances 48, 64, and 105 km.). Also my two stations Oslo and Oscarsborg were now in action and obtained five successful photograms. After 22 h. the aurora retired to the north and remained stationary as a low diffuse arc near the horizon.

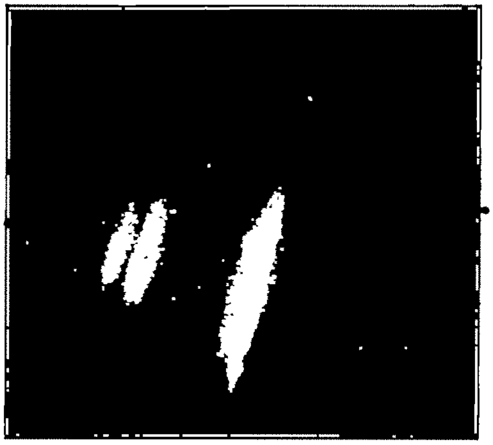

FIG. 1.—Auroral curtain, photographed at Bygdø at 18 h. 36 m. The stars γ, δ, ε, ζ and η of the Great Bear are seen very well on the picture.

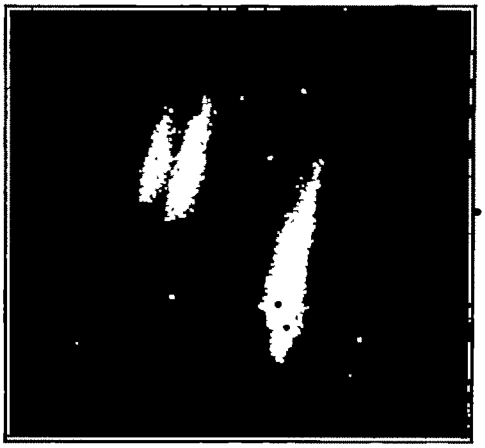

FIG. 2.—The same curtain photographed simultaneously by Carsten Borchgrevink at Tømte. Notice the great parallax referred to the same stars.

The third great aurora appeared on March 9. I am sorry that I was absent from my station during the maximum activity of the aurora. Nevertheless, some photographs of the corona were obtained, and a few photograms, none of which have yet been calculated. Other auroræ, but not so brilliant, were observed and photographed from my stations on February 10, 11,

---

[1] I have seen an analogous phenomenon previously (see *Naturwissenschaften*, 1923, p. 338).

13, 23, on March 3, 10, 11, 12, 13, 14, 16, 19, 21, all on April 10, and on May 3.

In connexion with these phenomena, Mr. Boldermo in Hemnesberget, Ranen, Norway, has made an interesting observation. In a letter to me dated March 12 he says: "About three weeks ago I observed that the northern lights influenced my wireless set. I observed that every time the northern lights appeared against the zenith and on the southern heavens, there was heard a cracking noise in the telephones.[1] I uncoupled the antenna from the apparatus and the latter appeared to have static charges. Against earth these ran over to a distance of up to 15 mm. about three times a second. As soon as the northern lights decreased, the charge by degrees disappeared. The night was almost clear with a slight wind. I have observed the same phenomenon twice later on."

In a subsequent letter he gave me a drawing of his antenna, which shows that the top of it is about 12 metres above the ground. From this it seems that the aurora sometimes modifies enormously the potential gradient in the atmosphere, and this phenomenon should be verified by other observers.

CARL STØRMER.

Propagation of a Single Harmonic Wave in a Medium in which the Group Velocity and Wave Velocity are the same.

IT is, I believe, held by many physicists that it is impossible to initiate or transmit a single wave in which the displacement is a simple harmonic function of time and space throughout.

The object of this note is to show that, given certain initial conditions, single waves or finite trains of waves which from beginning to end are of the simple harmonic type can be initiated and will travel unchanged in form; and further that, with slightly modified conditions, fractional parts of such waves can also be propagated unchanged, and will travel with the same velocity as the complete wave of which they would form a part.

Consider first an infinite train of waves in which the displacement referred to the axis XX, Fig. 1, is

FIG. 1

given by $y = a \sin pa$, where a is the amplitude and $p = 2\pi/\lambda$.

At each maximum and minimum value of y the medium is at rest and the displacement velocity is zero. If the curve is referred to an axis OX′, touching the maxima or minima with the origin at O, the equation becomes $y' = a(1 - \cos px')$. At $x' = 0, \lambda, 2\lambda$, etc., the displacement velocity is 0, and the acceleration ap^2.

Now suppose (*a*) that all the waves except those included between O and A are removed and that the medium outside these limits is at rest. Then the conditions for the continued propagation of the remaining waves are fulfilled, for the velocities and accelerations within the series remain unchanged, and the terminal accelerations are supplied by the excess of pressure (proportional to a/λ) within the series over that in the medium outside, which is at rest.

(*b*) If it is required to propagate an odd number of half wave-lengths the medium on either side of the wave series must be at rest, but having pressures differing by a quantity proportional to $2a$/wave-length. When (*c*) fractional parts of a wave are to be propagated, not only must the pressures on either side of that part be different, but also the two parts of the medium separated by the wave must have a relative velocity, determined by the displacement velocities at the limits of the propagated fraction.

Case (*a*), where a single wave or a whole number of waves is under consideration, can easily be made the subject of experiment.

Let a tube of unlimited length and of any diameter (Fig. 2) be provided with a piston on which a harmonic motion can be imposed. Let the air in the tube be at rest and the piston at the position of maximum displacement. If now the piston is caused to make one complete oscillation and to return to rest at its original position, the result will be that a simple harmonic wave will travel along the tube from each side of the piston, and that in one of these waves (namely, that in which the air is at first compressed) the mean pressure will exceed the still air pressure by a quantity proportional to a/λ, while in the other there will be a defect of pressure of the like amount. A barrier, therefore, placed in the tube will experience an average force during the action of the wave in a direction away from or toward the piston, according as the initiation of the wave starts with an increase or decrease in the air pressure. If the barrier is such as completely to absorb the wave motion, the magnitude of the force will be measured by a/λ, or by $2a/\lambda$ if the wave is completely reflected.

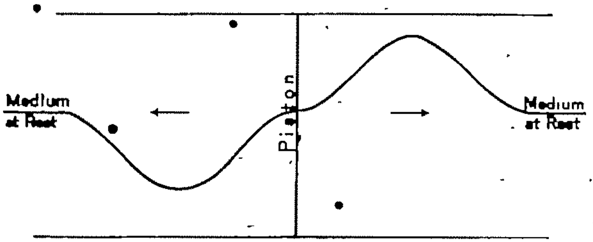

FIG. 2.

In cases (*b*) and (*c*), where an odd number of half wave-lengths or fractions of wave-length are concerned, it would be more troublesome to reproduce experimentally the required conditions. In the latter the motion is analogous to, though not identical with, the progress of a 'bore' in a river where the boundary between deep and shallow water travels as a wave with an accompanying change of stream velocity.

A. MALLOCK.

Exeter.

Barlow's Tables.

REQUIRING recently the square roots of the numbers from 1 to 100 to ten figures, or one more place of decimals than is given in Barlow, I was led to the discovery that his last figure for numbers above 1250 is not to be depended upon for its accuracy. It is true that De Morgan, in issuing a reprint of Barlow's Tables in 1839, admitted that his method of checking Barlow's entries by differencing left "remaining a possibility of any of the last figures being a unit wrong in the columns of square and cube roots."

The purpose of this note is not to criticise a work that must ever remain a monument to the industry and zeal of an enthusiastic computer at a time when calculating machines were not in existence, but merely to place on record what must, I am afraid, be a very incomplete list of errata, all the more important because Barlow is a standard work, and the constant companion of the practical man. By the very nature of my original inquiry, I only examined one entry in each double page of Barlow, that is, one out of a hundred. These were 1300, 1400, 1500, etc. Out of 87 entries examined after 1250, 19 are wrong by one in the last place. A little further investigation, too, soon showed that in certain parts of the table the error is continued throughout a series of consecutive entries.

---

[1] That noise was also heard by engineer Max Rich. Hennig in Ångermanland, Sweden, during the aurora on March 9.

The conclusion is irresistible that in no case throughout this portion of the table can the last figure of the square root be depended upon. Of course the average man feels very happy if he has the perseverance to push his results to five, six or even seven figures. But there are some who have need of all the figures that existing tables give them, who sometimes wish, indeed, that more were available. For such the warning conveyed by this note is intended. It is a matter for surprise that 5000, 7200, 7500 and 9800, in particular, are in error, since the figures of the roots are those of $\frac{1}{\sqrt{2}}$, $6\sqrt{2}$, $5\sqrt{3}$ and $7\sqrt{2}$ respectively, and $\sqrt{2}$ and $\sqrt{3}$ have long been known to a very large number of places. The list of errata is subjoined, the correct result being in each case given.

Number.	Square Root.	Number	Square Root.
1400	37·4165739	6100	78·1024968
2000	44·7213595+	6600	81·2403840
4300	65·5743852	6900	83·0662386
4697	68·5346628	7100	84·2614977
4698	68·5419580	7200	84·8528137
4699	68·5492524	7500	86·6025404
4700	68·5565460	7800	88·3176087
4701	68·5638389	8600	92·7361850−
4702	68·5711310	8700	93·2737905+
4703	68·5784223	9100	95·3939201
4704	68·5857128	9800	98·9949494
4705	68·5930026	9896	99·4786409
4998	70·6965346	9897	99·4836670
4999	70·7036067	9898	99·4886928
5000	70·7106781	9899	99·4937184
5001	70·7177488	9900	99·4987437
5600	74·8331477	9901	99·5037688
5700	75·4983444	9902	99·5087936

+ or − after final 5 or 50 means that the correct square root is greater or less than the result exhibited. Such a convention minimises the risk of error when the decimal is curtailed. JOHN WISHART.

Can Portuguese Oysters be produced on English Oyster Beds by Artificial Fertilisation in the Sea?

DURING a visit to the Blackwater oyster beds in the summer of 1925, I had reason to open 100 Portuguese oysters (*Ostrea* (*Gryphæa*) *angulata*), and found them, as on previous occasions, practically all sexually mature. It occurred to me at the time to try an artificial fertilisation in the sea with the view of increasing the stock of oysters on the beds. As, however, the beds were private ones, it was thought inadvisable to take the risk without consulting the owners, and the opportunity of trying the experiment did not again arise. It has been recorded in NATURE (August 12, 1922, p. 213) that Portuguese oysters have spatted in the waters of the river Blackwater, Essex, on experimental shells put out for the definite purpose of catching young oysters, and also (*loc. cit.*) that artificial fertilisations of the Portuguese oyster can be easily made.

The experiment would not have suggested itself but for the fact that on English oyster beds the Portuguese oyster spawns naturally only rarely, due no doubt to the relatively low temperatures occurring normally in English waters compared with those found in south European waters where the Portuguese oyster reproduces very abundantly. Nevertheless, there is no doubt that shelled larvæ can easily be produced artificially at temperatures which occur on English beds, but it is doubtful whether these temperatures are ordinarily high enough to ensure fixation of the shelled larvæ when the latter are ready to settle. The success of the experiment will depend partly on the occurrence of suitable conditions for fixation of the larvæ in the year of the experiment—and high temperatures and clean shell for attachment are probably the critical factors concerned in the sea,—partly upon the production of sufficient larvæ to leave a balance for settling after the enemies of the larvæ have had their fling, and partly upon the larvæ being reared in a body of water which will not carry them away from suitable places of attachment.

As a provisional experiment it is suggested that a thousand Portuguese oysters be cut into rather thick shreds and shaken in the sea over the oyster beds at half tide at the beginning of the neap tides. From 60 to 90 per cent. of the oysters would be female (see *J.M.B.A.*, vol. 14, p. 230, 1926), and from each would be released in this way an *estimated* average of at least three million eggs for medium-sized oysters. A plentiful supply of sperm would be available from the smaller number of males. If a thousand oysters were disintegrated in the sea on five successive days, there would be a greater chance of sufficient larvæ being produced to give a spatfall, other conditions being favourable. The time most likely to be favourable for the experiment may be fixed in the neighbourhood of the end of June in a normal year.

The experiment itself is so simple that it could be carried out by the normal summer staff at work on an oyster bed, but practical difficulties, such as the attraction of shoals of fishes and other marine animals to the locality of the experiment, might have to be obviated.

The creeks bordering on the Thames Estuary, north and south, and creeks and estuaries on the southern coast, such as occur at Salcombe and the Fal (River and Upper Estuary), and no doubt elsewhere on this coast where this oyster is unknown, would be suitable places to attempt the experiment.

A warning is, however, needed: the Portuguese oyster may procreate on some southern beds so well as to oust the native European, and it is not so valuable. At Arcachon (France) the Portuguese oyster was accidentally introduced on the fine beds of European oysters there and was regarded for decades as a pest, though at the present moment it is the salvation of many oyster-cultivators in that region.

I should be willing to give further suggestions on the method of carrying out the experiment to any oyster-producer who may desire to try the experiment.

Capture of Electrons by α-Particles in Hydrogen.

The phenomenon discovered by Henderson (*Proc. Roy. Soc*, 102, 496, 1922) of the capture of electrons by α-particles passing through matter has attracted much interest and has been subjected to theoretical investigation from various sides By comparing the statistical equilibrium between capture and loss of electrons by α-particles with an equilibrium of thermal dissociation, Fowler (*Phil. Mag.* 47, 416, 1924) was able to account for many of the characteristic features of the phenomenon revealed by Rutherford's careful examination (*Phil. Mag* 47, 277, 1924), in particular, for the fact that the ratio between the probabilities of capture and loss for α-particles of given velocity was nearly the same in all substances investigated and varied approximately as the fifth power of the velocity.

As pointed out by Bohr (*Zs. fur Phys.*, 34, 142, 1925), this theoretical argument involves difficulties when applied to substances of small atomic number in which the interatomic velocities of the electrons are all small compared with that of the α-particles Recently Mr. Thomas, working in this Institute, has examined this point more closely; his calculations suggest that the ratio between the probabilities of capture and loss in such light substances should vary as a much higher power of the velocity than that holding for the heavier substances examined by Rutherford, and that for high-speed α-particles this ratio should be much smaller for the light substances than that observed for the heavier substances

At the suggestion of Prof. Bohr, the writer undertook an experimental investigation in order to test these results. The apparatus was of the same type as that used by Rutherford to examine the capture and loss of electrons by α-particles in gases. In this method the beam of α-rays passing into a vacuum through a mica window is deflected by a magnetic field. The distribution of the scintillations then shows two distinct peaks corresponding to singly- and doubly-charged α-particles. If now gas is let into the deflexion chamber, this distribution is changed on account of the loss and capture of electrons by the α-particles when passing through the gas.

On increasing the pressure of the gas the peak corresponding to the singly-charged particles gradually disappears and there is established between the two peaks a continuous distribution of scintillations due to particles which have either lost or captured an electron during the passage through the gas When the pressure was so adjusted that the number of singly-charged particles had decreased in a given ratio, it was found that the continuous distribution in air was essentially different from that in hydrogen, the density of scintillations for any given deflexion in air being more than double that in hydrogen. This shows that the probability of capture is considerably larger in air than in hydrogen in circumstances in which the probability of loss is the same

This conclusion was confirmed by a closer examination of the continuous distribution of scintillations in air and hydrogen at different pressures. While in air a considerable part of this distribution had to be ascribed to capture, it was found that the distribution in hydrogen could be accounted for within experimental error on the assumption that it resulted solely from the loss of electrons by the α-particles In close agreement with Rutherford's measurements, the mean free paths for capture and loss in air (reduced to normal pressure and temperature) were found to be 2·1 mm and $1{\cdot}0 \times 10^{-2}$ mm respectively. The velocity of the α-particles was $1\ 75 \times 10^{9}$ cm. per sec At this velocity the mean free path for loss in hydrogen was found to be $7{\cdot}8 \times 10^{-2}$ mm., in satisfactory agreement with ionisation theory As a lower limit for the mean free path for capture in hydrogen the experiments gave 200 mm. Although the probability of capture in hydrogen predicted by theory corresponds to a still longer mean free path, the experiments seem to afford suggestive support for the theoretical considerations.

Birth of Peripatus in England.

A record of the birth of living Peripatus in England is perhaps worthy of note, especially since the case is probably unique. At least it serves to show how a creature which is particularly susceptible to its environment may be carried very long distances overseas and kept in captivity. The present case is all the more striking because only a single animal was brought from Australia; it is not, therefore, one survivor out of many.

During 1925 one of us (Miss Fordham) visited Western Australia for the purpose of collecting certain zoological material for research Amongst other items in the programme it was intended to collect a number of Peripatus late in the season (the animals disappear at the beginning of the dry season in Western Australia—say, October or November). Unfortunately the wet season was remarkably dry last year and extremely few Peripatus were to be found. Only one living Peripatus commenced the voyage from Australia to Europe, and this was captured on September 20. At this time of the year fertilised females may be found.

Contrary to our expectations, the specimen survived the ocean voyage and continued living at Liverpool, where it arrived in January. The animal turned out to be a female, and during the month of April, six months after its capture and at least five months after contact with other Peripatus and four months after leaving Australia, gave birth to young of which two are actually living now with the mother (May 18)

The specimen is kept on its native soil in a large glass museum jar with glass stopper. It has pieces of bark for shelter, and it is given bits of woodlice, which apparently it does not eat. A few termites were present in the soil and there are numbers of Protura.

It is thus quite clear that the Western Australian Peripatus receives spermatozoa during the wet season (winter), and that the period of gestation is upwards of six months, when normally the animals are hidden away within rotting wood or below the soil during the dry season.

The Sensitivity of Selenium Cells.

The selenium cell, as a light-sensitive element, has always been held to have the inherent drawbacks of inertia and lag, and therefore to respond too sluggishly to changes in light intensity, and to return to its normal low conductivity much too slowly when the illumination to which it has been subjected is cut off. Several forms of photometer are now in use in which selenium or photo-electric cells are employed, and were selenium more certain and more prompt in action it would offer certain advantages over the photo-electric cell.

A. Korn did much to increase the utility of selenium by simultaneously subjecting two cells of different sensitivity to the source of light, using them on opposite arms of a Wheatstone bridge arrangement. He found that for an increase of illumination δI, the current y obtained for a given voltage passed through the cell was $\alpha\delta I e^{-\beta t^{-1/m}}$, where β is an inertia constant, and m the 'exponential inertia'; m should be as much below 1 in value as possible and depends on the mode of preparation of the cell.

By selecting two cells such that

$$\frac{d(y_1 - y_2)}{dt} = 0$$

where y_1 and y_2 are respectively the small increments in conductivity for an illumination of time dt—which means that the product $\alpha\beta$ of each cell is practically the same — wonderfully sharpened action can be obtained which should be of the greatest value if it were applied to photometric work

I have recently tried passing a single-phase alternating current through a Kipp and Zonen selenium cell, and, as I anticipated, the lag is automatically eliminated at each alternation of current, with the result that the cell responds with great celerity to changes in illumination and returns to zero—*i.e.*, its 'dark conductivity'—with great swiftness. The cell returns to the same zero time after time after quickly repeated illumination, very unlike its ordinary behaviour when the conductivity in the dark creeps up each time the illumination is cut off through cumulative ionisation. The periodicity of the current must of course be greater than that of the changes in light intensity.

It is quite easy to rectify the current that is passed through the cell so that an ordinary galvanometer can be used. The experiments indicate that by using alternating current an entirely new field of possibility is opened up for the selenium cell. Some years ago, when reproducing records of the voice on kinematograph film with selenium, I found that so many as 8000 vibrations per second could be dealt with distinctly, which indicates that our conception of the rate with which selenium can respond to changes in light intensity has been greatly handicapped. By the employment of alternating current, and so accelerating its rate of change, we may find that the selenium cell is of an extremely high order of sensitivity

Magnetic Properties of Single Crystals of Iron.

In a letter to Nature, May 29, p. 753, Messrs. Honda, Kaya and Masuyama give a short account of some magnetic properties of single crystals of iron. In this laboratory I have investigated various magnetic phenomena in single crystals. In the *Proc Roy Soc.*, 107, 496, 1925, an account of the variation of the susceptibility with the direction in the crystal has been given, and it may be mentioned that later a theoretical explanation of the effect has been given by Mahajani (*Camb. Phil. Soc.*, 23, 136, 1926) In the *Proc. Roy. Soc.*, 109, 570, 1925, experiments on the effect of crystal structure on magnetostriction have been described. This work is similar to that now described by Honda, Kaya and Masuyama, and their results are in very good agreement with those of the present writer. The rods used by them were much larger than those of our experiments, and their accuracy may be higher, particularly in the measurement of the magnetic intensity, but our results are more definite in that the rods used by us were orientated, within two or three degrees, parallel to a (100), (110), or (111) crystal axis For example, we showed definitely that for the (111) direction there was only a contraction, a fact surmised by Honda, Kaya and Masuyama.

We hope to publish shortly some work already completed, on the change of resistance of iron-crystal rods in a longitudinal magnetic field. The results of this work have an important bearing on the phenomenon of magneto-striction, as they indicate that the increase in length for the (100) axis is quite different in origin from the decrease in the (111) direction.

The Taxation of Research.

We have received notification that the Inland Revenue authorities are about to challenge the right of the Chemical Society as a charitable institution to recover the income tax deducted at the source from the interest on its invested capital. For eighty years the Society has published freely new knowledge in chemistry, and has carried a financial burden which could not have been borne had not Governments in the past provided rent-free accommodation and relieved the Society from taxation.

The great increase which has taken place, and is still taking place, in the amount of research work in chemistry emanating from our universities and university institutions renders it difficult, even under present conditions, for the Society to carry out the duties assigned to it by its charter, in view of the fact that within the past seven years its expenditure has increased by some 7000*l.* a year.

The margin between solvency and bankruptcy is small and may disappear if the Society is subjected to the taxation suggested.

The Coal Fire.

It is the opinion of every one with whom I have spoken on the matter, that a coal fire possesses some subtle qualities which a gas or electric fire lacks. In her letter to Nature, March 6, p. 343, Dr Stopes instances the great curative powers of a glowing coal fire, and the renewed vitality she experienced after exposure to it during convalescence. My own experience with chickens has a direct bearing on the subject.

A number of chickens hatched during April, and housed in dry quarters well heated by oil lamps, round which they could cluster, appeared to be in a half-dying condition and looked exceedingly unhappy. On being placed before a bright coal fire, recovery was rapid, and they became so lively in an hour or so that they were often difficult to recapture.

Contrary to the experience of Prof Hill with animals (Nature, April 3, p. 487), close up electric lamps apparently do not exert a similar beneficial influence on chickens. A visit to any establishment in this city where these birds depend on electric lamps for warmth and in part for light will bear this out.

The Relationship of Physics to Aeronautical Research.[1]

By H. E. WIMPERIS, Director of Scientific Research, Air Ministry.

AVIATION is now entering upon a new and intensely interesting phase—one which will call for every scientific resource at our command. The materials of construction are changing: wood is giving place to metal. The engine proves to have most unexpected possibilities ahead of it through the increase of intake pressure; whilst the very lifting structure itself may possibly change, for some purposes at least, from linear motion to rotary. Now in aeronautical work there can be no doubt that scientific studies have been considerably stimulated by problems which have arisen directly from aeronautical engineering. The thought of those physicists who have in recent years done such brilliant work on the mathematical theory of fluid motion was stimulated in no small degree by the results obtained either in the wind channels of our aerodynamic laboratories or in free flight on the full scale.

Aeronautics by its youth escaped the medievalism of the old-time practical engineer; it was launched well in the modern scientific path by the formation some seventeen years ago of the Advisory Committee for Aeronautics, which after two phases of re-adjustment is still with us as the Aeronautical Research Committee. When I first knew it, it was presided over by that kindly and gracious being the late Lord Rayleigh; in those days the field of work was small enough for all matters to be dealt with by the single Committee. Now the scale is so much greater that many sub-committees and panels have to share its responsibilities. The latest phase is the organisation under the Air Ministry of a separate scientific research department to ensure that scientific investigations shall receive their due, and be vigilantly guarded against any competition for money, staff or facilities by the seemingly urgent claims coming from other quarters.

The scientific research staff of the Air Ministry closely resembles the corresponding staff at the National Physical Laboratory in its method of recruiting, its scales of pay, and its conditions of work. This staff is about eighty in number, and of this general 'pool' some four-fifths work in the laboratories at Farnborough and the rest at such stations as Martlesham, where the performance of new airplanes is studied, Felixstowe, where corresponding work is done for seaplanes, and the Air Ministry Laboratory in the Imperial College of Science, where special problems, mainly physical and chemical, are studied.

The examination of the flow around aerofoils and of the fluid forces brought into play has naturally formed one of the chief items of physical research in the wind channels of the aerodynamic laboratories throughout the world. The simpler measurements usually made on aerofoils are the lift and drag coefficients and the motion of the centre of pressure. These, the ordinary methods of classical hydrodynamics, are not capable of predicting from theoretical considerations alone, since the mathematics deal only with the motion of a fluid in which viscosity plays no part.

In the case of a simple mathematical shape, such as a cylinder placed at right angles to the flow, the positions of the streamlines, as determined for an inviscid fluid, differ appreciably from those which would arise in a viscous medium such as air. In the former fluid, moreover, no resultant force acts upon the cylinder, whereas measurements made in an air channel show that considerable forces are brought into play. Indeed, without such forces flying would not be possible.

If now to the streaming of the inviscid fluid past the cylinder there be arbitrarily added a 'circulation' of the fluid around the cylinder, there at once comes into existence a resultant force at right angles to the stream. This has an immediate analogy with the lift force experienced by an aerofoil, and with the propulsive force produced by the action of the wind on the rotating cylinder of the Flettner rotor ship.

It is seen, therefore, that by the addition of the idea of a 'circulation' around the body, a possible explanation is given for the existence of lift forces, and in recent years, by the employment of this convention, successful efforts have been made actually to predict the lift of certain forms of wing section. Naturally, a theory such as this has had to face much criticism, but some years of experience with it have enabled comparisons to be made with data obtained in the laboratory, and such comparisons have shown that it affords a close approximation to what actually happens. The theory itself was built upon the work of many investigators, and among that many I would like specially to refer to the work of Lanchester, Joukowsky and Prandtl. As a result of the work of these and other pioneers, therefore, we find it useful in aerofoil design to study the effect of imposing upon the motion of an inviscid fluid a 'circulation,' of unknown origin, around the aerofoil of sufficient amount to carry what is known as the 'stagnation point' to the trailing edge of the wing. 'Circulation' must have a physical existence, since the velocity is greater above the wing than it is below, though this real circulation is a circulation with no slip, whereas the mathematical circulation has slip. Hence the rather amusing situation arises of adding to the mathematical study of streamlines a conventional motion which could not really arise in an inviscid fluid! So long, however, as the limitations to the theory are borne in mind no harm can be done, whilst the results of such mathematical work are of the greatest utility as a first approximation as to what is happening.

One great merit of Prandtl's work is that his theory enables the lift of a wing of limited span to be deduced from the known performance of a wing of the same cross-section but of unlimited span; in other words, that the results of three-dimensional flow can be deduced from the known two-dimensional. The two-dimensional flow can be studied in two ways: experimentally, by means of a model wing-section stretching right across the wind channel; and mathematically, by the method initiated by Joukowsky, who found a way of predicting these forces by the mathematical step of converting a circle into the desired aerofoil shape by means of a suitable conformal transformation. For a limited number of aerofoil shapes it is therefore possible to deduce theoretically the performance for two-dimensional flow, whilst by the Prandtl theory it is possible to convert these results from two-dimensional to three-dimensional conditions. This work has been put to use by the Air Ministry scientific research staff, and some six aerofoil sections have been designed on this basis with the object of obtaining in the first instance a good thick wing, and in the second, a good racing wing. This theoretical work has been fully confirmed by subsequent experimental results on such aerofoils, whilst on certain of these wings full-scale work in free flight has been put in hand.

---

[1] From a lecture delivered before the Institute of Physics, at the Royal College of Science, South Kensington, on June 7.

Many attempts have been made to build a type of aircraft known as a helicopter, which is fitted with rotating wings driven by one or more engines. Little success has, however, been met with in spite of considerable expenditure. But in the last year or two, real success has been achieved by Señor de la Cierva with his 'autogiro'; this machine is not strictly a helicopter, however, since the windmill is not power driven. But I think there is little doubt that it is through the autogiro, or, in English, the gyroplane, that we have the best means of studying the performance of all rotating wing machines. One of the difficulties with a rotating wing is that the part which is moving in the direction of flight has a higher airspeed than the retiring part, and this leads to greater lift on one side of the machine than the other. Mechanisms to balance these forces mechanically are most complicated to build and still more complicated to control. Cierva cut the knot of this difficulty by hinging his blades close up to the vertical shaft. This meant that the advancing blade merely lifted a little above its average position while the retiring blade fell a little below that level; thus the wings oscillated in a vertical plane during each rotation and presented some analogy to the flapping flight of birds. Centrifugal force prevents the wings from folding up about their hinges.

Owing to wall interference in the wind-channel tests that have previously been made on such windmills, or for some other reason, their capacity for slow descent under load was underestimated. This underestimate was first realised as a result of the tests carried out at Farnborough last summer with a Cierva gyroplane in which the vertical velocity was some 15 feet per second only, about half the speed of fall of a parachute carrying the same load and having a diameter equal to that of the windmill.

Full-scale tests on aircraft components usually require a greater space than can be given in a laboratory, and in consequence the physical investigations arising therefrom need to be carried out through the medium of models. It is no difficult matter to make an accurate scale model of any form of aircraft, and to provide a wind channel of such dimensions as will make the test reasonably representative. That is relatively simple, but a difficulty soon arises through what is known as 'scale effect.' The study of scale effect is intricate and much work has yet to be done. But it has been proved that model tests in the wind channel would represent what happens on the full scale if a certain physical ratio were preserved; this ratio is the product of length by velocity and divided by the kinematic coefficient of viscosity. This ratio is a non-dimensional one and it is coming to be known as the 'Reynolds' Number.' Model tests in wind channels as we at present know them give a value of the Reynolds' Number of but one-tenth of that appropriate to full scale. This is unfortunate, since it means that within the range of velocities available in the ordinary wind channel only a very small portion of the correction for the change of the characteristic under measurement with the Reynolds' Number can be studied: hence to deduce full-scale results from wind-channel experiments may mean extrapolation in the ratio of something like 10 : 1.

A limit to the air velocity in the channel is imposed by the considerable increase of horse-power for such operation; there is also an obvious limit to the dimensions of channels, and it follows that the only opportunity of obtaining a Reynolds' Number comparable with that applicable to full-scale conditions is by means of an increase in density of the air, or else of its replacement by some fluid having a higher specific gravity. Much interest has been taken in the pressure channel recently built at Washington, which is capable of being operated at an internal pressure of 20 atmospheres, so realising a Reynolds' Number equal to that of full-scale work, when allowance is made for the fact that a pressure tunnel is best run at about half the airspeed of an atmospheric tunnel, so that the amount of the forces acting upon the model may be kept within bounds. It is too early to say whether this channel has entirely fulfilled its constructors' hopes, but from such tests as have been reported it seems that the method of testing rendered possible by its use will prove to be of great utility.

Another form of model-testing is that carried out in the Yarrow tank at the National Physical Laboratory. This tank was originally built for the testing of ship models, but in recent years it has also been used for work on models of seaplanes. Investigations of this sort become specially necessary when the seaworthy characteristics of seaplanes need study. These craft have to be designed in relationship not only to their performance as flying machines, but also as to their habits when travelling on the surface of the water before they become entirely air-borne. For the aerodynamic characteristics the wind channel suffices, but for the study of the period prior to flight the tank is necessary. When considering the size and speed of a tank for this purpose one is faced with the consideration that the model must run at what naval architects term the 'corresponding speed' to that of the full-scale machine; speeds are said to be corresponding when the ratio of the velocity to the square root of the length of the model is equal to the velocity of the ship divided by the square root of its length. This ratio, it will be seen, is quite different from the Reynolds' Number above mentioned and it leads to totally different design requirements.

It might be thought from what has been said that the main purpose of the tank is to make accurate quantitative measurements. This, however, is not the case, since probably the chief use of such tests is a qualitative examination of the wave motion created by the hull, particularly in relationship to the position in which the engines and propellers are proposed to be placed.

The physical problems presented by the aero engine are for the most part not peculiar to aeronautics, but are part of the general study of the internal combustion engine. The use of this type of prime mover for aircraft does, however, present special problems owing to the urgent demand for 'reliability' on one hand and lightness on the other. Moreover, there is always the tenuity of the air at altitude to be reckoned with.

As a matter of fact, the aero engine has improved enormously in recent years—not so much perhaps as the result of scientific study as by sheer hard efficient work on the part of the engineering staffs of the engine-builders. As witness to this remarkable success, I would specially mention the performance of the Napier water-cooled engine on the flight to South America, the excellent behaviour of the air-cooled Jaguar engine on Mr. Cobham's flight to South Africa and back, and by no means least, the remarkable achievement of an air-cooled Jupiter engine in flying 25,000 miles without any overhaul.

Need for lightness of construction brings in quite other considerations. For high output, high efficiency is necessary, and this calls for increased compression pressures and a consequent liability to the troubles induced by detonation. The study of detonation and the means of avoiding it are fitting studies for physicists. Equally fitting are the investigations necessary to ascertain whether the output of the engine in relation to its weight can be increased by what is known as supercharging, and if so, how far in that direction it is expedient to go. All the while it has to be borne in mind that the engine must not only be capable of operating in a normal atmosphere such as that in which most internal-combustion engines work, but also in conditions in which the pressure may be only one-third of that at sea level and in which the atmospheric temperature may be no less than 50° Centigrade below zero.

This sensitivity of the engine to atmospheric pressure has led naturally to attempts to create an artificial atmosphere of increased density in the engine intake. A scheme of this sort was indeed mooted by Sir Dugald Clerk more than twenty years ago, and was called by him 'super-compression.' It is now known as 'supercharging' when the effort is to maintain an intake pressure at all altitudes equal to that at ground level, or 'boosting' when the effort is to increase the intake pressure by a constant fraction at all heights. These developments present an infinitude of problems most of which are now beginning to be seriously tackled—their close relationship to detonation is a complicating phenomenon. There are such great possibilities in this direction that a material decrease in weight per horse-power at altitude may confidently be looked for in the not distant future.

We live in a wonderful age. Just as in the thirteenth century the splendour of life must have seemed most to surround the work of the architect, or in the fifteenth century that of the painter, so it appears to me in the present age does it crown the labour and achievement of the physicist.

Iron in Antiquity.[1]

By Dr. J. Newton Friend.

It would be difficult to find a subject of greater interest than the study of iron in antiquity. Man's first acquaintance with the metal undoubtedly dates back, in certain districts, to the Stone Age. At that time meteoric iron would be much more common than now, and primitive man would soon observe that the metal was more malleable than ordinary stone, and could be cold worked, by repeated hammering, into simple shapes for ornament or for personal use. Probably this was the origin of the metal beads, the oxidised remains of which have been found in predynastic tombs in Egypt, dating back to about 4000 B.C. But it was not until man had progressed slowly upwards through ages of unremitting toil that he learned of the connexion between metallic iron and certain of the stones around him, and succeeded in reducing the metal from its ores.

Iron appears to have been manufactured in the Near East at a fairly early date. The Hittites were beginning to use iron weapons for military purposes about 1300 B.C., and Rameses II., King of Egypt, is known to have applied to the Hittite king for a supply of the metal. Whether he obtained it or not is unknown, but a mutilated letter has been found, possibly addressed to Rameses II., in which the Hittite king states that he is sending an iron dagger, and promises to forward a supply of iron

The Philistines are believed to have introduced the general use of iron into Palestine, although the metal was known many years prior to that. It is clear from references in the Old Testament (see 1 Sam. xiii. 19-22) that the Philistines retained the monopoly of working iron, with the result that at first there was no smith in Israel, and the only Hebrew persons possessing iron swords were Saul and Jonathan. In other words, the Philistines had already entered upon their iron age when the Israelites were still in their bronze age. By the time that David ascended the throne, however, the use of iron was becoming more general. Nevertheless, it is interesting to note that no iron tool was allowed to be used in the construction of Solomon's temple at Jerusalem. The employment of iron would have been offensive to God, who had in previous years spoken against the use of metal, and had ordered (Ex. xx. 25) any altars erected to Him to be made of unhewn stone. In view of this the following tradition is interesting. Whilst the present writer was in Jerusalem last year, his dragoman informed him of a curious belief prevalent amongst the Jews to the effect that if the crevices in the ancient wall at the famous Wailing Place are completely filled with iron nails, Jerusalem will once again be restored to the Jews.

---

[1] Substance of a lecture delivered at the Royal Institution on June 5

The Greeks and the Cretans would appear to have been the first European peoples to use iron. Homer, who lived about 880 B.C., was very familiar with the metal. The Homeric age, however, as depicted in the "Iliad" and "Odyssey," is several centuries earlier; the Phaeaceans referred to in the latter work are believed to have been the Minoans of Crete, famous for their sea power—the Britons of the Mediterranean. The Homeric period was transitional between the Bronze and the Iron Ages. Iron was listed amongst the treasures of the wealthy, but was in general use only in the peaceful pursuits of agriculture. Probably the metal lacked homogeneity and could not be relied upon in such thin strips as would be necessary for swords, owing to its tendency to bend or snap. The Vikings 2000 years later were familiar with this difficulty, as is evident from the Icelandic sagas. One frequently reads that the swords would not "bite," and occasionally we are told that the sword bent so seriously that the warrior often had to straighten it under his foot! This surely was giving his opponent too much of an advantage.

The Romans about 2000 years ago were skilled metallurgists. Virgil in his "Aeneid," written about 40 B.C., describes a smithy in full work, and refers to the steel hissing as it is quenched in water, showing that the art of tempering was practised. Pliny some years later showed a wide knowledge of the ores of iron and of the working of the metal. He appears also to record, in what is otherwise an obscure passage, the accidental production of cast iron For this product, however, there was at the time no practical use, as the Roman furnaces were incapable of dealing with it. The tendency of iron to rust was regarded by Pliny as Nature's punishment on the metal which, owing to its use in warfare, "brings the greatest dangers upon perishable mortality." Occasionally, as now, the rusting of iron was turned to good account. A very clever metallurgical conception was attributed by Pliny to Aristonidas, who, wishing to express in a statue at Rhodes the "fury of Athamus subsiding into repentance after he had thrown his son Learchus from the rock, blended copper and iron, in order that the blush of shame might be more exactly expressed by the rust of the iron making its appearance through the shining substance of the copper."

Iron was regarded as symbolical of Mars, the god of war, and the alchemists represented it by the symbol ♂, which is usually supposed to be derived from the shield and spear of that god The popular idea that iron is a useful remedy and invigorates the constitution owes its origin largely to this connexion with the virile god, who was supposed to transmit his strength to his dedicatee. Ancient legend has it that King Iphiclus of Phylacea about 1380 B.C was very anxious to beget children, and was successfully treated by the shepherd Melampus, who dosed him with iron rust in wine—the earliest *vinum ferri* of the pharmacist on record!

Iron was known to the Britons long before the advent of Julius Cæsar. The Romans greatly extended its use in Britain, and numerous objects of iron are continually being unearthed on the sites of various ancient Roman stations. One of the most interesting of these is an iron ring, probably the remains of a ferrule, found last year at Uriconium. It appears to have been made by bending a strip of iron into a circle and soldering the ends together with some copper alloy. This is the first recorded example of such work.

Cast iron was known in Sussex by 1350 A.D. and soon became quite a familiar commodity. It was at first used exclusively for casting purposes. In 1516 a cast-iron gun weighing nearly 5 tons was made, and in 1588 the Spaniards armed their Armada with cast-iron guns as well as with the more familiar bronze weapons.

When, many years later, it was found that cast iron was the most suitable starting-point for the manufacture of iron and steel, the demand for it increased rapidly. In 1800 the United Kingdom produced about ¼ million tons of pig iron, a quantity that in 1913 had increased to a maximum of more than 10 million tons. In 1925 it had fallen to little more than 6 million tons—the aftermath of the War.

Structural Features of the Earth.[1]

ARGAND'S distinguished services in unravelling the structure and history of the Pennine Alps, and of the Alps in general, ensure a respectful hearing for his present wider venture Wide it undoubtedly is, for its seemingly ample title, "La tectonique de l'Asie," in no way contains it. Asia furnishes the text, the subject is Suess's own, the face of the earth.

It is interesting to find de Margerie, who did so much to secure recognition for Suess's masterpiece, acting as godfather to the new arrival. Argand explains that the basis of his memoir is a manuscript map, of which he prepared a first draft in 1912. The following year, de Margerie introduced this map to the notice of the Canadian meeting of the International Geological Congress, and since then has done all in his power to secure its publication. The Belgian meeting, 1922, promised us the map. The memoir, at any rate, is in our hands. In acknowledging his debt to de Margerie, Argand admits that he could not have faced the task without the help of this 'prince de la bibliographie.' Where so much is given, it may seem churlish to grumble, but many a student will miss any attempt at a considered bibliography in connexion with Argand's memoir. Perhaps the author felt that, when one writes of the world, the catalogues of libraries are themselves the bibliography.

Argand considers that modern knowledge requires a modification and extension of Suess's achievement, not a reconstruction. He starts by adopting Bertrand's *time-definition* of mountain building, employing it in a somewhat elastic sense: the Caledonian Cycle of mountain-building belongs to Lower Palæozoic times; the Hercynian to Upper Palæozoic times; and the Alpine to Secondary, Tertiary, Quaternary, and Recent times.

The deformations produced by horizontal pressure acting during any particular cycle are of several different kinds. Argand employs the following classification—the particular examples quoted belong to the Alpine Cycle:

---

[1] "La tectonique de l'Asie," *Compt rendus*, Congrès Géol Internat., Session XIII, 1922 Belgique, 1924. By E. Argand Pp. 171-372 (Contents, pp 363-372), Figs. 1-27

(1) Deformation of thick comparatively unconsolidated marine sediments. This gives rise to *coastal chains*, such as girdle the Pacific Ocean, and to *geosynclinal chains* (generally double), represented by the great series that reaches from the Himalayas, by way of Persia, Anatolia, and Greece, through the Carpathians and Alps, and so into Spain. The Indo-African-Eurasian geosynclinal series unites with the Asiatic coastal series in the Malay Archipelago.

(2) Continental deformations that affect the foundations and cover of continental areas. The foundations of a continent consist of sediments compacted by some early cycle of mountain building (along with batholithic intrusions). The cover is the veneer of relatively unconsolidated sediments locally deposited on the foundations in epicontinental seas, fresh-water lakes, etc. *Foundation folds*, or *plis de fond*, may reach from any depth up to the surface. Where cover exists, it may be bent along with the foundation, and so give rise to one type of *cover fold*. Another type is exemplified in the Jura mountains, where cover has parted company with foundation.

Argand attributes very great importance to foundation folds. Their existence can be detected in a variety of ways. In Scandinavia it is the *present* height of the mountain chain that betrays its Alpine date. The Alpine fold responsible for the elevation (or re-elevation) is of so great a radius of curvature that it escapes purely geological search—all the readable folding and thrusting in this district are admittedly Caledonian. In the Pyrenees, Caucasus and Thianshan, matters are easier for the geologist. These chains consist of groups of accentuated foundation folds that have broken into semi-rigid nappes, and have involved very considerable thicknesses of post-foundation cover. Many foundation folds, and these the more important, are a direct expression of the same push as makes the geosynclinal folds. Others, like the Mt. Blanc massif, have been produced indirectly through interaction with geosynclinal folds.

In his more definitely theoretical pages, Argand adopts Wegener's hypothesis of continental rafts of sial drifting upon sima. Geosynclines are intracontinental regions characterised by thick marine sedimentation. Their site is generally determined by a tendency for two parts of a continental complex to drift asunder. The connecting sial stretches, and as it stretches, its upper surface sags and thus provides a trough for the sea and its sediments, while its lower surface rises, followed by underlying sima. So long as the stretched connecting sial holds together, the subsidence is geosynclinal. Where the sial parts, the subsidence becomes oceanic. Eurasia and Indo-Africa have passed through long periods when they tended to drift apart. Such periods have seen the growth of the geosynclinal sea known to geologists as the Tethys, of which the Mediterranean is the latest recrudescence. During other periods, the two continental masses have tended to drift together, and have squeezed up geosynclinal mountains, that include the Himalayas of to-day as a supreme example.

One might continue this summary indefinitely, and discuss the making of the Mediterranean or the bow and stern phenomena of drifting continental rafts as exhibited along their oceanic margins. Space forbids. Let us merely recall the advice given to young Darwin preparing for his voyage on the *Beagle*. Lyell's "Principles" had just appeared. "Get the book," said orthodox old Henslow, "study it, but don't believe it." Argand has succeeded in correlating an enormous number of geological phenomena, and has thus given them a realisable unity. It may be wise, for the present, to consider his co-ordinating principles with a perfectly open mind; but this should not render us any the less grateful for the accomplishment of a singularly arduous and helpful piece of research.

E. B. BAILEY

Obituary.

SIR STEWART STOCKMAN.

IN the debate on foot-and-mouth disease in the House of Lords on Thursday, June 3, Lord Bledisloe, Parliamentary Secretary to the Ministry of Agriculture, said that Sir Stewart Stockman, Chief Veterinary Officer to the Ministry of Agriculture, had died on Wednesday in Scotland, and Sir William Leishman, chairman of the Foot-and-Mouth Disease Investigation Committee, had died in London. In both cases the Ministry had lost very able research workers and administrators, and the loss, so far as his department was concerned, was a very serious one.

Stockman's name will be readily connected with the drastic action taken in Great Britain during recent years, at enormous expenditure, in dealing with the menace of foot-and-mouth disease by the 'stamping out' process—a method of disease control obviously impracticable to the epidemiologist, but in certain circumstances the proper means of combat in the face of epizootic diseases. Although in its application crude, *primâ facie*, consisting in the wholesale slaughter of known infected and all possibly contaminated animals, the policy of 'stamping-out' as understood by epizoologists is the rationally correct mode of attack when no other system can be readily applied or is likely to be efficacious, and the cost of the process is estimated to fall most decidedly below the losses to the community that will most certainly occur without resort to the method. It is by the adoption of the 'stamping-out' system that the cattle population of England was effectively cleared of formidable scourges in the shape of cattle-plague (rinderpest) and contagious pleuropneumonia during the latter half of the last century, and the same method was applied to foot-and-mouth disease, with, when one compares the incidence of this disease in neighbouring continental countries, most salutary influence upon the live-stock industry of the country.

During this period the disease has reappeared from time to time, usually for some mysterious reason, among our herds, but has been dealt with consistently in the same manner. Within the last few years, however, the disease has made its appearance with disturbing frequency and spread often to an alarming extent before it could be coped with by the "stamping-out" process. The heavy responsibility of deciding upon adherence to the standard policy fell during this time upon Sir Stewart Stockman, in his technical capacity as Chief Veterinary Officer to the Ministry of Agriculture, and the amount of direct observation and estimation of the technical situation that devolved upon him must have told very heavily upon his physical strength, for he was never a robust man. It is in connexion with his clear-sightedness and determination in the face of problems in disease control of almost unprecedented economic gravity that scientific workers in this pursuit will in future years appraise Stockman as a man of exceptional merit, claiming a status in epizoology comparable to that of the greatest workers, such as Gorgas, in the field of epidemiology.

Born in 1869, the fourth son of the late Mr. W. J. Stockman, merchant, of Edinburgh and Leith, Sir Stewart Stockman was educated at the Edinburgh High School and received his professional training at the Royal (Dick) Veterinary College, Edinburgh, whence he qualified as member of the Royal College of Veterinary Surgeons in 1890. He then studied at the École Nationale Vétérinaire, Alfort, Paris, and afterwards occupied the posts successively of demonstrator of pathology and professor of pathology at the Royal (Dick) Veterinary College, Edinburgh. He resigned his teaching appointment in 1900 to serve in the South African War (where he contracted dysentery, which undermined his health in later years), and after the termination of the war accepted a post in the Indian Civil Veterinary Department, which had then just been thrown open to recruitment by civilian veterinary surgeons. His stay in India was brief, for he was appointed Principal Veterinary Officer to the Transvaal in 1902; but while in India he already showed promise of his capacities for dealing with epizootic disease; his work on rinderpest in that country was of high value. In South Africa he was confronted with most acute problems in epizoology, for the cattle population of the country had become exposed to the ravages of rinderpest since 1896, and new epizootics, in the form of East-coast fever and "red-water," had appeared, threatening the virtual ruin of the live-stock industry of the country. The dispositions taken by Stockman then to bring under control and eradicate these diseases and restore the live-stock industry to one of paramount importance in the economy of the country remain models of veterinary police organisation, and his researches in collaboration with Sir Arnold Theiler, then veterinary research officer to the Transvaal, exhibit his genius as an experimenter. His early training, therefore, first as a research assistant and teacher, serving a prolonged apprenticeship under such masters as McFadyean, in England (with whom he remained in lifelong collaboration), and Nocard, in France, and secondly, as an executive administrative officer in countries where epizootic disease plays an extraordinarily conspicuous rôle in the economy of their populations, fitted him peculiarly for the assumption of the specially arduous duties of his later years.

In 1905 Stockman was appointed Chief Veterinary Officer to the Board (now the Ministry) of Agriculture and Fisheries, to administer the Diseases of Animals Acts. His activities lay in two directions in this capacity—first, in the organisation and development of a field service, comprised entirely of qualified veterinary surgeons trained to deal promptly and efficaciously with epizootics, and secondly, in the foundation of a properly staffed research section, to carry out investigation work into the nature and proper methods of control of disease directly affecting the interests of the British agriculturist. He was admirably supported in developing the research activities of his department by the Right Hon. Walter Runciman while Minister of Agriculture, and a first-class laboratory—the first institute of its kind in Great Britain—was erected near Weybridge for research into the animal diseases. The laboratory has since been amply justified, both by the character and output of the researches from it, and among works published dealing with animal pathology, those upon "red-water," epizootic abortion, and other diseases of cattle, scrapie and louping-ill of sheep, swine fever, and certain diseases of poultry, deserve special mention, while the investigations now carried out there upon the nature of the foot-and-mouth disease virus are of a highly delicate technical order and aim at the solution of one of the most distressing factors besetting the valuable live-stock industry of Britain. Stockman's research work into animal disease, and in particular his researches into bovine epizootic abortion, performed largely in collaboration with Sir John McFadyean, have earned him an international reputation as a shrewd and careful observer and as a resourceful experimenter. He was appointed Director of Veterinary Research to the Ministry when the Laboratory was opened.

As mentioned above, however, it is as an epizoologist that Stockman must be meted the largest measure of distinction. He worked laboriously to mitigate the dangers of epizootic disease afflicting British live-stock, and succeeded, taking advantage of the insular situation of the country, to an extent wholly unknown elsewhere. Mention may be made of his efforts to suppress rabies, to eliminate glanders, to mitigate the ravages of swine fever, to control epizootic abortion, and bring about the gradually diminishing incidence of sheep-scab. The responsibility shouldered by him, practically alone, in the face of the recent incursions of foot-and-mouth disease, is well known, and the strain entailed must have told very heavily upon him. He had only just returned from a three months' tour to the Argentine, to investigate the conditions of the meat trade there with Great Britain, but was unable to resume his duties on his return. He had journeyed to Glasgow to consult his brother, Dr. Ralph Stockman, professor of materia medica and therapeutics in the University of Glasgow, about his health, and succumbed suddenly at his residence on June 2.

Stockman was joint editor of the *Journal of Comparative Pathology and Therapeutics*, a member of the council and president for the year 1924–25 of the Royal College of Veterinary Surgeons, a former member of the council of the Royal Society of Tropical Medicine and Hygiene, member of the managing committees of the Tropical Diseases Bureau and Imperial Bureau of Entomology, and a member of the Board of Governors of the Royal Veterinary College, London. He edited

Walley's "Meat Inspection." He was knighted in the New Year's honours list of 1913 for his services. By his conscientious and unassuming manner he inspired the confidence to an extraordinary degree of the Ministry he served, the veterinary profession, and the farming community of Great Britain. He married in 1908 Ethel, elder daughter of Sir John McFadyean, Principal of the Royal Veterinary College, London, and he is survived by her and two daughters, to whom we tender our deepest condolences in their sad loss.

WE regret to announce the following deaths:

Dr. Albert B Lyons, for many years a consulting chemist in Detroit, and formerly a member of the committee of revision of the "U.S. Pharmacopœia," on April 13, aged eighty-five years.

Sir Henry Morris, Bart., president in 1906–9 of the Royal College of Surgeons and in 1910–12 of the Royal College of Medicine, on June 14, aged eighty-two years.

Sir Frederick Walker Mott, K.B.E., F.R.S., formerly pathologist to the London County Asylums, on June 8, aged seventy-two years

News and Views.

THE letter from the president and treasurer of the Chemical Society, printed on p 859 of this issue, raises a question that is of considerable direct importance to learned societies in Great Britain and of no small moment to the cause of science. Hitherto the Inland Revenue has allowed the Society's claims for repayment of income-tax deducted at source, and now such claims are to be disputed. The grounds upon which the Inland Revenue is changing its attitude are not stated, but presumably it will contend that the societies in question (for other societies are also involved) are not described as "charitable institutions" in their charters, and, perhaps, also that they lose any right to this appellation by making profits from advertisements inserted in their publications. On the other side, the societies will rightly contend that they should not be classed with purely commercial undertakings; their work is not undertaken for pecuniary profit, and it is of educational nature and of national importance. Remembering Napoleon's gibe and the saying that "a country has the government it deserves," our national neglect of science is not surprising, but it would not have been so persistent if scientific organisations had learned to speak with one voice. Here is an excellent opportunity for united action, and if a test-case comes into court, it is to be hoped that the scientific societies will stand together, possibly under the leadership of the Royal Society, which is a "charitable institution" by the terms of its charter.

IN view of the difficult times through which the professional classes and the learned societies have been passing since the War, it is very regrettable that the Inland Revenue should now go out of its way to increase their hardships, and unless a strong stand is made we fear that some of the scientific societies will be severely hit by the new exactment. The statement made by Profs. Baker and Thorpe with reference to the Chemical Society that the "margin between solvency and bankruptcy is small, and may disappear if the Society is subjected to the taxation suggested," seems to require, however, some slight modification. According to its published accounts in the year 1925 the Society had more than 39,000*l.* invested in high-class securities, and it recovered 188*l* in respect of income-tax deducted at source. If the Inland Revenue were to claim tax on dividends from the 5 per cent War Loan, 1929/47, which are paid free of tax, the maximum total claim for income-tax (at 4*s.* in the *l.*) from the Society would be about 340*l.* Now the excess of income over expenditure in 1925 was 466*l.*, so that the question is one of a margin between a surplus and a deficit on a year's working, and not of a margin between solvency and bankruptcy. We point this out because we think that any semblance of overstatement should be avoided in prosecuting what is from every point of view (except, possibly, the legal one, upon which we express no opinion) a very strong case

IN the House of Commons on June 8, in Committee on the Finance Bill, a discussion took place on Clause 10 (Continuation and Amendment of Part I. of the Safeguarding of Industries Act 1921). This clause provides, among other things, for the continuance in force for a further period of ten years from August 19, 1926, of Part I. of the Act. The materials affected by the proposed duties are numerous—one speaker said that no fewer than six thousand separate articles were included in Part I. of the Act. The industries to be safeguarded in the way prescribed by the Act include the manufactures of optical glass, optical instruments and the component parts of optical instruments, as well as, for example, the manufactures of magnetos, fine chemicals and arc carbons. In the course of the debate some interesting statements were made by the President of the Board of Trade, Sir P. Cunliffe-Lister. Out of 37 motor manufacturing concerns in Great Britain only three were using British magnetos before the War, to-day all but three are using exclusively British magnetos It was also stated that Great Britain is producing something like 75 per cent. of our home consumption of fine chemicals, compared with 10 per cent. before the War. In respect to insulin, Great Britain has a very large share, not only of the home market, but also of the world market as well. To-day there are three or four times the number of skilled chemists employed in the British fine chemical industry compared with the number employed formerly, while the optical glass industry is now being developed (This is but a pale paraphrase of the tribute to the progress of that industry paid by Mr. F. Twyman in his presidential address to the British Optical Instrument Manufacturers' Association) Those responsible for equipping the Army, Navy and Air Forces have all said that their most minute requirements are met by the optical industry, and the industry has developed a new testing apparatus which is better than any apparatus developed in other countries. (This, presumably, refers to the camera lens and photographic lens interferometers of Messrs. Adam Hilger, Ltd)

THERE were the usual arguments advanced from the Protectionist and Free Trade sides respectively, arguments with the general character of which any student of politics for the past twenty years must be perfectly familiar. These political and fiscal considerations, as such, do not concern us here; but there are certain aspects of this question which touch nearly the interests of science and of scientific workers. In the first place, there seems to have been common agreement in the debate that there are certain industries which, from their character rather than from their size, are essentially key industries, that is to say, industries which, in the interests of the nation, both in peace and in war, cannot be allowed to languish and die, whatever fiscal system be regarded as best suited to the industries of the country as a whole. Whether the best method of safeguarding such essential industries be by a protectionist tariff, a direct subsidy, or a total prohibition of imports except under licence, is a matter of acute difference of opinion The optical industry in 1920, for example, expressed its preference for the last course. Taking the optical industry by way of example, the scientific worker has two main interests If there is not in Great Britain an efficient and progressive optical industry, in which there can be constant and close contact between the manufacturer and the scientific worker, the interests of the scientific worker and of science must suffer. If, on the other hand, the scientific worker is hindered, by tariffs or in other ways, in obtaining the materials and instruments he needs, or has to pay enhanced prices for them, again the interests of the scientific worker and of science must suffer, with inevitable injurious reactions upon the home industry itself. It should not be impossible to reconcile these apparently conflicting interests. But whatever be done, the primary and paramount duty of fostering scientific research, and more especially in any 'safeguarded' industry, remains. Safeguarding will be undoing if from a false sense of security it should lead to neglect of that most potent means of reviving a distressed industry, scientific research

APPARATUS has now been installed for transmitting photographs between London, New York and San Francisco. The journey from London is over the 220-mile land line to the Marconi radio-telegraphic station in Carnarvon, thence by radio-transmission across the Atlantic Ocean to the Riverhead Station of the Radio Corporation of America on Long Island, and afterwards by land lines. A description of the transmitting and receiving apparatus for the radiograms is given in the *Electrical Review* for June 4. The principles of the method of picture transmission over telegraph wires were clearly specified by Alexander Bain in 1842. Practically every system is based on the division of the picture into small unit areas and the transmission of the dots in these areas successively. When, however, it is remembered that the number of dots per square inch in an ordinary newspaper half-tone block is about 4000, it will be seen that the operation would be very laborious. To make it commercially feasible it has to be quickened up very considerably. At Radio House, London, the photograph or document to be transmitted is first copied photographically on to a transparent celluloid film mounted on a horizontal glass cylinder. A powerful beam of light is projected into this cylinder and then refracted out radially. The light passes through small areas of the film progressively, the intensity of the issuing beam depending on the transparency of the portion of the film it passes through. It then falls on a photo cell, the current from which is proportional to the intensity of the beam. The effects produced by this current after amplification are transmitted by the land wires and by radio-transmission to the photogram receiver. The received impulses actuate a siphon recorder mounted on a travelling carriage and operated by a motor controlled by a tuning fork. One of the main difficulties has been to obtain sufficient signal strength to over-ride the effects of atmospheric disturbances. It seems highly probable that the sending of photo-radiograms will soon be a recognised method of communication.

IN his discourse on "The Spectrum of the Aurora," delivered at the Royal Institution on June 11, Prof J. C. McLennan gave a short review of the knowledge of the constitution and state of the upper atmosphere We are gaining interesting information regarding the constitution of the atmosphere at great heights from investigations on the spectra of the auroral light From the work of Lord Rayleigh, Slipher of the Lowell Observatory, and Vegard, it is now known that the element responsible for a large proportion of the auroral spectrum is nitrogen. Vegard's view is that the well-known auroral green line originates in finely divided solid nitrogen in suspension, when bombarded by a corpuscular radiation from the sun. Prof McLennan's work on the spectrum of solidified nitrogen, however, shows that none of the spectral lines found in the spectrum of nitrogen in this state agrees in wave-length with the "green line," while the phosphorescent spectrum of solid nitrogen consists of eight distinct wave-lengths, none of which is included in the spectrum of the auroræ. Prof McLennan and his co-workers have observed a line at 5577 35 in the spectrum of oxygen when an electric discharge is passed through this gas, with helium present in excess. This spectral line possesses all the characteristics of the auroral green line, and it seems probable that both have their origin in oxygen. The line can be obtained with pure oxygen alone, but not with the same intensity as when helium is present. In seeking for the position of the wave-length 5577 35 in the spectral scheme of atomic oxygen, Prof McLennan and his co-workers have been able recently to show that the spectral system of oxygen consists of three sets of terms, one of which involves triplet and quintet terms, and the others singlet and triplet terms. The line 5577 35 belongs to one or other of the singlet-triplet systems, but it has not yet been assigned to any definite position From the observations on the spectrum of the auroral light it is clear that nitrogen and oxygen exist in the atmosphere at a height much greater than was supposed hitherto, while neither hydrogen nor helium appears to be present. While it is difficult to understand how this comes about, it may be that the forces, probably electrical, that maintain oxygen and nitrogen at the great heights mentioned is sufficient to draw away the hydrogen and the helium completely from the earth's atmosphere.

THE *North Western Naturalist*, a new quarterly journal, the first number of which has just appeared, is successor to the *Lancashire and Cheshire Naturalist.* Under its new title it appeals to a somewhat wider geographical and faunistic area in the hope that sufficient support will be forthcoming to justify the enterprise and to meet the undoubted needs of this important region. Several universities and many societies and associations devoted to the study of natural history and archæology are included in the area, and it is indeed surprising that past attempts to maintain a journal which would link up these various activities should have met with so little success. To judge from the contents of the first number, the scope of the journal is varied and wide. Mr H F. Barnes contributes a valuable paper on the crane-flies of Carnarvonshire, in which both the geographical distribution and ecology of the species are considered. Prof. Boycott records the occurrence of algal cysts in the tissues of *Limnæa peregra*, a hitherto undescribed association, the elucidation of which will be awaited with interest. News from the universities, local societies and museums, résumés of current periodical literature, book notices and reviews, and interesting notes and records, go to the make-up of an interesting number. The journal is attractively produced, and will be issued for the present in quarterly numbers at a subscription rate of 7*s* 6*d*. per annum. If the standard of this number can be maintained there should be no doubt of the success of the venture, and it is to be hoped that the editor, Mr. A. A. Dallman, will meet with that financial support which his enterprise deserves.

Popular Astronomy for May reproduces a short article distributed recently by Science Service—the scientific news agency of Washington, D.C., U.S.A.—in which it is stated that, according to information received from Leningrad, the 41-inch objective of the telescope being constructed at Newcastle-on-Tyne for the Simeis Observatory, in the Crimea, had failed to meet the optical tests specified and was absolutely useless. At the time when this report was received we sent a copy of it to Messrs. Sir Howard Grubb, Parsons and Co., and we are now informed that the statement is entirely erroneous. As a matter of fact, the degree of separation between the components of the object-glass and the radii of curvature were only officially agreed upon between the authorities at Polkovo and Sir Howard Grubb, Parsons and Co. at the end of April of this year, and until these were decided very little grinding could be done. One of the flint components of the objective was exhibited by the Parsons Optical Glass Co. at the Wembley Exhibition, and its quality and homogeneity were almost perfect. As, however, the company wishes in so large a lens to approach so closely as possible to perfection, several alternative flints have been cast, and others are in course of preparation, the best will be selected from them for the Russian telescope. The crown component is a perfect piece of glass, and is undergoing a final and more extensive process of annealing than has hitherto been employed in the manufacture of large telescope objectives. Prof. Kriloff was recently shown in England the report issued by Science Service, and we are authorised to say that "it is a complete misstatement of the matter." He adds: "The lenses for the 41-inch telescope have not yet been ground to curves, but only preliminary calculations of the curves have been made. There can therefore be no question of a test of the complete object-glass having been made and failed. The representatives of the Polkovo Observatory are now testing the discs intended for the object-glass in order to select the most perfect among several which are available."

IT is reported that Miss D. A. E. Garrod of the University of Oxford and member of the Institut de Paléontologie humaine, has discovered fragments of a human skull, including the frontal bone, associated with Mousterian implements at the Devil's Tower, Gibraltar, where she has been carrying on excavations for some time. The fragments were discovered at a depth of about 10 ft. and exhibit characters similar to those of the well-known Gibraltar skull which belongs to the Neanderthal group. If this is correct—and the preservation of the frontal bone, if it is complete, should place it beyond question—it affords a welcome corroboration of the attribution of this skull to the Mousterian period. Miss Garrod had already announced her intention of returning at an early date, and her arrival will be awaited with keen interest by anthropologists. The circumstances of the discovery will no doubt be fully described in the paper which Miss Garrod is to read at the forthcoming meeting of the British Association at Oxford.

MR J. R. JACKSON, Deputy Chief Veterinary Officer of the Ministry of Agriculture and Fisheries, has been appointed Chief Veterinary Officer in succession to the late Sir Stewart Stockman.

PROF A. BRACHET, professor of anatomy in the University of Brussels, has been elected a member, and Prof. Ch. Pérez, professor of zoology in the University of Paris, a foreign associate, of the Royal Academy of Sciences, Letters and Arts (Scientific Class) of Belgium.

THE annual phytopathological meeting of the British Mycological Society will be held at Harpenden, Herts, on July 3. Visits will be paid to the Pathological Laboratory of the Ministry of Agriculture and the Mycological Department of Rothamsted Experimental Station. The secretary, Mr. E. M. Wakefield, Herbarium, Royal Botanic Gardens, Kew, desires intending visitors to inform him not later than June 26.

WE are glad to learn from Mr C. Cuthbertson, F.R.S., that his request for 20 c.c. of krypton and xenon (NATURE, May 15, p 699) met with a ready response. He received several sympathetic replies, while M. Lepape, of the Collège de France, offered a supply of the gases at a very reasonable cost, and they have now reached London by aeroplane.

THE following officers were elected at the anniversary meeting of the Linnean Society held on May 27: *President*, Dr. A. B. Rendle; *Treasurer*, Mr. Horace W. Monckton; *Secretaries*, Dr. W. T. Calman (Zoology) and Mr. John Ramsbottom (Botany). *New Members of Council*: Mr. Reginald Cory, Prof. J. Stanley Gardiner, Prof. E. S Goodrich, Dr. E. Stuart Russell, and Dr. E. J. Salisbury.

THE Institution of Electrical Engineers is celebrating the jubilee of the telephone on June 24, when a luncheon will be held at the Hotel Cecil, Strand, London, W.C 2 In the afternoon Sir Oliver Lodge will deliver a lecture on "The History and Development of the Telephone" in the lecture theatre of the Institution. The lecture will be preceded by the presentation of the Faraday Medal to Col. R. E. B. Crompton. The annual conversazione will be held at the Science Museum, South Kensington, London, S.W.7, during the same evening.

WE have received a letter from Dr. L. A. Kulik of the meteorite department, Mineralogical Museum, Academy of Sciences, Leningrad, U.S S.R., pointing out that the earth passed very close to the path of Pons Winnecke's comet on June 30, 1908, and will do so again on June 27 of this year. He states that on that date in 1908 many meteors were observed and also night luminous clouds, which may have been associated with the approach of the earth to the comet's path. He asks that particulars of observations of any such phenomena this year may be sent to him.

THE spring meeting of the Prehistoric Society of East Anglia will be held at the Royal Anthropological Institute, 52 Upper Bedford Place, on Tuesday, June 22, at 2.30 P.M. Mr. A. Leslie Armstrong will be in the chair, and will give a short account of his recent work of excavation in the caves at Creswell Crags, from which his researches in previous seasons have produced valuable material bearing upon the northward extension of upper palæolithic settlements in England. Among other communications, a discovery of worked flints at Beer, Devon, will be described by Mrs. Mac Alpine Woods, and Mr. H. Rainbow will present some notes on an iron socketed celt from the Thames.

THE ninety-fourth annual meeting of the British Medical Association will be held at Nottingham on July 16-24. The incoming president, Mr. R. G. Hogarth, will deliver his presidential address on July 20, and a popular lecture will be given by Prof Leonard Hill on July 21. The annual exhibition of surgical appliances, foods, drugs, and books will be held on July 19-23. The honorary local general secretary of the annual meeting is Mr. A M. Webber, 2 The Ropewalk, Nottingham. The provisional programme includes the following discussions, the opener's name being given in brackets: The treatment of cancer by lead injections (Dr. W. Blair Bell), relationship of streptococci to scarlet fever and its complications (Dr R A. O'Brien), food deficiency conditions in relation to preventable illness (Dr. S. J. Cowell, Dr. Helen M. M. Mackay, Sir Percy Bassett-Smith, and Dr. J. Wheatley), and the physical and mental effects of fatigue and monotony in modern industrial work.

IN connexion with his article on "Fossil Insects in Relation to Living Forms," published in NATURE of June 12, p. 828, Dr. R. J. Tillyard asks us to state that the very beautiful illustrations were prepared as reductions from the very fine photographic enlargements of the fossils made by Mr W. C. Davies, Curator of the Cawthron Institute, Nelson, New Zealand.

THE Cambridge University Press announces the forthcoming publication, in two volumes, of "Aphasia and Kindred Disorders of Speech," by Dr. H. Head. Vol. 1 will contain a historical sketch of the progress of knowledge in this subject, an account of the new methods of examination employed by the author and the results of his clinical observations. Further sections are devoted to the question of cerebral localisation of function and to novel theoretical conclusions as to the nature and causes of aphasia. Vol. 2 will deal with a series of clinical reports of cases.

THE botanical library of the late Mr. J. S. Gamble, F.R.S., is to be sold by auction on Friday, June 25, at 115 Chancery Lane, W.C.2, by Messrs. Hodgson and Co. The works to be offered for sale include Van Reede's "Hortus Malabaricus," 12 vols.; Wallich's "Plantæ Asiaticæ Rariores," 3 vols.; Royle's "Botany of the Himalayas," 2 vols.; "Annals of the Royal Botanic Garden of Calcutta," 12 vols; and Watt's "Economic Products of India," 6 vols. in 9.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in geography at the University College of the South-West of England, Exeter—The Registrar (June 26). A senior demonstrator and a demonstrator of physiology at St. Bartholomew's Hospital Medical College—The Dean of the College, St. Bartholomew's Hospital, E.C.1 (June 28). Assistant lecturer in engineering, County Technical School, Wednesbury—Director of Education, County Education Offices, Stafford (July 6) A professor of mechanical engineering at the Manchester Municipal College of Technology—The Registrar (July 8). An assistant lecturer in physics in the University of Sheffield—The Registrar (July 8) A head of the mechanical engineering department and a head of the electrical engineering department of Robert Gordon's College, Aberdeen—The Secretary and Registrar (July 12). Lecturers in agriculture, chemistry, and economics at the Imperial College of Tropical Agriculture, Trinidad—The Secretary of the College, 14 Trinity Square, E.C.3 (July 13).

ERRATUM.—In NATURE for June 12, p. 839, last paragraph, for "short" read "Shortt."

Research Items.

ROCK PAINTINGS ON THE WEST COAST OF THE GULF OF CARPENTARIA.—Mr. Norman R. Tindale in vol. 3, part 3, of the *Records of the South Australian Museum*, in the course of the second part of his account of the natives of Groote Eylandt and the west coast of the Gulf of Carpentaria, discusses their pictorial art. They use four pigments—red, yellow, black and white. Three of these—white kaolin, yellow, a limonite and black, manganese oxide and clay—are found locally. The red pigment—a hæmatite—is obtained by trade from the interior of Arnhem Island in the country of the Rembarunga, who pass it on to various other tribes. It is much valued and used in colouring utensils, weapons, ceremonial objects, canoes, apparel, ornaments and persons. The pigments are produced by rubbing on a stone. The starchy liquid obtained by bruising the fleshy stems of various tree orchids is sometimes used instead of water for mixing, because it gives adhesive qualities to the colours. Brushes are either chewed sticks, pieces of bark, or pieces of leather one inch long fastened to a handle of the same length with gum or wax. Two or more colours are sometimes superimposed or mixed to give a special effect or tint, such as salmon colour. The designs are in most cases built up of dots and straight lines with occasional circles and other geometric combinations. No meaning is now known for the geometric designs, but sometimes the well-defined form of an animal is the central object. Tracing designs and pictures on the ground is a common amusement around the camp fire. Tracks of animals and birds are also cleverly imitated. During the enforced leisure of the wet season, designs are painted on the walls of rock-shelters and of the bark huts. The Ingura cave- and hut-paintings usually relate to sailing canoes, dugongs, turtles, fishes, parties of human figures, and hunting scenes. Hands are depicted by coating the rock with red clay on which the hand is imposed and used as a stencil, the outline being shown in white with kaolin.

SONGS OF THE COPPER ESKIMO.—In a further instalment of the Reports of the Canadian Arctic Expedition, 1913–18, forming vol. 14 of the series, Mr. D. Jenness, with the assistance of Miss Helen H. Roberts, deals with the songs collected by the Southern Party which worked on the Arctic mainland and adjacent islands, in this case at Barnard Harbour, in Dolphin and Union Strait, their headquarters. The songs were recorded by phonograph, and with some difficulty, as the Copper Eskimo had not previously been acquainted with the instrument, and thought a spirit was reproducing their words. It is, in fact, their custom not to sing their songs out of doors but only under cover, because they believe that in the former case a spirit might carry away their words and rob them of the breath of life. The songs recorded were, for the most part, dance songs and some incantations. The latter, though fewer than the dance songs, are sufficiently numerous to indicate that they form an important element in Eskimo life. All given here are incantations for fine weather, except one which is for healing the sick. The dance songs are essentially topical. They fall into two classes, the *pisiks*, in which the principal performer beats the drum, and the *atons*, in which one of the chorus of dancers beats the drum and the principal dancer's hands are free. A study of the distribution and comparison of the dances themselves suggests that the two dance forms were originally quite separate, and that the *pisik* is the characteristic form among the eastern branch of the race, predominating among the Copper Eskimo, and being known in the Mackenzie delta, while the *aton* belongs peculiarly to the western division, is the prevailing form in the Mackenzie delta, and exists in a minor form among the Copper Eskimo.

CRUSTACEA OF THE THAMES ESTUARY.—A report on the sea fisheries and fisheries industries of the Thames Estuary, prepared by the late Dr. James Murie, was published in 1903 by the Kent and Essex Sea Fisheries Committee. Mr W. Pollitt, Librarian and Curator of the Public Libraries and Museum, County Borough of Southend-on-Sea, writes: "Of Part II of this work only the first section (36 pages) was set up in type, and it is not probable that the work will be completed." He has for disposal practically the whole of the copies of this section of Part II and will be glad to forward one or more to any person interested. There should be many people wishing to avail themselves of this offer as the section in question is a continuation of Dr. Murie's notes on the Crustacea of the Thames Estuary, containing valuable local information gathered from various sources as well as much original observation. These pages deal entirely with prawns and lobsters. The author adds to his excellent account of the common prawn *Leander serratus* in Part I descriptions and details of distribution with notes on breeding of three others—the white prawn *L. squilla*, Leach's prawn *L. adspersus*, and the ditch prawn *Palaemonetes varians*, directing attention to the fact that the prawn family is more widely distributed in the Kent and Essex area than has been generally supposed. In 1923 Gurney (*Proc. Zool. Soc.*, London) gave a good general survey of all these together with *L. longirostris*, in which he states that *L. adspersus* (= *Palaemon Leachii*) is "by no means an abundant species," although "it is taken in some numbers by the eel catchers." Both this species and *L. squilla*, the so-called "small prawns," are, according to Dr. Murie, frequently captured in the Thames Estuary together with the larger species, and although no separate fishery is established for these they are certainly of some commercial value. It would be a great pity if this unfinished paper were lost owing to lack of knowledge of its existence.

THE OYSTER-SHELL SCALE INSECT.—Although the oyster-shell scale, *Lepidosaphes ulmi*, has been known as a pest in the United States since 1794, only recently has any investigation been made of the differences between those found on apple and those on other host plants, *e.g.* lilac. Grace H. Griswold (Memoir 92, Cornell Univ. Agr. Exp. Stat., 1925) has made a comparative study of the two forms. The author points out the differences in morphological characters: second stage larvæ from the apple have fewer dorsal glands than larvæ from lilac; the pygidia of adult females from the apple have fewer circumgenital pores, insects from the apple are slightly smaller, and observations on the development during five years show that the apple insects are in advance of those on lilac at every stage. At Ithaca, where the work was done, both forms have only one generation. The lilac form is found also on shade trees. Transfer-experiments have shown that insects from apple can complete their development on lilac and on other host plants, but in no case did insects of the lilac form live any length of time on apple or on pear. Whether the differences between the two forms are sufficient to warrant the erection of a new species or only of a new variety for the form on lilac is left in abeyance. Observations are added on the most common chalcid parasite, *Aphelinus mytilaspis*, which attacks the oyster-shell scale.

ORGANISATION IN PROTOZOA.—In an article on organisation and variation in Protozoa (*Sci. Monthly*, April 1926), Prof. G. N. Calkins points out that organisation in Protozoa is as definite and fixed as in any type of living things; that it is represented by visible structures which are not only temporary but are also subject to changes with metabolic activities. These visible structures are formed anew at conjugation or at fertilisation generally, or when parthenogenesis occurs, and they are formed anew at periods of cell division. With fertilisation, with endomixis, and with cell division there is evidence that the cell is completely reorganised and that the fundamental invisible organisation starts 'with a clean slate' after every one of these deep-seated phenomena. Gametes, when formed, are so modified that without fertilisation they cannot live, and ciliates without conjugation or endomixis in the majority of cases will live only with weakening vitality which ends in death.

INHERITANCE OF EGG-COLOUR IN BIRDS.—Certain writers have held that xenia exists in birds, *i.e.* that when species or strains differing in egg-colour are mated, the eggs laid will show changes in colour in the direction of that of the breed to which the male belongs. This has been recorded in crosses between canaries and finches, and also among domestic fowls. In an investigation which included a careful study of the variability of egg-colour in Leghorns (eggs nearly white) and Orpingtons (eggs brown), Kopec (*Journal of Genetics*, vol. 16, No. 3) concludes that no such effect exists. He finds a seasonal variation in egg-colour, the shell being darker during the winter months and lighter in summer. The colour also depends upon the age of the hen and whether she has previously been laying. Curves of egg-colour from the reciprocal matings, compared with control hens without mating, correspond closely in their seasonal variation. Repeated injections of Orpington testicular tissue into Leghorn hens and vice versa also produced no effect. It is concluded that seasonal variation in colour will probably account for the previous supposed observations of xenia.

LAVENDER OIL FROM THE IRISH FREE STATE.—Prof. J. Reilly, Mr. P. J. Drumm and Prof. C. Boyle of University College, Cork, have collaborated in a preliminary chemical examination of lavender oil distilled from plants of lavender grown at Cork and compared with oil obtained from English, French and Spanish sources. These workers have definitely in view the establishment of the cultivation of lavender and distillation of the oil as an Irish industry, and regard their preliminary laboratory experiments as hopeful in result and worthy of extension. Their paper is published in the *Economic Proceedings of the Royal Dublin Society*, vol. 2, No. 16, April 1926.

STARCH AND TRANSLOCATION.—We are beginning to realise how little is known about this problem. Starch is formed in the green assimilating tissue and in reserve organs of plants, but starch grains are also found in the parenchyma associated with the vascular strands. This latter starch is often spoken of as 'transitory starch' (the *wanderstarke* of the Germans), and the view has been taken that its formation by temporarily removing sugar from the cell sap, steepens the concentration gradient of the sugar along the vascular channel, which is assumed to be the driving force in the diffusion of the sugar. E. G. Pringsheim, basing himself in part upon the recent paper of his pupil, K. Bernhauer (*Beih. z. botan. Zentralbl.* 41, p. 84, 1924), reveals the inconsistencies of this point of view and its lack of experimental support in a brief discussion of the subject in *Die Naturwissenschaften* for April 9. Tollenaar has recently calculated that as starch appears in the chloroplasts of the tobacco leaf after five minutes' exposure to light, starch formation must follow when the concentration of sugar in the sap is increased by at most 0·01 per cent. On the other hand, as starch formation does not occur in a darkened strip of this leaf when the rest of the leaf is continuously illuminated for three days, apparently migration of sugar from the illuminated region is unable to raise the concentration in the darkened region by 0·01 per cent. in this time. Either, then, sugar is not actively translocated, or starch-formation is not simply determined by the sugar concentration; in any case the phenomena of starch formation and hydrolysis in the plant require much closer experimental analysis. Pringsheim seems to incline to the view that starch formation in starch leaves is of advantage as preventing an increase of turgor, which in sugar-storing leaves may reduce photosynthetic efficiency.

THE REVILLAGIGEDO ISLANDS.—Last summer the California Academy of Sciences, with the help of the U.S. Navy Department, sent an expedition under Dr. G. D. Hanna to the little known Revillagigedo and Tres Marias Islands off the Pacific coast of Mexico. Dr. Hanna gives a general report on the work of the expedition in the *Proceedings of the California Academy of Sciences*, 15, pp 1-113. The Revillagigedo Islands have never been uninhabited, although their possibilities as a sheep farm have been considered more than once. There has thus been no interference with the natural fauna and flora. The Tres Marias Islands, which lie relatively near the mainland, are inhabited. The narrative of the expedition refers to many interesting collections but contains no summary of the result of the expedition as a whole. This is promised in a series of further reports.

SALINITY OF NILE WATER.—Some investigations by Mr. R. Aladjem on the seasonal variation of salinity of Nile water at Giza are published in Bulletin No. 69 (Technical and Scientific Service, Cairo). Mr. Aladjem shows that the alkaline portion of the dissolved matter in the Nile is small and is seldom greater than 18 parts per million. Moreover, he shows that the low Nile contains more sodium and potassium and the high Nile more calcium and magnesium. This appears to indicate that water laden with alkaline bicarbonates drains into the river from the subsoil during low water, or that some calcium and magnesium of the bicarbonates are thrown down at that stage of the river. The irrigation water used in Egypt thus contains more calcium and magnesium than sodium and potassium, which prevents the soil becoming alkaline, compact, impermeable and comparatively barren. Detailed tables give the analyses of the Nile water at Giza throughout 1924 and 1925.

CRETACEOUS AMMONOIDS OF EASTERN AUSTRALIA AND JAPAN.—The Ammonoids of the Rolling Downs formation of eastern Australia have been studied by Dr. F. W. Whitehouse (*Memoirs of the Queensland Museum*, 8, 3, 1926, p. 195, pls. 34-41). They are especially characterised by the profusion of heteromorphic forms, hitherto referred to Crioceras, for which several new genera are instituted. The author has been able to recognise zonal horizons in the Rolling Downs formation belonging to the Hauterivian, the Aptian and the Upper Albian. Ammonites from the Chalk of Japan are described by H. Yabe and S. Shimizu (*Science Rep. Tôhoku Imp. Univ.*, Sendai, ser. 2, Geol. 8, 4, 1925, p. 125, pls. 30-33); they belong to the family Prionotropidæ, which is rather rare in Japan.

Permian Insects.—In part 7 of his work on the Permian insects of Kansas (*American Journ. Sci.*, 11, 1926, p. 133), Dr. R. J. Tillyard deals with the Mecoptera or scorpion-flies, an order with comparatively few representatives at the present day but not uncommon as a fossil, especially in the Upper Permian and the Mesozoic. From the Lower Permian of Kansas the author describes sixteen species belonging to six new genera. From what is known of the climatic conditions of Kansas in Permian times, Dr. Tillyard infers that the interpolation of the pupal stage in the life-history of the scorpion-flies was not for protection against severe cold, but that drought and heat were the determining factors. Since the Mecoptera are well represented in the Lower Permian, there can be little doubt that earlier forms existed, and the author believes that the Upper Carboniferous genus Metropator, hitherto placed in the Protorthoptera, is a true Mecopteron and a direct ancestor of some of the Lower Permian forms.

Fibrous Crystals of Sodium Chloride.—In further reference to notes which have appeared in Nature (October 24, 1925, p. 610, and March 13, 1926, p. 395) we have received a communication from Mr W. A. Macfadyen, Longships, Capel-le-Ferne, near Folkestone, enclosing some very beautiful specimens of fibrous and banded crystals of naturally occurring rock salt. One set of these crystals, about 2 cm. in length, is stated to be common in Egypt as secondary infillings in small fissures close to the weathered surface of the ground, especially in the soft sandy limestones and green shales of Miocene age. These specimens were found at Shallufa, ten miles north of Suez. The other crystals, which form fibrous bundles 10 cm. in length closely resembling sal ammoniac, were found near Gebel Gharamul in the eastern desert of Egypt, and are said to form the domestic salt supply of the Ma'azah Bedouin. The crystals are extremely beautiful, and are evidently parallel growths, but the facets are not sufficiently sharp to give a clear indication of the direction of the axes.

Dielectric Constants.—The issue of the *Physikalische Zeitschrift* for April 15 contains a summary of more than forty pages, by Dr. O. Bluh of Prague, of the practical and theoretical work done on dielectric constants during the past fourteen or fifteen years. So far as the theory is concerned, progress has been mainly in the application by Debye and others of the idea that each molecule is a dipole with a positive and a negative electric charge, first put forward by Sutherland in 1895 to explain the effect of temperature on the dielectric constant and the existence of anomalous dispersion. On the practical side, older methods of measurement of the constant have been improved, and new methods, generally depending on the use of the triode valve, have been devised. Gases and vapours have been investigated to a higher degree of accuracy, and the effects of temperature and pressure on the constants of liquids determined between 87° and 433° absolute and up to 200 atmospheres. Solutions of liquids in each other and of solids in liquids give results so divergent that no general laws have been evolved, but there seems little doubt that the dielectric constants of solutions play an important part in biological processes. In the case of solids the advances have been less extensive.

The Preparation of Levulose.—No. 519 of the *Scientific Papers of the Bureau of Standards*, by R. F. Jackson, Clara G. Silsbee and M. J. Proffit, describes the preparation of levulose, the sweetest of the sugars, from the Jerusalem artichoke and the dahlia, which contain considerable amounts (8·5 to 23·8 per cent. and 9·3 to 14 per cent. respectively, in the samples examined). After extraction the plant juices, consisting largely of polysaccharides, are converted to sugar by acidifying, and methods of purification are given in the paper. Crystallisation, a process previously requiring the use of absolute alcohol or glacial acetic acid, may be carried out by carefully controlled cooling and seeding of the aqueous syrup.

Electrometric Titration of Halides.—The estimation of halides by electrometric titration is described by W. Clark in the *Journal of the Chemical Society* for April 1926. A calomel cell is joined by means of an ammonium nitrate bridge to a tube dipping into the solution under investigation and silver nitrate is added drop by drop, while the electromotive force is read by means of a potentiometer. The end point is indicated by the maximum rate of change of E.M.F. With mixed halides, the breaks in the E.M.F. curves indicating the respective end points are displaced by solid solution effects. The addition of ions strongly adsorbed by silver halides, such as barium and sodium nitrates in 5 per cent. solution, gives correct end points for a wide variation in proportions of the constituents of the mixtures. The results of the work are applied to the examination of the materials used in the manufacture of photographic emulsions.

Radio Wave Propagation.—Radiotelegraphists have known for some years that when very short wave-lengths are used for transmission, the intensity of the received signals decreases as the distance from the transmitter is increased until it is too small to be observed, the distance then being of the order of one hundred miles. As the distance is further increased the signals are too faint to be detected over a well-defined interval. At a greater distance the signal strength rises to a maximum value and finally gets weaker gradually. The distance of the transmitter from the further edge of the interval of silence is generally called the 'skip' distance. This distance increases rapidly as the wave-length is diminished. For a specified wave-length it is longer at night than in the day, and it is longer in winter than in summer. Dr. Hulburt, in the *Journal of the Franklin Institute* for May, gives an interesting theory of radio wave-propagation round the earth which has the merit of giving simple explanations of most of the observed phenomena. He makes the assumption that there is a Kennelly-Heaviside layer in the upper atmosphere which is rich in electrons. From experiments carried out in the research department of the American Navy, it appears that for wave-lengths of 16, 21, 32 and 40 metres, the skip distances during daylight are 1300, 700, 400 and 175 miles respectively. The night skip distances are more than twice as great. The author considers that this phenomenon proves that the transmitted wave consists of two parts, one of which clings to the surface of the earth and decreases rapidly in intensity, while the other moves in an upward direction and returns after refraction at the conducting layer to the earth. Making certain assumptions as to the connexion between the electron density and the height above the earth, he concludes that during the daytime the electron density is a maximum at a height of between 70 and 150 miles. At night-time, when the sun's rays are absent, recombination of ions and electrons will occur. The electron density, therefore, becomes less and the radio rays must search higher altitudes before being turned back to the earth.

Activities of the South African Museum.

In the first report that he presents as director of the South African Museum, Cape Town, Dr. Leonard Gill insists on the need for more space. In spite of this the staff goes on collecting An expedition was made to the Kaokoveld in South-West Africa, carrying previous work as far as Zesfontein, where lives the decaying remnant of the Topnaar Hottentots; a further expedition was starting for the country north of Zesfontein, of which the natural history is almost unknown. Other expeditions were to Gordonia, between Upington and the border of South-West Africa, and to the Langebergen behind Swellendam, in continuation of the exploration of the mountain ranges in the south-west of the Cape Province. Various traces of early human occupation were also investigated. The whole report bears witness to activity in many directions in spite of crowding and the small number of the staff.

The output of the museum during the past year is represented by the issue of six parts of the *Annals of the South African Museum*. The old-established plan by which the papers are classified more or less strictly into homogeneous volumes (botanical, geological, entomological, etc.) is awkward in that it keeps so many volumes open for rather long periods, but it is decidedly convenient when once the volumes are finished and bound. The large amount of the year's work refers to South-West Africa (the former German territory), which is explained by the fact that a number of expeditions from the Museum have been at work in that territory in recent years. They have gone there by special invitation of the local Administration and with the aid of grants from it—an unusual example of enlightenment which deserves recognition. We are informed that several further papers on the flora and fauna of South-West Africa are already in type. Considering the fewness of their numbers, the amount of scientific work turned out by the members of the Museum staff themselves is noteworthy. It is in part due to the fact that the Museum itself is still awaiting its urgently needed extensions. Thus 'gallery work' is largely paralysed—a bad thing for the public, though it allows the staff more time than they would otherwise have for research.

Thanks mainly to the persistence and energy of Dr. J. D. F. Gilchrist, our knowledge of the marine fishes of South Africa, which was very inadequate some thirty years ago, is now approaching completion in regard to the characters of the species and their distribution. At the beginning of the century a survey of the shallower waters, up to 50 fathoms, of the Cape seas, succeeded in bringing to light many new forms, and also in discovering new fishing grounds. During the last five years a further survey has been carried out on a larger scale, its operations extending to Natal and including the deeper waters. Large collections from Natal made by Dr. Warren in 1906, and more recently by Messrs. Romer Robinson and H. W. Bell Marley, have been sent to the British Museum (Natural History) and have been described.

The present is an appropriate time for the results obtained to be brought together, and Mr. K. H. Barnard's memoir (*Annals of the South African Museum*, vol. 21, Pt. 1, "A Monograph on the Marine Fishes of South Africa, Part 1") should be of considerable service to ichthyologists and others interested in the fish fauna of South Africa. The scope of the work is much wider than the title would suggest, as it includes not only the fishes of the coasts of the Union of South Africa, but also those of East and West Africa northwards to 15° S., and oceanic fishes that have been recorded from within 200 to 300 miles of the east and west coasts and 400 miles southwards.

The fishes of Natal are mostly tropical, whereas those of the Cape are temperate and show Mediterranean affinities; we think that when Mr. Barnard comes to the perches, gobies, blennies, etc., which are so numerous in the Indo-Pacific region, he may regret that he has taken in the east coast northwards to Mozambique, and that only the fact that this area has not been too well explored will save his memoir from being overburdened with tropical species.

A number of papers enumerating and describing species belonging to various groups of S. African insects have been issued during the year. In a country so extensive as South Africa, animal life is abundant and of great interest, and we look forward to the time when the Government of that country will see its way to publish an authoritative "Fauna of South Africa." A model for such a work will be found in the "Fauna of India" series issued by the Secretary of State for India.

In vol. 19, Pt. 4, of the *Annals of the South African Museum*, 1925, Mr. L. B. Prout describes certain new species of Geometrid moths from material that has accumulated since his previous paper on the subject (*Annals S.A. Museum*, 1917), two well-executed coloured plates accompanying this article. In the same part Mr. F. W. Edwards deals with a number of species of Mycetophilidæ and Bibionidæ contained in the Museum collections. The most interesting feature brought to notice is the discovery of a living species of Heterotricha, a genus which has only been previously known in a fossil condition contained in Baltic amber.

Part 1 of vol. 23 of the *Annals* of the Museum is devoted to an extensive illustrated memoir on the Hemiptera of South-West Africa by Dr. A. J. Hesse. It lists all the known species of Heteroptera and Homoptera from that region, excepting those belonging to the families Jassidæ, Aphididæ, and Coccidæ. The Hemiptera of South-West Africa have been little studied in the past, and it is perhaps not surprising that as a result of the Museum expeditions up to 1924, together with the efforts of other collectors, 11 new genera and 58 new species are established. The most extensive additions pertain to the families Reduviidæ (3 new genera, 11 new species) and Fulgoridæ (5 new genera, 17 new species).

"Palæontological Papers published in conjunction with the Geological Survey" were added to the natural history publications of the South African Museum about a quarter of a century ago, thus extending their scope and usefulness. In the matter of the Mollusca, the non-marine early received attention, and if the papers have been few in number they have been important in matter. So early as 1900, Mr. W. E. Collinge had two papers on the slugs of South Africa; while one whole big part was devoted in 1912 to Major Connolly's valuable "Reference List of South African Non-marine Mollusca." This last was a piece of systematic work which has great value, on account of its carefully compiled synonymy and nomenclature, to others besides the immediate circle of those for whose benefit it was drawn up.

Lately another important molluscan paper, this time anatomical in character, has appeared (vol. 20, Pt. 4) from the pen of that past master in molluscan anatomy, Mr. Hugh Watson. He deals with "The South African species of the Molluscan genus Onchidella," and in addition to their anatomy discusses their affinities with the species found in other parts of the world and the geographical distribution of the genus. Eight excellent plates from the author's pencil and camera, with their keys and a map, are appended in illustration.

A first contribution to "Reports on the Marine Mollusca in the Collections of the South African Museum," by J. R. le B. Tomlin on the family Turritellidæ, accompanies the preceding. What it wants in length this paper makes up in importance. It is a purely systematic paper, but describes and illustrates two new species of Turritella, besides introducing a new term, "scalarescence," to denote a tendency to looser coiling sometimes exhibited in these shells. Conchologists will assuredly look forward to meeting with further such contributions in these *Annals*.

Vol. 22, Pt. 1, of the *Annals* contains five papers on South African fossils and fossil woods. Africa, especially in its more central parts, is still in large measure the undiscovered land so far as its extinct animals are concerned. The veil has been lifted a little on its Mediterranean borders chiefly through the work of the late Dr. C. W. Andrews. On the east coast, where the remains of the largest forms of extinct reptiles have been discovered, there is possibility of great further discovery. In the south our knowledge is fuller and of longer standing, though even here it must be recognised that the known and described forms can be only the merest fraction of the animals that lived and evolved there, and exploration is far from being finished. In South Africa is the well-known Karroo series of formations, which are perhaps the most important centre of reptilian and amphibian evolution that has as yet been explored. The earlier classical works of Owen, Huxley and Seeley are, many of them, based on specimens from here. So are the more recent classics of Watson and Broom.

In reviewing the labours of various researchers in this field, the assistance rendered by the Trustees of the South African Museum and by the Geological Survey of South Africa must not be underestimated; the *Annals of the South African Museum* contains many important papers on vertebrate palæontology by Broom and S. H. Haughton. A recent number contains the thirteenth paper by the latter author on extinct reptiles and amphibia of the district. The format of the publication, the typography, and the production of the plates are all excellent.

The grasses of Namaqualand, Damaraland, and Ovamboland are listed by Miss S. Garabedian (*Annals*, vol 16, Pt. 2); representatives of most of them are now in the Herbarium of the South African Museum. It is hoped later to issue a list of the grasses of the mountainous country on the west called the Kaokoveld and the sand-dune belt between the mouths of the Orange and Cunene rivers, known as the Namib. Genera are arranged according to the key given by Dr. Stapf in the "Flora of Tropical Africa." Under the different species there are often notes as to the value of the grass as fodder, or its disadvantage as a weed in cultivation or as injurious to grazing stock.

Experimental Investigation of Dengue.

When the Medical Research Board was organised for the Philippines in 1922 at the recommendation of the Surgeon-General of the United States Army, the investigation of the etiology of dengue was one of the most important problems to be studied. Lieut.-Col. J. F. Siler, Majors M. W. Hall and A. P. Hitchins were appointed, and commenced their labours in 1924 at Manilla, and in the *Philippine Journal of Science* of Jan.-Feb. (vol. 29, Nos. 1-2, pp. 304 + 8 plates) they describe their results.

The investigation was most carefully planned and most thoroughly carried out on the model of so many other etiological problems conducted by our American confrères. A very complete history of the disease is first given; the earliest accurate descriptions of dengue in epidemic form are from Cairo in 1779, from Batavia and Java in 1779, and from Philadelphia in 1780, showing that then it was widely distributed, and it still remains so, but there is reason to believe that its original home was in tropical America. Compared with yellow fever, to which the disease has many etiological similarities, this world-wide diffusion is remarkable. Throughout these areas some of the epidemics are often classed as "dengue-like" rather than true dengue, but the authors, after most careful consideration, state that "it would appear that among themselves they differ little, if any more, than do different outbreaks of dengue, and until specific etiological evidence is available the possibility of their essential identity must be borne in mind."

The experiments detailed in this monograph were carried out in the Philippines, and were made on sixty-four American soldier volunteers to determine the transmission of dengue by means of mosquitoes: the men were in screened wards and the mosquitoes used were bred from the egg. In one hundred and eleven biting experiments made by infected females of *Aëdes aegypti* (better known as *Stegomyia fasciata*), dengue was transmitted forty-seven times.[1] All experiments with *Culex fatigans* were negative, thus not confirming the early and useful work by Graham. The filterable virus of the disease is present in the blood of the case only during the first three days of the fever, and requires at least eleven days to develop in the mosquito before it can be transmitted. The infectivity of the insect continues throughout its life but is not passed on to its progeny. It was found that 58 per cent. of those who had suffered from the disease were immune, and in the others the course was modified. The rapidity of the spread of dengue is second only to influenza, but the diseases are not mutually protective.

The results brought out by the inquiry are in striking similarity with those observed in yellow fever, and strongly suggest some group relationship. Though so far in dengue the actual cause has not been definitely demonstrated, yet spirochætal forms have been reported for both. The authors were unable to transmit the infection to animals. From a practical point of view, the authors conclude that as dengue and yellow fever are transmitted by the same mosquito and the mechanism of transmission for each is almost identical, therefore epidemics of dengue and yellow fever are subject to the same control measures; the foremost of which is the reduction of the incriminating mosquito in the affected area; secondly, the protection of patients from mosquito bites during the first three days, by adequate mosquito nets, etc., during both day and night.

The previous work of other investigators is duly recognised and acknowledged, but the research here recorded is the most thorough and admirable on the subject.

---

[1] Of the sixty-four volunteers used, dengue was produced experimentally in fifty-two, or 81 per cent.

The Storage of Eggs.

MORE than four thousand million eggs are consumed in Great Britain during the course of a year; but this number would probably be increased if satisfactory methods of storing eggs produced at the glut period in the spring with the view of their consumption later in the year were generally introduced, especially as the producers would be encouraged to increase their stock, since the demand and the price fetched would show less marked fluctuations. But for a stored egg to be the equivalent of a new-laid egg in all respects requires considerable attention to detail: the factors on which good results depend are discussed by T. Moran and J. Piqué in a recent publication of the Department of Scientific and Industrial Research.[1]

In the first place, only carefully selected eggs should be submitted to storage: they must be clean and should never have been exposed to a temperature greater than 60° F, otherwise a certain amount of development of an egg, if fertile, may have occurred, resulting in its decomposition later in the store. The quality of an egg can be judged by its transparency to light, this process of examination being termed 'candling' A new-laid egg appears clear and transparent, the yolk being vaguely seen as a rosy-tinted mass: the air chamber is small. As the egg ages it becomes less transparent, appearing slightly marbled; the yolk is movable along the long axis and the air chamber is larger. Bad eggs appear opaque on candling.

In the second place, attention must be paid to the method of packing when, as is most usual, the eggs are kept in the cold store; the material used should be clean, odourless and moisture-proof, and the eggs should be so packed that a free circulation of air can occur around them. The temperature of the store should be maintained at 32-33° F. and be kept as constant as possible: the humidity of the air should be about 80 per cent.: a higher humidity favours the growth of moulds, whilst a lower humidity increases the rate of evaporation of moisture from the eggs. Under the conditions specified the loss of weight of the stored eggs is about 2·68 per cent. over a period of seven months. A free air circulation is essential to keep them in good condition and prevent the growth of moulds. The authors consider in detail the various methods of packing eggs and of obtaining the requisite temperature and humidity in the storage chamber: they suggest that the loss of weight by evaporation may possibly be prevented by wrapping the eggs in waxed papers, although this would presumably increase their cost somewhat.

Certain changes occur in the eggs during cold storage: the white becomes more viscous, losing water both to the yolk and externally by evaporation, the yolk membrane becomes more delicate, and when the egg is broken the yolk also is very liable to break, a familiar sign of age in an egg Moreover, after about six months the eggs acquire an unpleasant taste from the packing material unless, as mentioned above, this is odourless and moisture-proof. The food value of stored eggs, however, is probably little inferior to that of new-laid: no loss of vitamin A has been detected even after long storage.

The removal of eggs from cold store requires care, since unless their temperature has risen to that of the outside air, moisture will be deposited on their surfaces, or they will 'sweat,' as it is called: and a damp egg does not fetch so good a price as a dry one. The process of 'defrosting' requires about twenty-four hours.

After a short account of the storage of eggs in water-glass or lime-water, T. Moran describes some experiments on the effects of low temperatures upon eggs. After freezing and thawing again, it is found that the liquid part of the white has increased and the viscous part decreased in amount, the extent of the change depending on the temperature reached and the time of exposure to that temperature. On the other hand, the yolk shows no change unless the temperature has fallen below −6° C., and unless freezing has actually occurred. If the egg is kept at this temperature for a sufficient length of time, on thawing the yolk is found to be in a stiff pasty condition; if the processes of freezing and thawing are carried out sufficiently rapidly this change does not occur. It appears to be due to a precipitation of lecitho-vitellin, so that re-solution does not occur on thawing: it is to be noted that simple freezing alone, at a temperature above −6° C., does not produce the change, so that it occurs at a time when the egg is frozen solid

The effect of temperature on the life of the embryo was also studied. At −6° C. the embryo dies immediately: fertility is maintained longest at 8-10° C., up to a maximum of about five weeks. The author points out in this connexion that the embryo is cold blooded up to about the twentieth day of development.

Apart from its scientific interest, the report merits the attention of all those engaged in the commercial production of eggs in Great Britain.

Commonwealth Fund Fellowships.

THE Committee of Award for the Commonwealth Fund Fellowships has made the following appointments to the twenty fellowships tenable by British graduates in American universities for the two years beginning in September 1926:

Mr. A. M. Adamson, University of St. Andrews, to the University of California, in zoology; Mr. F. N. Astbury, University of Liverpool, to Columbia University, in architecture; Mr. I. W M. A. Black, University of St. Andrews, to Yale University, in physical chemistry; Mr. F. P. Chambers, Clare College, University of Cambridge, to Harvard University, in architecture; Miss M. E. Cranswick, King's College, University of London, to Columbia University, in education; Mr. R. Fisher, Hertford College, University of Oxford, to Yale University, in economics; Miss I Gordon, University of Aberdeen and the Imperial College of Science and Technology, London, to Stanford University, in zoology; Miss H. A C. Green, Westfield College, University of London, to the University of Pennsylvania, in literature; Mr. D. B. Harden, Trinity College, University of Cambridge, and the University of Aberdeen, to the University of Michigan, in archæology; Mr. R. L. Lechmere-Oertel, University of Birmingham, to Columbia University, in engineering; Mr. K. A. H. Murray, University of Edinburgh, to Cornell University, in economics; Mr. E. P. Mumford, University of Manchester and Christ's College, University of Cambridge, to the University of California, in agriculture; Mr. M. A. Peacock, University of Glasgow, to Harvard University, in geology; Mr. G. S. Pryde, University of St. Andrews, to Yale University, in history; Mr. C. B. Purves, University of St. Andrews, to Johns Hopkins University and the Bureau of Standards, Washington, D.C., in organic chemistry; Mr. R. A. Robb, University of Glasgow, to the University of Chicago, in mathematics; Mr. W. Rule, Armstrong College, University of Durham, to Cornell University, in physics; Mr. F. J. Whelan, University College, Cork, to Harvard University, in literature; Mr. H. Williams, University of Liverpool and the Imperial College of Science and Technology, London, to the University of California, in geology; Mr. N. C. Wright, of Christ Church, University of Oxford, School of Agriculture, University of Cambridge, and the University of Reading, to Cornell University, in agriculture.

The purpose of the Commonwealth Fund is to promote mutual amity and understanding between Great Britain and the United States by offering opportunities for education and travel in the United States to young British graduates of character and ability. By terms of the Foundation it is necessary to effect a geographical distribution of Commonwealth Fund Fellowships among the universities of the United States from the Atlantic to the Pacific, without handicapping any individual in the advanced work on which he will be engaged. There were 178 applicants this year for fellowships, offering in all twenty-nine different subjects.

University and Educational Intelligence.

ABERDEEN.—The University Court has appointed Dr. Allan W. Downie to the Georgina M'Robert lectureship in pathology, with special reference to malignant diseases.

CAMBRIDGE.—The University has been officially informed that the Statutes recently made by the University of Cambridge Commissioners have been approved by the King in Council, no petition or address having been presented against them, while they were laid before both Houses of Parliament.

The members of the University Automobile Club, which has now been wound up, have offered to the University the sum of 450*l*. to endow an annual Ricardo Prize in thermodynamics.

The report of the Committee for Geodesy and Geodynamics contains some interesting references to Dr. Vening Meinesz's method of determining the value of g; based on g at Potsdam 981·274 cm./sec.^{2}, he obtained a value for Cambridge 981·265; independent observations made by Sir G. Lenox-Conyngham and Mr. Manley with the Science Museum pendulums gave the value 981·266. These pendulums are being taken by Mr. Manley this summer to Eastern Greenland in order that he may make a gravity determination near "Pendulum Islands," where General Sabine made observations in 1823 in latitude 74° 32′ 19″ N. During the absence of Sir Gerald Lenox-Conyngham in Japan at the Pan-Pacific Science Congress, Lieut.-Col. J. E. E. Craster will act as his deputy.

The report of the Director of the Solar Physics Observatory records the safe return of the instruments taken to the Crimea in 1914 to observe the total eclipse of the sun. A 6¼-inch achromatic object-glass which used to belong to Sir George Stokes has been presented to the Observatory by Mrs. Laurence Humphry.

Dr. A. C. Haddon is retiring from the readership in ethnology, and the General Board of Studies will proceed shortly to appoint a successor. The stipend is 660*l*. per annum, with an allowance of 200*l*. per annum if the reader is not a fellow of a College. The appointment will in the first instance be for three years from October 1. Applications should reach the Vice-Chancellor on or before Wednesday, July 14.

DR. W. EITEL has been nominated professor of mineralogy at the Technische Hochschule in Charlottenburg.

VACATION courses for mechanics and glassblowers, under the auspices of the "Vereeniging tot Bevordering van de Opleiding tot Instrumentmaker" (Society for the Advancement of the Training of Mechanics), Leyden, Holland, are to be held in August in the workshops of the Physical (Cryogenic) Laboratory of the University of Leyden. Particulars may be obtained from Dr. C. A. Crommelin, the Physical Laboratory, Leyden, Holland.

THE University of London Club, which was founded in 1914 for members of that University, and has its Club House in Gower Street (London, W.C.), has recently undergone a complete reconstruction. One feature of the reconstruction has been the widening of the basis of membership, so as to include graduates of other universities besides London, holders of certain diplomas granted by the University of London or its colleges, and persons who hold certain professional qualifications. A pamphlet giving an account of the Club, and of the facilities provided for the promotion of the social life of graduates can be obtained from the honorary secretary, 19 Gower Street, W.C. The chairman and members' committee of the Club will be At Home on June 22 at 8.30 P.M. to meet the Vice-Chancellor of the University of London (Prof. Gardner) and members of the Senate. The president of the Club is the Chancellor, the Earl of Rosebery.

THE sixth and last of the Watson Chair Lectures for 1926 will be delivered on Monday next at the University of Bristol at 5.30 P.M., the subject being "A Vision Postponed; Grover Cleveland's British-American General Arbitration Treaty killed by the Senate." The holder of the chair this year, Dr. Robert McElroy, professor of American history in the University of Oxford, is the authorised biographer of President Cleveland. The chair was founded in 1919, on the return of the Prince of Wales from his American tour, with the object of "knitting more closely together the bonds of comradeship between the two great English-speaking democracies, upon whose goodwill and friendship the peace of the world depends," and is of interest in connexion with the articles on "The Universities and International Peace," and on the recent awards of Commonwealth Fund fellowships, appearing elsewhere in this issue. The Watson chair has been held in succession by the late Viscount Bryce, Ex-President Hadley of Yale University, President Nicholas Murray Butler of Columbia University, Prof A. F. Pollard of University College, London, and Sir Robert Falconer, President of the University of Toronto. Prof. McElroy's general subject is "Some British-American Crises: an Interpretation." He has delivered five lectures at London, Cambridge, Manchester, Leeds and Edinburgh respectively, and in addition an address, broadcasted by the B.B.C. on May 27, on "The International Mind in the Making."

Contemporary Birthdays.

June 19, 1858. Sir Henry J Oram, K.C.B., F.R S
June 20, 1861. Sir Frederick G. Hopkins, F.R.S.
June 21, 1862. Sir Humphry Rolleston, Bart., K C.B
June 21, 1860. Dr William D. Halliburton, F.R S.
June 22, 1864. Sir Daniel Hall, K C B., F.R S.
June 23, 1843. Prof. Paul Heinrich Ritter von Groth, For Mem.R S
June 23, 1860. Sir W. Baldwin Spencer, K C M G., F R S.
June 23, 1859. Lt-Col. A W Alcock, C.I E., F.R.S.
June 24, 1854. Dr. John A. Voelcker.

Sir HENRY ORAM, Engineer Vice-Admiral, received his technical training in Devonport Dockyard and at the Royal Naval College, Greenwich. He was Engineer-in-Chief of the Fleet from 1907 until 1917.

Sir FREDERICK GOWLAND HOPKINS, known widely for his long-continued researches in chemical physiology, especially in relation to the nutrition of the human subject, has been, since 1914, professor of biochemistry in the University of Cambridge. In 1918 the Royal Society awarded him a Royal medal. He was, indeed, among the very earliest to establish that minute quantities of certain bodies, the nutritive value of which had hitherto been unsuspected, exert an enormous influence upon growth and upon normal adult nutrition. He showed that without these accessory factors—vitamins—a diet otherwise full and seemingly complete is incapable of allowing growth, and even of maintaining body weight or life.

Sir HUMPHRY ROLLESTON, who was born at Oxford, was educated at Marlborough and St. John's College, Cambridge Regius professor of physic in the University of Cambridge since 1925, he was lately president of the Royal College of Physicians.

Dr HALLIBURTON, emeritus professor of physiology in King's College, London, a post which he adorned for thirty-three years, is a Londoner He was educated at University College School, London, and University College. President of the Physiological Section at the British Association's Belfast meeting in 1902, he gave an address on the position (as it then stood) of chemical physiology.

Sir DANIEL HALL was educated at Manchester Grammar School and Balliol College. From 1902 until 1912 he was director of the Rothamsted Experimental Station. As chief scientific adviser to the Ministry of Agriculture and Fisheries, Sir Daniel has now an enlarged scope of work.

Prof. PAUL H RITTER VON GROTH was born at Magdeburg and educated at the universities of Freiburg, Dresden, and Berlin. From 1872 until 1883 he occupied the chair of mineralogy in the University of Strasbourg, leaving to become professor of mineralogy in the University of Munich and curator of minerals in the State Museum, Munich Prof. Paul von Groth is a recognised authority in chemical and physical crystallography. For many years he was editor of the *Zeitschrift fur Krystallographie und Mineralogie* In 1908 he was awarded the Geological Society's Wollaston medal.

Sir BALDWIN SPENCER, formerly (1887–1921) professor of biology in the University of Melbourne, was born at Stretford, Lancashire, and he was educated at Owens College and Exeter College, Oxford A frequent correspondent of NATURE, we note a letter of his to this journal, so far back as 1885, on "The Eggs of Monotremes," and another, in 1886, on "The Parietal Eye of *Hatteria*."

Lieut-Col. ALCOCK was educated at Mill Hill and the University of Aberdeen. For fourteen years he was superintendent of the Indian Museum

Societies and Academies.

LONDON.

Royal Society, June 10.—**A. C Downing, R W Gerard and A. V. Hill** : The heat production of stimulated nerve The method adopted is thermo-electric The thermopile contains about 300 couples of constantan-silver, made by electroplating (Hamilton Wilson), and current is recorded (to 2×10^{-11} amp) by two moving-coil galvanometers coupled by a thermal relay (Moll and Burger) The heat appears in two stages: (*a*) during stimulation there is a rise of temperature of about 7×10^{-6}° C. per second of stimulation; (*b*) in the succeeding ten minutes there is gradual further production of heat about eight times as great as in stage (*a*), which for the present we attribute to a recovery process analogous to that occurring in muscle. Total heat corresponds closely to extra carbon dioxide found by Parker for stimulated nerve. There is difficulty, however, in explaining the *resting* values of oxygen and carbon dioxide found by him and others.—**A. S Parkes** (1) Observations on the œstrous cycle of the albino mouse. The average duration of the œstrous cycle (meta-œstrus to œstrus inclusive) of the unmated albino mouse was 5·7 days. The average duration of the cycle in normal females mated with vasectomised bucks was 11 days. This postponement of the next œstrous period is considered to be due to the formation of a decidua by the uterus, on mechanical stimulus by the vaginal plug, a process which has been demonstrated in the albino rat by Long and Evans. Pregnancy follows the detection of the vaginal plug in about 70 per cent. of cases, the gestation period being 19 days in almost all cases. The effect of lactation is entirely to inhibit œstrus (apart from the immediate post-partum period) for at least three weeks if an appreciable number of young are suckled. After the inhibition due to suckling, the cycle goes suddenly back to normal, even in cases where lactation is prolonged. Unilateral ovariotomy does not appear to influence the cycle. (2) On the occurrence of the œstrous cycle after X-ray sterilisation Of 25 mice sterilised by exposure to X-rays at three weeks old, 22 experienced at least one period of œstrus when puberty was reached. In all, 53 periods of œstrus were observed in these animals, many of which exhibited a series of complete cycles of the normal length. Since none of these animals had oocytes, follicles, or follicular tissue in the ovaries, neither follicles nor *corpora lutea* appear to be essential to the occurrence of the normal cyclic activity of the uterus and vagina The œstrous-producing hormone seems to be formed by the inter-follicular tissue, though also possibly by the follicles under normal conditions.—**I. Gordon** : The development of the calcareous test of *Echinocardium cordatum*. Bilateral symmetry is apparent almost from the beginning. The complex plating characteristic of the adult is only acquired at a comparatively late stage There is no trace of teeth or of the lantern ossicles, but the perignathic girdle is represented by a single internal process. The membrane round the mouth is at first circular, but soon becomes pentagonal and then gradually alters to the 'reniform' outline of the adult peristome.—**H. R. Hewer** : Studies in colour changes of fish (ii.-iv.).—**A. V. Hill** : The viscous, elastic properties of smooth muscle Gasser and Hill found that the sudden release during an isometric tetanus of the skeletal muscle of a frog is followed by an instantaneous drop of tension, and then by a gradual re-development along a curve identical with that of the original rise when stimulation began. This observation has been repeated on the smooth muscles of *Holothuria nigra*, in which the speed of contraction is less than 1/100 of that of frog's striated muscle. The return to the tension characteristic of the new length is precisely similar in its time relations to the initial rise of tension. It is concluded that the development of a contraction during stimulation, and its re-development after release, are due to the same process, namely, the formation of an organised molecular pattern, arranged in space, whether of two or three dimensions, in the fibres of the muscles. Such a molecular rearrangement, either on stimulation or during actual shortening, is the basis of the 'viscous-elastic' phenomena found in all contractile tissues.—J. **Walton**: Contributions to the knowledge of Lower Carboniferous plants. The morphology of the genus Rhacopteris is discussed. The evidence is considered to support the view that Rhacopteris is more probably a fern than a pteridosperm. The presence of a rachis in the angle of the fork of the frond of *Sphenopteris Teiliana* is demonstrated in several specimens, and shown to have some characters of a fertile rachis of Telangium, and is interpreted as indicating the fundamentally pinnate structure of the frond. Thus probably the fructification rachis of *Telangium bifidum* was attached to the frond bearing the foliage pinnules in the angle of the main fork of the rachis, and possibly in many Lower Carboniferous fronds with apparently dichotomous rachis the frond is in reality pinnate in structure.—J. H. **Priestley** and E. **Rhodes**: On the macro-chemistry of the endodermis. —D **Keilin**: A comparative study of turacin and hæmatin, and its bearing on cytochrome The absorption spectra of turacin, hæmatin and hæmochromogen vary with the degree of dispersion of these compounds, and the bands shift from 100 to 200 Å U towards the red end of the spectrum as the degree of dispersion decreases. Artificial hæmochromogens composed of hæmatin and one of the nitrogen compounds can be prepared, showing either three or four absorption bands resembling those of cytochrome. The three components of cytochrome seem to be derived from one hæmochromogen compound, present in two distinct degrees of dispersion (b' and c'), and partly modified (a') by active process of oxidation and reduction in which these components are directly involved.—E. **Ponder**: The equations applicable to simple hæmolytic reactions. Time-dilution and percentage hæmolysis curves of experiment in especial are discussed. The action of the simple lysins on the cells is describable by expressions like those for chemical reactions of the first order, but in which is a term relating to extent of cell surface acted upon. Allowing for the fact that the reaction takes place at cell surfaces only, and not continuously throughout the system, the effect of lysins on suspensions of different strengths is explained in a simple way.—J. P. **Hoet** and P **Kerridge**: Observations on the muscles of normal and moulting Crustacea. Glycogen was found in the muscles of normal hard-shelled Crustacea Only small amounts were found in those of soft-shelled specimens of the same species. An early onset of *rigor mortis*, associated with alkaline reaction, was observed in crustacean muscles poor in glycogen. When glycogen was present in the muscles, there was a post-mortem development of acid comparable with that in mammalian muscle.—C. H. **Best** and H. P. **Marks**: Additional note on the effect of insulin on the lactacidogen content of the skeletal muscles.

Physical Society, May 28—G. **Temple**: Static and isotropic gravitational fields. By limiting the investigation to the consideration of dynamical manifolds which are static and isotropic in character, it is practicable to abandon the notation and theory of the absolute differential calculus, and to substitute some classical theorems of Lord Kelvin and M. J. Liouville. This simplified theory serves to explain the construction and solution of Einstein's field equations, and their application to the problems of planetary motion and of the deviation of light in a gravitational field. It also makes explicit the various assumptions involved in Einstein's theory.—C V. **Raman** and K. S. **Krishnan**: The diffraction of light by spherical obstacles. The diffraction of light inside the shadow, thrown by a small source of light, of a sphere and a circular disc of the same diameter, was studied, with special reference to the relative intensities of the central bright spots. With the source at about 2 metres from the obstacles, with a $\frac{1}{4}$-in. polished steel ball, the bright spot could be detected visually up to 3 cm. behind the obstacle, while with a steel disc of the same diameter, with the edges perfectly sharp, smooth and circular, the spot could be traced up to 2 cm. At small distances behind the obstacles, the spot inside the shadow of the sphere is much feebler than the disc-spot, approximating to the latter farther back from the obstacles, but even at 100 cm. remaining appreciably feebler—A. L. **Narayan** and K. R. **Rao**. On the absorption and series spectra of nickel. The absorption spectrum of nickel was investigated by the under-water spark from $\lambda 6000$ to $\lambda 2000$. In the region $\lambda 3800$ to $\lambda 2100$, 180 wave-lengths were obtained in absorption The majority of these lines were classified by Bechert and Sommer. Intensity values of the absorbed lines showed that the intensity rule and the selection rule for inner quantum numbers were accurately fulfilled. The results confirm the recent classifications of Bechert and Sommer in this spectrum. —H. C. **Hepburn**: The influence of electrolytes in electro-endosmosis. Determinations were made with certain aqueous solutions of electrolytes in glass diaphragms, and values are obtained for the interfacial potential of the Helmholtz electrical double layer. The dependence of the conductivity on the electro-endosmotic flow was investigated by measurements of the current flowing through the diaphragm during each determination, and the data used to trace the variations in the thickness and the charge of the electrical double layer by the application of a formula derived by Smoluchowski.

EDINBURGH.

Royal Society, May 24.—Malcolm **Wilson** and Miss E. J. **Cadman**: The life history and cytology of *Reticularia Lycoperdon*—one of the mycetozoa. After spore germination the blepharoplast arises from the nucleus and divides to form the centrosomes before division of the swarm-cell; four chromosomes are present Fusion takes place between motile gametes which are identical with the swarm-cells. Before fusion of the gametic nuclei several swarm-cells coalesce with the zygote and their nuclei are ultimately digested Ingestion of entire swarm-cells takes place later. The nucleus of the zygote divides repeatedly and the plasmodium is formed; eight chromosomes are present Typical meiosis takes place after the emergence of the plasmodium from the wood, and cleavage and spore formation follow The pseudocapillitium and sporangial wall are formed from masses of degenerating protoplasm—Miss C C **Miller**: The slow oxidation of phosphorus trioxide (Part 2) The production of phosphorus tetroxide by direct oxidation of phosphorus trioxide. When phosphorus trioxide oxidises slowly at low temperature in oxygen containing a trace of water vapour, the only product of oxidation is phosphorus tetroxide.—A. C. **Aitken**: On Bernoulli's numerical solution of algebraic equations. The paper generalises Bernoulli's method of finding the greatest root of an equation. The extension gives a means of computing all the roots of the equation, whether real and different, complex or multiple.

Paris.

Academy of Sciences, May 10.—**Maurice Hamy**: A particular case of diffraction of the solar images —**André Blondel**: Remarks on the establishment of the régime in electrical circuits —**A Desgrez**, **H Bierry**, and **L. Lescœur**: The fixing of sulphuretted hydrogen in the blood.—**Charles Nicolle** and **Ugo Lumbroso**: Granular conjunctivitis of the rabbit and the origin of trachoma.—**Mirimanoff** · The game of heads or tails and the formulæ of Laplace —**J Favard**: Linear differential equations with nearly periodic coefficients —**E. Gau**: The transformation of a system of two partial differential equations in involution into a unique equation of the first order — —. **Lainé**: The application of the method of Darboux to the equations $s=f(x, y, z, p, q)$.—**S Zaremba**. A transformation of the problem of Neumann —**Georges Bouligand**: The continuity of zero order in hydrodynamics.—**A. Alayrac** · The theoretical study of bird-like flight.—**Jean Chazy**: The calculation of the advance of the perihelion of Mercury under the action of the other planets. Comparison of the results of Le Verrier, Newcomb, Doolittle, and Hill. —**Henri Malet** · The invariant expressions met with in electrodynamics in systems in movement.—**Félix Ehrenhaft**. The observation and measurement of very small isolated magnets The apparatus described is capable of determining the magnetic moment of isolated magnets down to a radius of 5×10^{-6}, and can fix the intensity of a magnetic field in an area as small as 0·01 sq cm It will prove useful in problems connected with the magnetic properties of small colloidal particles.—**Jean Thibaud**: A new technique in the use of gratings applied to the study of Millikan's ultra-violet. The use of a vacuum spectrograph with the method of tangential incidence permits the use of a grating with 200 lines to the millimetre instead of 500 to 1100 lines per millimetre used by Millikan, and the photographic plate is placed only 98 mm. from the grating. Details of the results obtained with copper are given —**A Portevin** and **P. Chevenard**: The complexity of the phenomena of tempering certain alloys —**Pierre Jolibois**, **Henri Lefebvre**, and **Pierre Montagne**: The influence of the capacity of the discharge circuit on the decomposition of carbon dioxide under reduced pressure by the electric spark. The decomposition of carbon dioxide under reduced pressure by the spark is strongly influenced by the capacity of the discharge circuit. For a given tube a high degree of dissociation is only obtained if the capacity of the condenser giving rise to the spark is large.—Mlle. **Suzanne Veil**: The magnetochemical reactions of the hydroxides in the presence of hydrogen peroxide.— — **Marinesco**. Adsorption on large molecules in solution Einstein's equation giving the relation between the viscosity of a suspension of fine solid particles and that of the intergranular liquid has been applied to the results of viscosity measurements on solutions of rhodamine (molecular weight 478) in water and various alcohols. The results show that the dissolved molecule is surrounded by a monomolecular layer in which the number of molecules of adsorbed solvent is fixed. Methyl alcohol furnished anomalous figures —**J. Laissus**: The cementation of ferrous and copper alloys by tungsten, molybdenum, and tantalum.—Mlle. **M. Pernot**: The potassium iodomercurates which crystallise in acetone solution. —**Clément Duval**: A general method for the preparation of nitrites. Application to the simple nitrites of cobalt and nickel and to that of cobaltihexammine.—**P Freundler** and Mlle. **Y. Ménager**: The estimation of rubidium by means of silicotungstic acid; the application of this reagent to the detection of rubidium in the ashes of *Laminaria flexicaulis* The fractional crystallisation of the chlorplatinates has been proved to be an unsatisfactory method for determining rubidium in the presence of potassium and sodium, and the use of the silicotungstate ($Rb_8W_{12}SiO_{42}$ at 100° C.) is suggested as preferable. Details are given.—**Jean Meunier**: The detection and estimation of strontium by the spectrographic method in the hydrogen flame.—**J. F Durand**: The direct preparation of mixed organo-beryllium compounds Various attempts to prepare organo-beryllium compounds under the conditions usual for the preparation of the magnesium compounds failed. In one experiment, in which some mercuric chloride was added to the reaction mixture, a compound behaving as $CH_3.BeI$ was obtained.—**R. Weil**: The temperature of paramorphic transformation of cristobalite.—**Paul Picard**. Violutoside, a new glucoside containing methyl salicylate, extracted from *Viola cornuta*. This glucoside was present in the proportion of 0·01 gram per kilogram of fresh plant. The new glucoside is formed from one molecule of methyl salicylate and one molecule of a hexopentose, and is not identical with monotropitoside.—**R. Combes**: The migration of nitrogenous substances in the beech in the course of the autumnal yellowing. —**G. Lafon**: The amplification and collective audition of the beats of the heart and the other sounds of auscultation An account of the application of the methods of radio telephony to replace the stethoscope.—**Jean Saidman** and **L. G. Dufestel**: The visibility of the initial portion of the ultra-violet spectrum. It is shown that the line 365 Å.U. can be perceived by the human eye under favourable conditions. That it is not usually seen under ordinary conditions is due to the fact that the visibility of the eye in this region is only one-millionth of that of the radiations strongly impressing the retina.—**Émile Haas**: New researches on the successive differential light sensibility for white light.—**L. Vellux**: Contribution to the study of narcosis. The distribution coefficient of hypnotics between water and organic solvents, particularly solvents possessing ethylene linkages.—**Jean C. Faure**: The essential factors of a biological complex —**Alfred Maubert**: The influence of thorium X on the ammoniacal fermentation.—**J. Cantacuzene** and **O. Bonciu** · The modifications undergone by streptococci of non-scarlatina origin in contact with filtered scarlatina products

Vienna.

Academy of Sciences, April 29 —**R Kremann** and **A. Trostek**: Electrolytic conduction in molten metallic alloys (xvii.) Experiments on the electrolysis of zinc with lead, cadmium, of antimony with lead and bismuth, and of cadmium with lead and bismuth — **R. Kremann**: Communication xviii. Comprehensive consideration of the results so far obtained in this series of communications.—**K. Spitzer**: On the content of ortho-dioxy-benzole derivatives in the cocoons of the Emperor moth (Saturnia).—**J. Krames**: On the degeneration of striction lines in ruled surfaces. **O. Koller**: Some new fishes from the island of Hainan. Includes a new genus of Siluridæ and a new species of Cyprinidæ.—**O Koller**: A critical review of the hitherto described central and south European species of the Cyprinid genus Barbus—**O. Richter**: On the large iron requirements of the rice plant, *Oryza sativa*.—J. Hepperger: The influence of the attraction of the earth on the frequency of meteors.—O. Dischendorfer and H. Grillmayer: Investigations in the domain of photo-chemistry (iii). On betuline.—F. Seidl: Investigations on 'self-sounding' crystals. A possibility of the transformation of electric into acoustic vibrations finding application in a telephone without diaphragm.—K. Przibram: The interpretation of the coloration of salts.

Official Publications Received.

Department of Commerce: Bureau of Standards. Scientific Papers of the Bureau of Standards, No. 521: Measurements of the Index of Refraction of Glass at High Temperatures. By C. G. Peters. Pp. 635-650. (Washington, D.C.: Government Printing Office.) 10 cents.

A Bibliography of Indian Geology, Part 4. Palaeontological Index. Compiled by T. H. D. La Touche. Pp. iv+vii+414. (Calcutta: Government of India Central Publication Branch.) 7·14 rupees, 11s. 6d.

Records of the Botanical Survey of India. Vol. 9, No. 4: Freshwater Algae from India. By Dr. Nellie Carter. Pp. 262-303+2 plates. (Calcutta: Government of India Central Publication Office.) 14 annas; 1s. 6d.

Report of the Felsted School Scientific Society for the Years 1924 and 1925. (No. 29.) Pp. 23. (Chelmsford.)

Diary of Societies.

SATURDAY, JUNE 19.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (North-Eastern District) (at Town Hall, Stockton-on-Tees), at 10.45.—W. A. Smith: The North Tees Joint Town Planning Scheme and Notes on Stockton-on-Tees Housing Schemes.—J. P. Wakeford: Notes on Stockton and some of its Municipal Works.

MONDAY, JUNE 21.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—Prof. W. H. Lang: Contributions to the Study of the Old Red Sandstone Flora of Scotland. III. On *Hostimella (Ptilophyton) Thomsoni*; IV. On a Specimen of Protolepidodendron from the Middle Old Red Sandstone of Caithness; V. On the Identification of the 'Large Stems' in the Carmyllie Beds of the Lower Old Red Sandstone as Nematophyton.—S. Williams: A Critical Examination of the Vittarieae.—Dr. F. R. Cowper Reed: Some New Ordovician and Silurian Fossils from Girvan.—Prof. Graham Kerr: Note on the Fossil Fang of an Extinct Snake.—*To be read by title*.—J. M. Whittaker: On a Polarised Light Quantum.—Dr. W. W. Taylor: (*a*) Note on a Theory of von Weimarn; (*b*) Ferric Hydroxide and the Lyotrope Series.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—F. H. Cecil Brook: Implications of the Philosophy of Bergson.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—Presentation of the Royal Gold Medal.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (Summer Meeting, Scarborough) (continued on June 22 and 23).

INSTITUTION OF NAVAL ARCHITECTS (in Belgium) (continued until June 27).

TUESDAY, JUNE 22.

PREHISTORIC SOCIETY OF EAST ANGLIA (at Royal Anthropological Institute), at 2.30.

ROYAL SOCIETY OF MEDICINE, at 5.30.—General Meeting.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—V. Gordon Childe: The First Colonisation of Central Europe.

WEDNESDAY, JUNE 23.

ROYAL COLLEGE OF PHYSICIANS, EDINBURGH, at 5.—Dr. J. Cowan: The Failing Heart (George Alexander Gibson Lecture) (1).

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. H. F. Osborn: Methods and Results of American Museum Explorations in the Gobi Desert of Mongolia (Lecture).

RADIO SOCIETY OF GREAT BRITAIN (at Institution of Electrical Engineers), at 6.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (Summer Meeting at Norwich) (continued on June 24 and 25).

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (at Bristol) (continued until June 26).

THURSDAY, JUNE 24.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.30.—Sir Oliver Lodge: The History and Development of the Telephone (Lecture).

ROYAL SOCIETY, at 4.30.—J. C. McLennan and A. B. McLay: On the Structure of the Arc Spectrum of Gold.—J. C. McLennan and H. G. Smith: On the Series Spectra of Palladium.—A. M. Tyndall and L. R. Phillips: The Mobility of Ions in Air. Part III.—L. C. Jackson: Investigations on Paramagnetism at Low Temperatures. Part II.—Sybil Cooper and D. Denny-Brown: Responses to Rhythmical Stimulation of the Cerebral Cortex.—*Papers to be read in title only*.—Karl Pearson: Researches on the Mode of Distribution of the Constants of Samples taken at Random from a Bivariate Normal Population.—Lord Rayleigh: Further Spectroscopic Studies on the Luminous Vapour distilled from Metallic Arcs.—Sir William Hardy: A Microscopic Study of the Freezing of Gel. Part I. and Part II.—Sir William Hardy and Millicent Nottage: Studies in Adhesion. I.—T. Moran: The Freezing of Gelatin Gels.—W. Jevons: The More Refrangible Band System of Cyanogen as developed in Active Nitrogen.—J. A. V. Butler: The Equilibrium of Heterogeneous Systems including Electrolytes. Part I.—(The late) Mrs. Hertha Ayrton: Primary and Secondary Vortices in Oscillating Fluids: Their Connexion with Skin Friction.—T. T. H. Verschoyle: Isotherms of Hydrogen, of Nitrogen, and of Hydrogen-Nitrogen Mixtures at 0° and 20° C. up to a Pressure of 200 Atmospheres.—E. W. Marchant and J. L. Miller: The Loss of Energy in Metal Plates of Finite Thickness, due to Eddy Currents produced by Alternating Magnetic Fields.—W. Sucksmith and H. H. Potter: On the Specific Heat of Ferromagnetic Substances.—L. B. Pfeil: The Effect of Occluded Hydrogen on the Tensile Strength of Iron.—T. E. Allibone: The Infra-red Secondary Spectrum of Hydrogen.—D. C. Rose: The Scattering of Alpha Particles through Small Angles.—V. H. Stott, D. Turner, and H. A. Sloman: Effects of Thermal Treatment on Glass as shown by Precise Viscometry.—J. E. Lennard-Jones and Miss B. M. Dent: The Forces between Atoms and Ions. II.—J. Topping and A. E. Ludlam: Tables of log $K_0(x)$ over the Range $x=2$ to $x=12$ at Intervals of 0.001.—B. Lambert and E. T. Hartley: An Investigation of the Effects of Variations in the Radiation Factor on the Efficiency of Dewar Vessels.—J. E. Lennard-Jones and W. R. Cook: The Molecular Fields of Hydrogen, Nitrogen, and Neon.—H. Florey: Observations on the Resolution of Stasis in the Finer Blood Vessels.—T. S. P. Strangeways and Honor B. Fell: Experimental Studies on the Differentiation of Embryonic Tissues growing *in vivo* and *in vitro*. II. The Development of the Isolated early Embryonic Eye of the Fowl when cultivated *in vitro*.—Nesta Ferguson: The Aloinae—a Cytological Study, with especial reference to the Form and Size of the Chromosomes.

ROYAL COLLEGE OF PHYSICIANS, EDINBURGH, at 5.—Dr. J. Cowan: The Failing Heart (George Alexander Gibson Lecture) (2).

OPTICAL SOCIETY (at the Imperial College of Science), at 7.30.—M. von Rohr: Joseph Fraunhofer and the Development of Optical Instruments.

FRIDAY, JUNE 25.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.

DIESEL ENGINE USERS' ASSOCIATION (at Caxton Hall, Westminster).—J. H. Stackford: Some Deleterious Properties of Lubricating Oils.

SATURDAY, JUNE 26.

BRITISH PSYCHOLOGICAL SOCIETY (at University College, Gower Street, London, W.C.1), at 3.—Prof. C. Spearman: The Passing of the Psychology of 'Shapes' (*Gestalten*) into that of 'Wholes' (*Ganzheiten*).—Rex Knight: Modern Theories of the Self.

SATURDAY, JUNE 26, 1926.

Science, Industry and Education.

THE relationship of science to industry is a subject that has been frequently discussed in these columns, and if we return to it once again it is because as time goes on we recognise more and more that industry without science is like a ship without a rudder, a thing that drifts hopelessly on the ocean of reality. Although we stand in the first place for culture—a knowledge of the best that has been thought and done in the world—we cannot overlook the fact, so abundantly proved by history, that nations of the highest culture become ready preys to the forces of barbarism and disorder when knowledge and attainments cease to maintain adequate connexion with the material realities of life, when capacity for action is "sicklied o'er with the pale cast of thought." Science has its idealistic side no less than religion, art, and morals, and its dominion should be coterminous with theirs in extending over the whole range of human activities: its content touches human life at a multitude of points, and its method is capable of almost universal application. Nevertheless, we have to realise that the battle of life is still fought mainly below the belt, and therefore we must look to science to play its part, not only in shifting the arena from the lower levels of brute force, cunning, and cupidity to the higher ground of truth, justice, and regard for posterity, but also in helping us to conquer in the fight as it is fought to-day.

Great Britain needs the help of science in a peculiar degree. Over-population, combined with neglect of agricultural possibilities, has forced us to rely for our material existence upon imported products, and these have to be paid for mainly by exporting manufactured goods. We have few, if any, closed markets, and success depends upon the high quality or novelty of our wares, and upon industrial organisation, all of which are dependent upon science. What progress are we making in promoting science and its application to industry and national life?

Apart from the valuable work which was done by the Government committee appointed to inquire into the teaching of science in our secondary schools, and that which is being done under the Department of Scientific and Industrial Research, we see few signs of progress. Disregarding exaggerated statements, we believe that the progress of science teaching in secondary schools has fallen below expectations, and that the methods pursued in our universities and technical colleges still leave something to be desired. From the point of view of science, the popular Press remains in the throes of barbarism, and literary men speak openly, if foolishly, of "the bankruptcy of science."

The chief cause of this unsatisfactory state of affairs is ignorance, and the chief remedy is organised, concerted action to popularise the teachings of science; to bring home to the layman what science has done for mankind in the past, the nature of the problems awaiting solution, and what science may do, if adequately supported, in the future.

Alone among scientific organisations, the British Science Guild and the British Association have done valuable work in disseminating scientific knowledge among the people, and their present efforts to establish a publicity service, similar to Science Service in the United States, are worthy of every encouragement and support. The collection, preparation and distribution of interesting and accurate notes and articles upon scientific subjects likely to be accepted by the public Press is, however, too great a burden for such voluntary organisations to bear unsupported, and, the question being one of national importance, it seems right that a Government which expends nearly 50,000,000*l.* annually on education —not reckoning the 30,000,000*l.* contributed from rates—should contribute towards the cost. In addition to a scientific news service, we need popular accounts of researches that have led to new knowledge, and more especially of those which have resulted in new developments or improvements in industry, transport, and public health.

The co-operation of the Department of Scientific and Industrial Research would be particularly desirable in this connexion. The publications of this Department are well known to and much appreciated by scientific workers; but they are not addressed to the layman or written in a style to attract him, and the more learned communications that occasionally see the light in the transactions of societies are even less suitable for the purpose. It is essential that the subject matter should be written up in an attractive style, as free as possible from technical terms, due regard being given to the human element Experience having shown that, as a rule, the research workers and inventors are ill-fitted to describe their work in a manner understanded by the people, the writing should be done by those who have the gift of popular exposition, though the materials therefor should, when possible, be supplied, and the manuscripts revised, by the discoverers. An interesting development in this direction is the publication in the United States of Popular Research Narratives, collected by the Engineering Foundation of New York. The two volumes of "tales of discovery, invention, and research" that have been issued to date are excellently got up, and though many may think that they err on the side of brevity and 'scrappiness,' there is no doubt that the mode of presentation is good and that the writers and publishers will succeed in their attempt to interest the public.

It may be objected that, owing to the short period during which the Department of Scientific and Industrial Research has been in active existence, the results so far obtained are too meagre for the purpose we have in view; nevertheless, we believe that the twenty or so research associations, and national institutions like the Medical Research Council, the National Physical Laboratory, the Fuel Research Station, and Rothamsted, could provide between them an abundance of material; and if matter ran short, the wealth lying dormant in the records of learned societies, and in certain reports of Government Commissions, could easily be tapped. Another likely objection is that the publication of results of research in applied science would be against the interests of the manufacturers who subscribe to the research associations.

The answer to this contention is that it is nearly always possible to write a broad general account of a discovery or invention without disclosing important details of manufacture. Success in manufacture depends more often than not upon important details of plant or method of operating. True, but the public is not interested in such details; and, if necessary, the manufacturer can usually protect himself by letters patent. The manufacture of sulphuric acid by the contact process necessitated long years of work and a large expenditure of money before it was made a commercial success, yet the process was described at an early date in the columns of the *Berichte* with all the detail that even a scientific man desires; and similar statements could be made of many other processes, including those of Birkeland and Eyde, Franck and Caro, Haber, and Claude for the fixation of atmospheric nitrogen. In spite of assertions to the contrary made during the War, undue secrecy continues in our midst to the manifest disadvantage of the cause of science.

Another educational problem demanding attention is the training of science students who are destined for industry. In his Streatfeild memorial lecture (NATURE, December 12, 1925, p. 876), Mr. F. H. Carr, now president-elect of the Society of Chemical Industry, condemned the present training of chemical students for being too stereotyped: too much stress is laid upon training in research and too little on fostering ability to apply scientific knowledge to works' processes; there are many types of student-mind and many fields of possible application, yet we persist in casting all our material in the same mould. Prof. A. W. Crossley expressed the same view in his recent presidential address to the Chemical Society, likening the teacher of chemistry to the manufacturer who persists in offering to foreign customers the goods he thinks they ought to want, rather than those for which they actually ask. The main types of chemist required in industry, Prof. Crossley points out, are the research worker, the equally important man who can apply new scientific data to industrial development, the chemist to control works' processes and undertake, or supervise, analytical work, and the chemical engineer. Each of these types requires in the first place a broad general training in, say, three sciences before specialisation is allowed, but thereafter the training must be adapted to the future career: the 'pure' chemist, the industrial chemist, the school or university teacher, each requires a different curriculum.

The blame for the present inadequate or misdirected training is not, however, entirely the teacher's; the manufacturer is also culpable in not making clear his wants, or making the fulfilment of those wants into practical possibilities. Last year, in commenting upon Prof. Wynne's address to the Chemical Society (Nature, August 8, 1925, p. 195), we expressed the hope that manufacturers would devote attention to this matter, and we are now pleased to learn that, following the lead given by Sheffield, the British Dyestuffs Corporation has initiated a scheme whereby students may gain practical experience in its works during the long vacation. The result from the students' point of view, Prof. Crossley states, has been an unqualified success, and we do not doubt that the advantages will be mutual, for such vacation courses should afford the manufacturer excellent opportunity to select promising personnel for future employment.

We hope that this movement will spread, not only in the chemical industry, but also in the large and virgin field of applied physics. It is a happy omen that the demand in industry for trained physicists is considerably in excess of the supply. In the past, physicists as well as chemists have been trained too exclusively on academic lines, as if they were all to become teachers or 'pure' research workers. Important as these callings are, we are inclined to agree with the critics that an adequate supply of men whose special faculty lies in the application of scientific knowledge to industrial problems is at least of equal moment. Such men, it may be said, are born and not made; yet, if we believe in education at all, we must look to the universities and technical colleges to discover where this special ability is latent, and, knowing the needs of the manufacturer, to nurture it in the most fruitful way.

Modern Views on the Origin of Birds.

The Origin of Birds. By Gerhard Heilmann. Pp. vii+208. (London: H. F. and G. Witherby, 1926.) 20*s.* net.

Divergent views on much contested problems are often traceable to some rash statements, the authors of which were scarcely aware of there being involved some serious problem.

Numerous fossil three-toed footprints of obviously bipedal creatures were discovered about 1835 in the Triassic sandstone of Connecticut, and described by E. Hitchcock as Ornithichnites, bird-tracks. According to their size and configuration, which is all we know of their owners, various generic and specific names became assigned to them. Ch. L. Bonaparte (1856) combined these Ornithichnitidæ with the dodo, the subfossil Aepyornis, and the Eocene Gastornis as Inepti, a subgroup of his order Columbæ. A curious jumble of ineptness and sense.

Serious speculation about the origin of birds arose with the discovery (1860) of the famous Archæopteryx, from the upper Jurassic oolite of Solnhofen, near Eichstaedt, north-west of Ingolstadt, Bavaria. This specimen, now in the British Museum (Natural History), was first described by A. Wagner as Griphosaurus, "a reptile with bird's feathers." R. Owen monographed it (1863) as *Archæopteryx macroura*, "a bird with certain embryonic features" W. K. Parker (1867) published valuable remarks "On the relations of the Bird to the Reptile." Haeckel ("Generelle Morphologie," 1866) divided the birds into Saururæ (Archæopteryx) and Ornithuræ. T. Huxley, in his famous classification of birds (1867), retained the first name as Saururæ, but rightly discarded the Ornithuræ, dividing these with Merrem (1813) into Ratitæ and Carinatæ, and in his "Manual" (1871) he was the first to summarise clearly and concisely the descent of birds from reptiles, hence his term Sauropsida.

A second, much better preserved specimen, now in Berlin, was discovered (1877) also near Eichstaedt; first described and discussed by C Vogt (1879) as "an intermédiaire entre les oiseaux et les reptiles." It has been exhaustively monographed by W. Dames (1884).

Heated discussions arose whether Archæopteryx was a direct forerunner of the Carinatæ, or merely a lonely offshoot, or last but by no means least, a true intermediate link or 'Schaltform' between reptiles and birds, a view which was disallowed by the Prussian Government. Dames added some further detail of the limb girdles in 1897; but both specimens remained otherwise undisturbed until, in 1917 and after, Petronievics persuaded the authorities to expose them. He distinguished the Berlin specimen as *Archæornis siemensi.*

Meanwhile (1875) zoologists had been startled by O. C. Marsh's discovery of birds with numerous teeth from the mid-Cretaceous of Kansas. They were sumptuously monographed as Odontornithes (1880), this new subclass to contain the large flightless aquatic Hesperornis, the well-flying Ichthyornis and Archæopteryx. Later considerations showed, however, that they were only a heterogeneous assembly, in fact that probably all birds had retained teeth unto the end of Cretaceous times.

Although Marsh himself emphasised the undoubted affinity of Hesperornis with the recent diver-grebe group, he also took the complete absence of a keel in the flat sternum as indicating close relationship to the Ratitæ. Dollo (1881) took up this idea and with merciless logic united Hesperornis with the Ratitæ proper, calling the former "une autruche carnivore aquatique," a nightmare which, thanks to a popular article by Wiedersheim, became a "schwimmender Strauss" and "swimming ostrich."

Dollo was probably instigated by P. Albrecht, an erratic genius who discovered the so-called fourth, or inner, distal, trochanter of Hesperornis, Iguanodon, and traceable in ducks, a coincidence which led him to say that iguanodon also was a swimmer. Thus it came to pass that the dinosaurs were roped in with the Ratitæ, and the Triassic ornithichnites were taken as welcome proof of the necessary great age of the whole assembly. This incredible muddle went so far that moas, cassowaries, kiwis, ostriches were, not in popular literature alone, looked upon as the direct survivors of some suitable dinosaurian side-branch, whilst the much later Archæopteryx was the progenitor of the modern flying birds.

The literature bearing upon the problematic origin of birds has assumed great dimensions. Within the last few years the most noteworthy serious contributions have been made by a Dane, a Swiss, and a Serbian. Their several publications overlap each other.

H. Steiner of Zurich (1917) settled the vexed question of the remiges ("Problem der Diataxie der Vogelextremität," *Jena Zeitschr.*). In 1922 followed a renewed study of the development of the wing-skeleton, a work not yet fully appreciated which will revolutionise our hitherto very faulty knowledge ("Ontogenetische und phylogenetische Entwicklung des Vogelflügelskelettes," *Acta zoologica*, Stockholm, 1922). By careful, well-illustrated comparison with recent and extinct reptiles, he concludes these birds form one great natural assembly with dinosaurs, crocodiles (including the ancestral Para- and Pseudosuchia), and the aberrant pterosaurs, all of which agree, unlike all other reptiles, by the preponderance of the sharp-clawed 1st to 3rd finger, while the 4th and 5th steadily tend to reduction; indicating undoubtedly arboreal, climbing adaptation. This view he justifies by good argumentation. It applies also to the presumable common ancestor. Crocodiles proper have, of course, taken to aquatic life in a tertiary way, while others, like dinosaurs, have descended or returned to the primary terrestrial, tetrapodal, and eventually bipedal life.

Comparison of dinosaurs with Ratitæ reveals no direct ancestral relationship. Therefore dinosaurs can be compared only with birds which did fly, and Archæopteryx, the sole available material, dates from a time when these reptiles were already too far pledged. Both classes produced the most surprising convergences, but these occur crosswise, mutually contradicting relationship; for example, this bird's foot agreeing most with that of some of the Saurischian division of the dinosaurs, whilst the bird's pelvis agrees most with that of the Ornithischian division, namely, iguanodonts.

Exaggeration of the still very imperfectly known differences between the London and Berlin Archæornithes and comparison with Struthio only, to the utter neglect of all the other modern Ratitæ, led Petronievics to the following surprising conclusions (B. Petronievics and A. S. Woodward, "Pectoral and pelvic arches . . . of Archæopteryx," *Proc. Zool. Soc.*, 1917; B. Petronievics, "Über die Berliner Archæornis, Genf. 1925" (Reprint of *Ann. Géolog. de la Péninsule Balcanique*, Belgrade, 1924)). The Archæornithes (the reviewer's term, 1893), still without a keel, diverged already in Jurassic times, so that (at the same place and time, in the lithographic slate) Archæopteryx as the Ur-Ratite founded the teethed Ratite Hesperornis and the toothless modern Ratites.—Archæornis produced the toothed Carinates, for example Ichthyornis, and all the toothless modern Carinates. This scheme he calls "a rational classification based upon strictly morphological characters, and further explanation unnecessary."

The common ancestor, the Protornis or Proavis, could fly, but had not yet a keel. Its immediate ancestors were the Protoherpornithes (the reviewer's Herpetornithes, 1893), which were covered with down only! This "eidechsenartiger Urvogel" arose from some primitive group of the Lacertilia. (He does not mention Steiner's work.)

Now, if there is anything proved by Fürbringer and others, "it is that what we call Ratitæ (namely, ostriches, cassowaries, kiwis, etc.) are the direct descendants of birds which have lost the power of flight; therefore also lost the keel, a reduction which is still happening to various Carinates, which even if losing all power of the keel could thereby never become Ratitæ, because these have retained other important ancestral characters no longer existing in modern

Carinates. The same complicated process has happened long before ostriches became flightless, a consideration which led Fürbringer in his elephantine work to invent the staggering terms of Proto-Deutero-Trito-Apteornithes. Originally no feathered bipeds had a keel, but we must not be hypnotised by this deficiency lest we relapse into the belief in the "swimming ostrich" of fifty years ago.

G. Heilmann's carefully composed and extremely well illustrated book appeared first in Danish as "Fuglenes Afstemning," several instalments of which appeared in *Dansk Ornithol. For. Tidskr.* 1913–15, and an English version has now been prepared. More than half of the work contains the countless embryological and anatomical agreements of reptiles and birds and an exhaustive description of Archæopteryx; a good introduction for those who are not well acquainted with the subject. By reasoned elimination he restricts the possible ancestors of birds to the pterosaurs, predentate or ornithischian dinosaurs, cœlurosaurs, and pseudosuchia. The first group he disposes of easily.

The predentates, for example iguanodonts, present difficulties, but in spite of all resemblances these dinosaurs are found wanting. Perhaps by discarding their pelvis he protests too much, because the pelvis problem will not be solved without the hypothesis that it is fundamentally a polymetameric compound; further, the so-called pectineal process may be either entirely iliac or prepubic or both, according to the origin and extent of the ambiens muscle. The author feels convinced that this process of birds is iliac, therefore not the homologue of the reptilian prepubis. By thus ingeniously getting rid of the predentates he turns to the older group, the cœlurosaurs, which fascinate him by their cavernous vertebræ, a feature which he wrongly connects with the pneumatic skeleton of birds.

Concerning the forelimb the author closely agrees with Steiner (cf. Fig. 19), whom he does not mention. But even these creatures are not to be trusted, since their strong birdlike resemblances may be analogous adaptations. Thus he narrows the possible ancestry to the Pseudosuchia, which as probable ancestors of the theropodous dinosaurs and cœlurosaurs seem to possess in their still generalised condition all the necessary material and trend for future birds, as notably the structure of limbs, girdles, and skull. The final result is the origin of birds traced well into the Trias to the common ancestor of the archosaurian division of reptiles, in close agreement with Steiner.

For the impetus to flight Heilmann prefers with Abel and Steiner the arboricolous climbing life which encouraged jumping from branch to branch, and thus parachuting by patagia and enlarged feathers. Not Baron Nopcsa's dinosaur which gets the necessary momentum by running; nor does our author favour Beebe's 'Tetrapteryx,' although on p. 199 his own restoration of the Proavis shows no less than four or five feather parachutes. Those which forsook the trees and took to ground life specialised increasingly as runners.

The frontispiece, by the author, gives a charming picture of a loving couple of Archæornis, she of demure look and garb, he in full dress of brown, white, and—beautiful blue! H. GADOW.

More Relativity.

(1) *The A B C of Relativity.* By Bertrand Russell. Pp. v+231. (London: Kegan Paul and Co., Ltd.; New York: Harper and Bros., 1925.) 4*s.* 6*d.* net.

(2) *The Einstein Theory Explained and Analysed.* By Samuel H. Guggenheimer. Pp. ix + 326. (New York: The Macmillan Co., 1925.) 10*s.* 6*d.* net.

POPULAR accounts of the theory of relativity continue to appear, and one must presume from this that public interest in the subject has by no means died out. Writers at this time of day, however, are under an obligation which did not burden early expositors, in that they have to justify their intrusion into an already overcrowded field. However unsuccessful existing literature may have been in making the new ideas clear (the fact that interest in the subject is still maintained shows that a considerable measure of success must have been attained), the mere accumulation of volumes directed towards the same end is in itself an evil quite independent of the intrinsic worth of the volumes themselves. Too many cooks, though they be all masters of the gastronomic art, will nevertheless spoil the broth. Mr. Russell justifies his attempt on the ground that previous popular accounts of relativity "generally cease to be intelligible just at the point where they begin to say something important." Mr. Guggenheimer offers no apology, but breaks new ground by providing, not an account of the theory, but a critical examination of the manner of exposition which he finds in the English translation of Einstein's own popular book. It is extremely doubtful whether the motive is in either case a sufficient justification of the result.

(1) Mr. Russell, however, has written an extremely readable and lucid book, the substantial accuracy of which, of course, goes without saying. Perhaps its most characteristic and helpful feature is the excellence of the verbal illustrations which occur frequently and most of which are quite new. The chapters dealing with the relativity of time—the most difficult aspect of the subject to the beginner—are particularly clear, and the author is commendably precise in stating the possibilities of arranging events in a time order. The

widespread vague notion that, on the relativity theory, any event may be either before or after any other event, according to the time-system used, is effectively dispelled.

The choice of a title is not a happy one. It suggests the alphabet of the subject, which is of very little use to any one who does not intend to become a physicist. What Mr. Russell has actually presented is a much more valuable thing; namely, the *meaning* of relativity. He has rightly concentrated attention on the revolution in our concept of Nature which the theory brings about, and dealt effectively with the problem of separating, in our world of experience, the parts which belong respectively to external events and to the observer. The chief defect of the book seems to be the lack of any obvious connecting thread running through the whole. The reader who is able to follow each chapter quite clearly may be left at the end quite incapable of forming a definition of relativity suitable for a dictionary. As a particular example of this apparent disorder may be cited the discussion of 'force' in Chapter xiii. which harks back to a point already clearly raised and to some extent dealt with in Chapter viii. On the whole, however, Mr. Russell's book is certainly among the best popular accounts of relativity which have appeared.

(2) Mr. Guggenheimer's book, as has been said, is not an exposition of the theory at all, and its title is misleading. The author is confessedly neither a mathematician nor a physicist, and it is clear that he is not an astronomer. He approaches the subject from the metaphysical side, and subjects a number of passages of Einstein's elementary treatise to minute dissection. To the reviewer, who finds Mr. Guggenheimer's work far less intelligible than that of Einstein, he appears to introduce difficulties into Einstein's exposition and then to devote a considerable space to their elucidation. For example, several pages are occupied with a discussion of whether Einstein, in speaking of 'absolute' as contrasted with 'relative' motion, is "attempting to penetrate the noumenal world" and becoming involved in "an ultimate, absolute, and infinite First Cause."

The book may appeal to those who delight in mental gymnastics and are indifferent to the meaning of scientific relativity, but those who wish to understand Einstein's theory should carefully avoid it. The citation, with examples, of two defects will suffice to reveal its danger—the scientific statements are vague, and they are often inaccurate. As examples of vagueness we give two typical sentences: "All matter consists, in the last analysis, of one substance or energy in different conditions of electric charge or force" (p. 38). "Although body A may be at rest relative to body B, from which A appears to be moving, to an observer on B it will be A which appears to move, and neither is actually moving" (p. 167). Examples of inaccuracy are abundant in the very biassed discussion of the tests of the relativity theory. Thus, the existence of an intra-Mercurial planet is said to be "highly probable," and the deflexion of light by a body is said to increase with its radius, because a large radius "gives the force a longer time to exercise its accelerating pull upon the fast passing light." The author appears to have some power of thought and expression, which should be concentrated on a subject with which he is better acquainted.

H. D.

A New Brunswick Geologist.

Loring Woart Bailey: the Story of a Man of Science. By Joseph Whitman Bailey. Pp. 141+12 plates. (St. John, New Brunswick: J. and A. McMillan, Ltd., 1925.) n.p.

IN this volume we are presented with an interesting life-history of one of the earliest leaders of scientific thought and education in the Maritime Provinces of Canada. In his scientific work, Dr. Bailey was closely associated with Dr. G. F. Matthew and rendered notable service to Dawson, Logan, and Selwyn in the earliest researches on the geology of what was then an unknown region. But he will perhaps be best remembered as having been for nearly half a century an active member of the faculty of the University of New Brunswick and as one of the little group of men who nurtured the Natural History Society in its infancy.

One of Dr. Bailey's ancestors sailed from England in the good ship *Angel Gabriel*, built for Sir Walter Raleigh. The ship was wrecked near Bristol, Maine, in 1635, but John Bailey survived. His descendant, the subject of this biography, was born in 1839 at West Point and was educated in the United States, but when he was not yet twenty-two years of age accepted an offer of a professorship at the University of New Brunswick at Fredericton. The appointment was opposed on the ground of his alien birth and extreme youth, but Bailey survived to become one of the leading figures of the institution. Here he built Sunnyside in open fields extending to the banks of New Brunswick's great river, and extended hospitality to many old friends, amongst others to his old pupil, the late Sir George Parkin.

After the publication of the "Origin of Species" the more aggressive types of scientific men and theologians commenced an acrimonious discussion, which is still liable to blaze. Dr. Bailey had sufficient tact to remain in harmony with both sides and was consulted by laity and clergy alike on scientific questions. In 1907, after forty-seven years' service, he retired, held in the highest esteem by the students as well as by members of the faculty.

Dr. Bailey's scientific researches related to the Maritime Provinces. He was greatly interested in diatoms, but his more important work, done in association with Dr. Matthew, lay in collecting the fossils and determining the age of the geological formations of an unknown region. Within 15 miles of St. John he recognised representatives of formations ranging in age from Lower Laurentian to Trias. The work was commenced as a labour of love, but was continued from 1867 as a part of the programme of the Geological Survey. In 1913 Dr. Bailey acted as scientific guide to one of the excursions of the International Geological Congress. To one at least of that party his intimate knowledge of the geology of Albert, St. John and Victoria came as a revelation of what could be accomplished in unsympathetic surroundings. He died in 1925 in his eighty-sixth year.

Magnetism.

Modern Magnetics. By Prof. Felix Auerbach. Translated by H. C. Booth. Pp. vii + 306. (London: Methuen and Co., Ltd., 1925.) 15*s.* net.

THIS work gives an admirable account of all the older work on magnetism. It does not assume much knowledge to start with, and without using much mathematics it takes the reader on to quite advanced subjects. The style is pleasant and easy—with perhaps a touch of the rather glutinous brightness of the German journalist. The book will be of value to many who already claim considerable knowledge of the subject.

The student who has worked out examination questions on magnetism has the impression that he understands all about magnetic force and magnetic induction, and that all that is necessary is to multiply together the mystical letters H and μ to get the still more mystical B. The present work will disabuse him of this impression and will replace it by a wholesome respect for the difficulties to be faced, both theoretical and practical. In this connexion it is really a pity that induction and permeability play so large a part in the mathematical text-books, for, in fact, magnetisation and susceptibility are not only more primitive ideas, but also are much more useful in the study of magnetism itself, especially in the case of ferromagnetism.

The volume claims to deal with the whole field of magnetism, and it is disappointing to find that a work published in 1925 makes no mention of an experiment of such fundamental importance as the Stern Gerlach experiment, which directly exhibits the magnetic moments of atoms. The German original came out in 1921, which would explain this omission, but it would not justify the absence of any account of the almost equally important gyromagnetic effects and of, at any rate, the earlier of the recent developments of the theory of the Zeeman effect. Indeed, it is a little surprising to find the name "Modern Magnetics" applied to a book containing a bibliography—and a very full one—with no reference to work later than five years before its publication in German, and nearly ten years before the translation.

It is a great pity that a supplementary chapter or two has not been added so as to bring the account a little more closely up-to-date. Still, this is perhaps a tribute rather to the rate at which the subject has developed than a criticism of the content of the book—which may be very strongly recommended to any one wishing to acquire a knowledge of the more classical parts of the theory of magnetism.

Our Bookshelf.

Contemporary British Philosophy: Personal Statements. (Second Series.) By James Ward, E. Belfort Bax, Douglas Fawcett, G. Dawes Hicks, R. F. Alfred Hoernlé, C. E. M. Joad, G. E. Moore, J. A. Smith, W. R. Sorley, A. E. Taylor, J. Arthur Thomson, Clement C. J. Webb. Edited by Dr. J. H. Muirhead. (Library of Philosophy.) Pp. 365. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Co., 1925.) 16*s.* net.

THE twelve contributions contained in this volume cover a very wide field and are naturally unequal in value. Some writers attempt a sketch of a complete philosophy, while others deal with special problems. The first place is given as a "tribute of respect" to the article by the late Prof. James Ward, which, as the editor tells us, may be looked upon as Prof. Ward's "last will and testament to his contemporaries on the subject of general philosophy." The function of the latter he takes to be to understand experience as a whole, "to find a unity and meaning in the entire sum of things, beyond the so-called system of nature as science conceives it." His general position is well indicated in the title of his article, "A Theistic Monadism." It owes much to Kant and Lotze, and especially to a lifelong study, of great penetration and insight, of the natural sciences; though, as he points out, he has often been, strangely enough, accused of 'attacking' and 'reviling' them.

The view of philosophy as synoptic is also taken by other contributors, notably by Prof. R. F. A. Hoernlé and by Prof. J. Arthur Thomson. On the other hand, Prof. A. E. Taylor takes a more modest view of the nature of metaphysical speculation, the object of which, according to him, is not the unification of the sciences, but "the necessarily imperfect and tentative reconciliation of the exigences of scientific thinking with the imperative moral and religious demands of life." He devotes his article to a study of "The Freedom of Man," and gives a spirited defence of indeterminism and real contingency as involved in the moral life of man. Stress is also laid on moral values by Prof. W. R. Sorley, who seeks to bring out the bearing of the objectivity of value upon central metaphysical problems.

On the side of epistemology the most noteworthy articles are those of Prof. G. E. Moore on "A Defence of Common Sense" and of Prof. G. Dawes Hicks entitled "From Idealism to Realism." The latter gives a lucid account of the main principles of a realistic theory of knowledge at which he has been working for many years. His central position is that cognition is of one character through all its forms, and consists essentially in an act of judging, and that the primary function of discriminating, comparing and relating is present from the very beginning of cognitive apprehension.

In an interesting preface the editor points out the chief directions in which, despite apparent conflict and opposition, contemporary thinkers tend to approximate to one another and to arrive at common results.

M. G.

Industrial Electricity. By Prof. Chester L. Dawes. (Electrical Engineering Texts.) Part 2. Pp. xv+480. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 13*s.* 9*d.* net.

The great progress that has been made in recent years by electrical engineers in the application of theory to their craft is well illustrated by this volume. When alternating currents are employed the use of polyphase systems is almost universal, the principal exception being a few single-phase railways. One advantage of the polyphase system is the steady torque produced on the generators and motors, it being analogous to a multicylinder petrol engine. In the chapter on transmission and distribution we were interested to find that the author sometimes uses 'earth' and sometimes 'ground.' The former word is everywhere used in Great Britain and the latter is practically always used in the United States. The importance of keeping down earth currents in tramway systems is pointed out. The first method given is to use good bonds between the rails, and the second is to induce the gas and water companies to insert occasional insulating joints in their pipes. We are told that in some American cities the voltage drop along the rails must not exceed 15 volts. In Great Britain the maximum permissible drop is 7 volts, but series dynamos (negative boosters) are generally used to keep down the pressures at various points of the track. The chapter on photometry is good. We are glad that the author does not strive to use different symbols for all the various quantities he discusses. He uses I both for current and candle-power.

The chapter on electron tubes (vacuum tubes or thermionic valves) will be very helpful to the older engineers, excellent descriptions being given of the three-electrode valve, regeneration, power valves, carrier waves, and broadcasting apparatus. Modern methods of wiring buildings for the electric light are next described. Supply pressures of 300 volts are mentioned. In England 240 volts is the maximum, and in Europe much lower pressures are often used. A useful collection of 260 problems is added, telephone relays and loud speakers replacing the carbon lamps and tangent galvanometers of an earlier generation.

Transformers for Single and Multiphase Currents: a Treatise on their Theory, Construction and Use. By Prof. Gisbert Kapp. Third edition, revised by Reginald O. Kapp. Pp. xi+391+11 plates. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 15*s.* net.

The late Prof. Kapp prepared the second edition of this book in 1908. He pointed out that "during the last twelve years enormous improvements have taken place in the construction of transformers." He also said that transformers so large as 1000 kilowatts have been constructed. His son in this edition says that single transformers up to 60,000 kilowatts, or better 60,000 kilovolt-amperes, are in service and testing transformers have been built which give a million volts. The tendency towards the centralisation of power supply during the last eighteen years has become very marked and the electric output has vastly increased. Remembering that most of the electrical energy generated passes through two transformers at least, the capacity of the transformers installed in Great Britain at present must be very great. The trend of development during recent years has been to pay far greater attention to the problems of economical manufacture and mechanical construction and to improving the insulating materials employed.

The book is intended for electrical engineering students and for the engineers of supply stations. More space is devoted in this volume to points of construction, installation and maintenance. Much of the matter dealing with the general theory of electrical engineering has been omitted, and also descriptions of devices which are now obsolete. Examples of the latest types of transformers by well-known makers are fully described. The book will be found helpful by practical engineers.

Manual of Injurious Insects. By Prof. Glenn W. Herrick. Pp. xxi+489. (New York: Henry Holt and Co., 1925.) 4.50 dollars.

The author of this book, who is professor of economic entomology at Cornell University, remarks in his introduction: "It is hoped that the book may be useful to the teacher and to the student of economic entomology; and that it may serve as a reference book to any one interested in the activities, injuries and control of the more common injurious insects of the United States." It should fulfil all these hopes to a greater or lesser degree, since it is accurate, clearly and concisely written, well illustrated, and has sufficient references to guide its readers to sources of fuller information. The various pests are dealt with under the plants which they affect, while there are also chapters on pests of live-stock and of the household, but forest insects are, for some reason, omitted.

The book presents certain features not usually found in works of this character. First, there is a pleasing absence of most of the time-honoured illustrations that have done duty in almost every book on the subject for the last twenty years; more recent and often original figures have been utilised. Secondly, there are more than 100 small maps showing the distribution in the United States of each of the major pests for which trustworthy data are available. Thirdly, there is some account (although brief) of the control of pests by biological methods. The book will doubtlessly prove of service in Canada as well as in the United States, and, it may be added, a considerable number of references to the literature of Canadian economic entomology are included. A. D. I.

Phototopography: a Practical Manual of Photographic Surveying Methods. By Arthur Lovat Higgins. Pp. xv + 130 + 9 plates. (Cambridge: At the University Press, 1926.) 6*s*.

This book describes, clearly and concisely, the theory and practice of ground photo-surveying. Surveys carried out by this method suffer from two serious disadvantages. There will always be some 'dead ground' which has not been surveyed, and plotting a map from photographs is such a long and complicated process that the time gained in the field is usually lost in the office. The plotting and drawing are much simplified by the use of a stereoplanigraph, but this machine is very expensive, and few survey establishments can afford to purchase it.

Ground photographs have been used for the surveys of mountainous areas in Canada, but the method has not hitherto been employed in other parts of the British Empire. A photographic survey of Kashmir will be carried out by the Survey of India this year, and the most modern instruments and methods will be thoroughly tested. Future developments will depend upon the experience gained in Kashmir. Meanwhile, this book can be recommended to all who are interested in the subject. The stereoplanigraph is not described in detail. For this a separate volume would have been required, for the instrument is as complicated as it is expensive.

It is to be hoped that as the methods develop some simplification of the technical terms may be found possible, and that words such as 'stereophototopography' may be allowed to die a natural death.

Psyche: the Cult of Souls and Belief in Immortality among the Greeks. By Erwin Rohde. Translated from the eighth edition by W. B. Hillis. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvi + 626. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Ltd., 1925.) 25*s*. net.

Rohde's "Psyche" marked a turning-point in the study of comparative religion when it first appeared in 1893; it has become a classic, and has been through eight German editions without change since the premature death of the author in the interval between the second and the third. Now it appears in a carefully translated English version, with the notes transferred to the end of each chapter, and the appendices to the end of the volume; a practice deplored by Rohde himself, but a great improvement in a book which appeals quite as much to the 'general reader' as to the specialist.

The translator has done another considerable service in revising the whole of the references to ancient authors, whom Rohde used to cite from the edition nearest his hand as he wrote. Only one other thing he might have done with advantage, namely, to record the pagination of the first German edition, by which Rohde's earlier critics quoted him. How convenient this is, in a book of this sort, those who have used the later German editions know. Rohde's chapters are long, and not divided into sections. But the main thing is to have an English version of Rohde's work at all, and it should be widely appreciated.

Lehrbuch der Pflanzenphysiologie. Von Prof. Dr. S. Kostytschew. Erster Band: *Chemische Physiologie.* Pp. vii + 567. (Berlin: Julius Springer, 1926.) 24 gold marks.

This first volume of a new plant physiology, hailing from Leningrad, is of quite exceptional interest. The citation of literature is exceedingly full and complete, and in many cases the references to Russian literature deal with work which is very little known in Great Britain. Thus Russian work upon the colourless chromogen, leucophyll, said to precede chlorophyll during development in the dark, and Russian work upon the nutrition of flowering plants when grown under sterile soil conditions, is somewhat fully referred to. This first volume, recognising that the modern botanist requires a critical chemical equipment, deals with the processes of metabolism from a chemical point of view and commences with an introductory chapter upon the fundamental chemical questions involved in interpretations of plant physiology.

In the second volume, problems of the entrance and translocation of solvents and solutes are to be dealt with, together with problems of growth and plant movements, and also tissue differentiation and correlations.

The Physiology of Plants: the Principles of Food Production. By Prof. G. J. Peirce. Pp. x + 363. (New York: Henry Holt and Co., 1926.) 3 dollars.

This is a somewhat discursive treatment of some of the main problems of plant physiology, particularly nutrition, water movement, respiration, and irritability. These problems are handled more fully than they would be in an elementary text; on the other hand, neither the necessary physics and chemistry, nor the essential physiological considerations, can be said to be handled thoroughly, whilst there is considerable repetition arising from the discursive nature of the book. Many readers may find the author's viewpoint interesting, however, even when he is traversing familiar ground. Thus the human and industrial contacts of plant physiology are often emphasised, and a considerable amount of recent work is discussed from an individual and, to some extent, a critical point of view.

Laundry Chemistry: a Short Handbook on the Chemistry of Laundry Materials and Methods. By A. Harvey. (Lockwood's Manuals.) Pp. viii + 116. (London: Crosby Lockwood and Son, 1926.) 4*s*. net.

This book contains brief accounts of those parts of chemistry which are involved in laundering processes, with a short introduction to elementary chemistry. Much of the information is otherwise obtainable only in large treatises or dictionaries, and it is undoubtedly useful and convenient to have it collected in a small manual of this kind. The information is accurate and up-to-date. The book is well printed, and should prove useful to students and those engaged in laundering. The author has evidently an excellent practical knowledge of the subject.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Ether Drift Experiments.

The editor has kindly shown me the proof of a letter from Sir Oliver Lodge, relating to my ether drift experiments, and in particular to the account of this work recently given at the Royal Institution. Sir Oliver has in a very courteous manner described the principal argument put forth, and, as he says, the matter is now before the scientific world, *sub judice*. Notwithstanding this, it may not be out of order to make further explanation of some of the points raised by Sir Oliver.

It seems necessary to direct attention again to the fact that this experiment has never given a true zero or 'null' effect in general; it has only given a 'negative' result, that is, it has answered 'no' to a specific question. Following the report by Morley and Miller, in 1905, Prof. Einstein made the hypothesis that the motion of the observer produces no effect upon the apparent velocity of light. This hypothesis has been given in hundreds of books as the correct interpretation of the experiments, and has been accepted, perhaps without fully examining the original papers. Michelson and Morley, in 1887, said: "Considering the motion of the earth in its orbit only . . . the relative velocity of the earth and the ether is . . . certainly less than one-fourth of the orbital velocity. . . . In what precedes only the orbital motion of the earth is considered. If this is combined with the motion of the solar system, concerning which but little is known with certainty, the result would have to be modified." In 1905 Morley and Miller, using a much larger interferometer, included in the calculations with the orbital motion of the earth a presumed motion of the solar system of twenty kilometres per second towards the constellation Hercules (still leaving the orbital motion predominant), and came to practically the same conclusion. But, in each of these reports the effect to be expected was calculated in advance, both as to direction and magnitude, and then the observations at two different times of day (as determined from the expected result) were combined so as to add together the expected components, and so as to cancel effects other than those being looked for.

In all of these observations there was a definite positive result, which is observed as a periodic displacement of the interference fringes; but, for the two calculated times of day, the phases of the positive periods differed in such a way that when the two sets of readings were added, they neutralised each other and left only the very small result which was correctly reported as that obtained for the orbital component of any existing ether drift. It is this positive effect, then eliminated, that is now being examined. While it is not large, it is by no means insignificant; the present amount of observed relative motion is 10 kilometres per second with a probable error of ±0·5 kilometres per second. As this effect was not 'expected' it was not easy to interpret. The history of the experiment has been given in *Science* for June 19, 1925, and in a more concise report in NATURE for July 11, 1925, p. 49. The re-examination of all of the observations from 1887 to 1926, is the subject of a paper presented to the National Academy of Sciences in Washington on April 26, 1926, and not yet published. It is hoped to give a summary of this paper shortly in NATURE.

Sir Oliver Lodge asks what would appear if the results were plotted on the hypothesis that the south side of the housing is warmer than the north side, or with regard to other conditions. It is exactly for answering these questions, and others, that the experiments have been continued over a period of six years, in which time the thousands of readings have been made. Every disturbing cause that could be thought of has been exhaustively studied; among these are: daily and annual variations in temperature, meteorological conditions, radiant heat, magnetism, magneto-striction, differential gravitation, gyrostatic action, influence of method of illumination, transparent and opaque coverings of the light path, speed and direction of rotation, lack of balance in the rotating parts, position of the observer, and other conditions. One after another, these disturbances have been shown *not* to produce the observed effects. Finally, it has been possible to combine into one logical solution *all* the readings made to test all these varying conditions, without any omissions (excepting a few readings made under abnormal conditions, such as artificial heating), without any corrections, and without assigning any weights. This solution is entirely consistent with the observations of Michelson and Morley of 1887, and with those of Morley and Miller of 1902–1906.

The observations with the interferometer are made to detect a periodic shift of the fringes, periodic in each half-turn of the instrument; it is not the absolute position of the fringes that is important, but rather the periodic, vibratory change in the position of the fringes, as the interferometer turns through 180°. This can be detected best by having the instrument in slow and uniform movement, while the observer watches the fringes continuously. The instrument turns once in about a minute, and floats so freely that when once started it will continue in rotation for more than two hours without being touched. A series of readings is made in less than fifteen minutes.

The important part of the argument is that the reported effect has always been present, and is evident in every single observation and not merely in the mean; it is not related to the instrument, or to its surroundings; neither is it dependent upon day and night, or summer and winter; it is clearly shown to be directly related to sidereal time, that is, to a cosmical cause. This is explained, with numerous curves showing the results of the 1925 observations, in *Science* for May 1, 1926. The final arguments are based upon four very complete series of observations made at Mount Wilson for the epochs April 1, August 1, and September 15, 1925, and for February 8, 1926, thus covering various seasonal conditions, and various orbital positions of the earth.

In making the observations, two independent quantities are noted, the direction in which the interferometer points when the effect is a maximum; and the amount of the periodic displacement of the interference fringes. Each of these two sets of readings leads to an independent determination of the right ascension and declination of the 'apex' of the supposed motion of the earth in space. It is very significant that these two determinations are wholly concordant.

Dayton C. Miller.

Note on the Law of Radiation.

In connexion with the distribution of black-body temperature-radiation among different wave-lengths, the law of that distribution suggested by the late Lord Rayleigh for long wave-lengths is now well known to require the interesting and important correction factor $\frac{x}{e^x - 1}$ (where x is $\frac{hc}{RT\lambda}$ or, as Dr Jeans has virtually pointed out, very nearly $32\pi^3 \frac{\epsilon^2/K}{RT\lambda}$, the electronic charge being ϵ), in order to adapt it to all wave-lengths. This factor could not have been deduced from dynamical reasoning, even with the help of the electron and the laws of probability, without the postulate of a previously unsuspected discontinuity in the interaction between ether and matter Not because the expression for x (which in itself is full of speculative interest) contains any discontinuity, but because the denominator of the correction-factor ($e^x - 1$) suggests, as my brother has pointed out (Nature, May 30, 1925), a continuous accumulation at compound interest with the periodic emission of a dividend. The steady growth of a tree through a summer, with occasional spasmodic drop of an apple to a lower energy level, may be in some respects a permissible analogy.

There seems some risk that in order to emphasise the novel character of this discovery of Max Planck's, supplemented as it was by Einstein, teachers of senior physics may convey the impression that Lord Rayleigh had enunciated his law as complete; whereas he was under no such mistaken impression. He knew that his law was a partial one, and could apply only to long waves. I had thought of quoting from his original 1900 Memoir on the subject, together with a footnote added in 1902, in support of this contention (see vol. 4 of Rayleigh's "Collected Papers," p 485), since there seemed a risk of its being overlooked by readers of Dr. Jeans's admirable Report to the Physical Society on "Radiation and the Quantum Theory." But I have found that the true position is clearly admitted and stated by Dr. Jeans in his book on "The Dynamical Theory of Gases" (p 359, third edition).

Rayleigh's law, I may remind readers, is that if E is the total radiated energy at the temperature T (which energy may be plotted as an area with a wave-length base) its distribution among different wave-lengths (or the ordinates of the continuous-spectrum energy curve) will be:

$$dE/d\lambda = 8\pi RT\lambda^{-4}.$$

Rayleigh threw out his suggestion as the simplest definite form of Wien's thermodynamically-derived and well-established so-called "displacement law" connecting energy at each wave-length with absolute temperature:

$$\lambda^{-5}\phi(\lambda T).$$

The new form represented a special case; and the replacement of λ^{-5} by $\lambda^{-4}T$ was convenient for several reasons: (1) Because it emphasised the fact that atomic energy in each mode must be proportional to T (which was disguised in Wien's form); (2) because it brought in the known gas constant instead of an unknown function; and (3) because it was in accordance with the Maxwell-Boltzmann law of equipartition.

Rayleigh expected that his expression might represent the true law of radiation when λT was great; and so it has turned out. The law is true so far as *matter* is concerned; that is, it is true if an atom radiated, as a sounding body does, into a material medium. That something more was required to bring in non-matter, like the ether, was clear, because for some unknown reason equipartition would not apply to that; even proportionality to temperature need not hold in the ether. No one could deduce the complete law without further discovery. Each step from matter to ether, or back again, demanded the quantum factor, and does demand it wherever such interaction occurs. The gradual Keplerian manner in which the true law was guessed was a triumph of genius. Bohr's subsequent pictorial representation of the quantum at work, in the structure and behaviour of a radiating atom, was another. In this connexion I find that an ancient address of Clerk Maxwell's to the Chemical Society in 1875 (which I had the privilege of hearing, and which is reported in Nature, vol. 11, pp. 357, 374) contains the following now rather amusing anticipatory paragraph (see also p. 435, vol. 2, of Maxwell's "Collected Papers"):

"The theory of the possible vibrations of a molecule has not yet been studied as it ought, with the help of a continual comparison between the dynamical theory and the evidence of the spectroscope. An intelligent student, armed with the calculus and the spectroscope, can hardly fail to discover some important fact about the internal constitution of a molecule."

We are living in a period of remarkable discoveries, which rather tend to put in the shade some of the older physics. Nevertheless, as an intermediate stage, complete so far as matter is concerned, Lord Rayleigh's partial statement was most useful. It never pretended to be more complete than it was, and it is only fair to his well-known care and scrupulous caution to emphasise this. Oliver J. Lodge.

Plastic Deformation of Single Metallic Crystals.

In a letter to Nature (May 22, p 720), Messrs. Millington and Thompson discussed the wedge-shaped fracture which ordinarily results from a tensile test on a single metallic crystal. On the assumption of uniform slip on a number of parallel planes they calculate the magnitude of an angle which they assume to be the angle of a wedge-shaped fracture produced by the slip. May I point out that uniform slip of the type they consider, on one or more sets of parallel planes, would result in uniform extension together with a uniform change in the cross-section over the whole of the portion of the specimen which is slipping, and consequently no wedge-shaped fracture could result? The angle which was calculated in the letter referred to is the inclination of the axis of the 'slipped' portion of the specimen to the axis of the portion which has not slipped, and this has no connexion whatever with the angle of a wedge fracture.

In the earlier stages of a tensile test on a single crystal the act of slipping on any plane increases the resistance of that plane to further slip. This has the effect of distributing the slip more or less evenly over all the planes of the same type so that uniform extension results. At some stage, however, this strengthening action appears to become exhausted and a zone of weakness is set up. The final wedge fracture results from non-uniform slip in this region, the extent of the slip on the set or sets of planes involved becoming progressively greater as the weakest point is approached from either side. No calculation of the angle of the final fracture can be made without some information as to the nature and extent of the zone of weakness referred to, and there appears to be no evidence available on this point. However, it may, I think, be definitely stated that the occurrence of a wedge-shaped fracture is an indication that non-uniform slip has occurred in its neighbourhood. The only deduction that can safely be made from the shape and orientation of the wedge concerns the number of sets of parallel planes involved. In general slip occurs on two such sets, and the final line of cleavage will be parallel to their lines of intersection. The actual examination of a number of fractures of single crystals of aluminium encountered by the writer and his colleagues in the course of an experimental research into their behaviour under stress, shows that in every case the faces of the wedge are not plane but are definitely curved surfaces.

I would strongly suggest that general deductions as to the distribution and amount of slip, from geometrical considerations or from the representation of atoms by hard spheres, unless supported by carefully obtained experimental evidence, should be treated with great caution. S. J. WRIGHT.

Dipole Moment and Molecular Structure.

DEBYE (Marx, "Handbuch der Radiologie, 6, 597) has shown how the electrical moment or dipole moment of a molecule can be determined from dielectric constants and refractive indices of vapours and dilute solutions. Debye and other workers find that the dipole moment for a series of homologous compounds is nearly constant. The dipole moment, therefore, may be associated with a definite polar group in the molecule, whilst the rest of the molecule is non-polar. The dipole moment is a vector quantity. Hence the dipole moment of a molecule, which contains several polar groups, should be the vector-sum of the dipole moments of the groups; compare Errera, *J. Phys. Radium, VI.*, 6, 390 (1925).

To test the above theory the present experimental investigation has been carried out. The results are collected in the following table. The experimental dipole moment μ is calculated for infinite dilution in benzene solution. Simultaneously the association constant k may also be determined. The theoretical dipole moment v is calculated as the vector-sum of the moments of the monosubstituted derivatives, assuming the angles between the ortho, meta and para directions to be 60°, 120° and 180° respectively. The following dipole moments have been taken from earlier publications, namely, $\mu = 3·75 \times 10^{-18}$ E.S.U. for nitrobenzene, and $\mu = 0·43 \times 10^{-18}$ for toluene.

	μ.	v.	k.
Chlorobenzene . .	$1·58 \times 10^{-18}$	..	0·04
Bromobenzene . .	1·56	..	0·10
Dimethylaniline .	1·39	..	
o-Dinitrobenzene .	5·95	$6·5 \times 10^{-18}$	0·36
m-Dinitrobenzene .	4·02	3·75	0·26
p-Dinitrobenzene .	0·8	0·00	
sym Tribromobenzene	0·3	0·00	
O-Nitrotoluene . .	3·56	3·62	
p-Nitrotoluene . .	4·30	4·18	0·24
o-Chloronitrobenzene	4·25	4·75	
m-Chloronitrobenzene	3·38	3·27	
p-Chloronitrobenzene	2·52	2·17	0·07
p-Bromonitrobenzene	2·69	2·19	

The small dipole moments are not exact, because of the so-called atom-polarisation: L. Ebert (*Z. Phys. Chem.*, 113, 1 (1925)). The polarity of groups must be due to charges on the atoms in the groups. If it is assumed that one charge is on the group and the opposite on the benzene ring, it is found, from the relative directions of the component moments, that chlorine, bromine and the nitro-group are charged in the same manner, whilst the methyl group is oppositely charged. The work is being continued.

The present work was carried out in the Chemical Laboratory of the University of Copenhagen. The author wishes to express his thanks to Prof. Billmann and to the Orsted foundation of the Great Northern Telegraph Co., Ltd., for a grant.

KRISTIAN HÖJENDAHL.

Efficient Use of Thermopiles.

IT is well known that when using a very delicate thermocouple or a thermopile for the measurement of weak intensity radiation, it is of advantage to work the pile *in vacuo*. The effect obtained is threefold: (*a*) Increased sensitivity; (*b*) Improved constancy of the galvanometer deflexions; (*c*) Increased steadiness of the galvanometer.

The value of the first is small, the factor being about three times, unless special care be taken to reduce to a minimum the conduction of heat along the wires of the thermo-elements. (Cf. Moll and Burger, *Z. für P.*, 32, 575, 1925; also *Phil. Mag.*, 50, 624, 1925.)

(*b*) In the absence of a vacuum, and when the total radiation falling upon the pile is great enough to cause an appreciable difference of temperature between the two sets of junctions, minute convection currents are set up in the air, with consequent fluctuation in the magnitude of the galvanometer deflexion. This trouble is not noticeable if the deflexions are small.

(*c*) This is of very real value. The major portion of the disturbance experienced in working with a thermopile in air is due to the unequal heating and cooling of the two junctions of each thermo-element, by the minute and continual adiabatic variations of pressure of the atmosphere. These disturbances become relatively very large as the sensitivity of the galvanometer used for the measurement of the thermo-electric current is increased. It may not always be convenient to work with a vacuum pile, but to secure the benefits conferred by (*c*) it is only necessary to enclose the pile in an air-tight casing, an experimental problem very much easier of solution than the construction of a casing to hold a high vacuum indefinitely. Apparently this simplification of the problem is not generally realised, and I can from my experience here vouch for the efficacy of the method.

In this connexion, it may also be of interest to note that when working with a galvanometer of the Paschen type, of a figure of merit of about 19,000, also when using a Boys' radiomicrometer, it was found possible to eliminate mechanical disturbances only when the instruments were stood directly upon a concrete pillar let into the foundations of the building. Earth tremors, etc., might then produce a temporary minute disturbance, which died rapidly away, leaving the zero unchanged; whereas if any system of suspension or mounting upon rubber in any form were used, chance earth tremors maintained the suspended system in a continual state of minute vibration.

The Evolution of Beauty.

DARWIN sought for an explanation of the ornaments of animals, their bright colours, beautiful songs, and all their structures and habits that could not be explained as the result of natural selection, and he found a perfect one in the instincts possessed by the unornamented sex, usually the females, of choosing as mates the more beautiful of their suitors. But this theory, although it explains the ornaments by the instincts, makes no reference to the evolution of the instincts.

It seems plain that a female which gives her descendants dangerous habits and structures will soon have no descendants, yet some of the practices and structures of the males are dangerous, and the female instinct to choose these has evolved, apparently in defiance of natural selection.

The better mate an animal can get the more chance its descendants will have of survival, and it is obvious that a male that has to face more danger and yet manages to survive has in all probability a greater capacity for keeping alive than one which lives through less danger. Therefore the female that chooses a mate with a dangerous habit or structure chooses what is, apart from the dangerous part, a better and more fit mate.

No species can rise directly above its environment, for if there is less killing there is less selection, and variations for the worse soon drag the whole species down into the arena, even if it does contrive to climb out. The only way in which selection can be escaped is for some individuals to be handicapped and sacrificed, taking the selection upon themselves, so that their descendants, or at all events some of them, may escape it.

This is exactly what has happened. The female has forced the male to seek danger and endure rigorous selection in order to win her, and, while his handicap has descended only to the male line, the vitality which was his that he might bear it has descended to both sexes equally.

The whole advantage is on the female side, consequently anything which tends to make the female more valuable than the male favours the development of sexual selection. Compared with the females the males of polygamous animals are valueless, and it is noteworthy that among the higher animals all, or almost all, the polygamists indulge in sexual selection.

The Line Spectra of Isotopes.

COMPARISONS of the spectra of the isotopes of lead have shown that they are indentical, except for slight wave-length differences of the order of a few thousandths of an Ångström unit. Our inability completely to separate the isotopes of other non-radio-active elements in quantities for spectroscopic investigation has left this the only experimental result of a direct nature. In order to find possible evidences of the effect in two other elements, the writer has made an accurate comparison of the spectra of samples of mercury having different atomic weights, and also of similar samples of chlorine. These have been produced by long-continued fractional diffusions in the laboratory of Prof. W. D. Harkins, who kindly made them available for this investigation.

The best mercury used had an atomic weight difference of 0·18 units. A calculation showed that the proportions of isotopes 198 and 204 in these samples differed by about 20 and 27 per cent, respectively, of their values for ordinary mercury. The lines were compared, using an echelon of R.P. 400,000 and a plane grating the R.P. of which in the fifth order was 478,000. No differences in the wave-lengths of the lines λλ5461, 4359, 4078, and 4047, or any of their satellites, were found which were greater than the error of measurement (3×10^{-4} Å.U.) The relative intensities of the satellites of a line were always visually identical in the two spectra. This observation has a direct bearing on some recent discussions which have appeared in the columns of NATURE, particularly those of Nagaoka and his associates, according to whose ideas we should expect intensity differences of 1/4 and 1/5 in the satellites corresponding to isotopes 198 and 204.

The chlorine lines from two specimens differing by 0·097 atomic weight units, when examined with the echelon, showed distinct evidence of shifts in some cases. Wherever these were observed, the heavier chlorine appeared to give the shorter wave-length. The shifts were small, however (0·0012 Å.U in the largest of the trustworthy cases, λ4741), and their exact values cannot be given, since they were at most only two or three times the experimental error.

The experiments were carried out in the Physics and Chemistry Departments of the University of Chicago, and the writer is indebted to Prof. H. B. Lemon for many valuable suggestions. A fuller report of these results will be given elsewhere.

The Isotopes of Sulphur.

SULPHUR is one of the elements used in the fundamental calculation of atomic weights, and there is no reason to doubt the substantial accuracy of the fractional value 32·06 ascribed to it. The results of its analysis by the mass-spectrograph (NATURE, July 1, 1920, p. 547) were indecisive, owing to the fact that the resolving power of the instrument, about 1 in 130, was insufficient to separate the line due to molecular oxygen from that of a sulphur atom of the weight above, if the latter existed. There were many other lines on the plates, which might have been due to isotopes present in small percentages. Those at 33 and 34 were particularly noted (*Phil. Mag.* 40, 632, 1920), but with the knowledge then available it seemed safer to ascribe these to hydrides and to rest content with the certain conclusion that atoms of mass number 32 were present in preponderating amount.

I have now been able to raise the resolving power of my new instrument to about five times that of the old one, sufficient to show the lines of O and CH_4 clearly separated by more than half a millimetre. Subject to this analysis the line 32, obtained under conditions such that O_2 and S must both have been present, showed no sign of doubling. This proved that isotopes of higher mass-number must exist. Further study with gases containing SO_2 indicated that the suspected faint companions at 33, 34 (S); 49, 50 (SO); 65, 66 (SO_2), were present on all spectra, even when the conditions were such as to make the presence of hydrides very unlikely. They also showed intensity relations consistent with true isotopic character.

The matter has now been put beyond reasonable doubt by the negative mass-spectrum obtained by using pure SO_2 and exposing for an hour with both fields reversed. All three lines were visible, and again showed the same intensity relations. Sulphur is therefore a triple element like the two even ones, magnesium and silicon, which precede it in the periodic table. The lightest mass-number is far the most abundant in all three cases. S^{34} appears to be about three times as abundant as S^{33}; the two together probably amount to about 3 per cent of the whole.

The band spectra of suitable sulphur compounds should well repay a careful study, since they should exhibit an isotope effect similar to that so beautifully demonstrated by Mulliken in the case of silicon.

Cambridge, June 12.

Numerical Reduction of Instars in the Metamorphosis of Euphausids.

THE development of an animal from the zygote up to the adult condition is usually accompanied by a more or less regular and continuous increase in size. In the case of the Arthropoda, however, the enclosure of the body in a hard inextensible layer of chitin renders this impossible, and in accordance with this the chitinous exoskeleton is shed from time to time, each moult or ecdysis being followed by a rapid spurt of growth until the process is again blocked by the hardening of the new chitinous layer. In many of the better-known arthropods particular moults are associated with the attainment of particular stages of development—*e.g* the penultimate and the last moult of a Lepidopterous insect—and the idea is very generally held that this applies to *all* ecdyses or moults in the Arthropoda. Consequently, when in the study of plankton it is found that specimens of the young of some particular crustacean fall into a large number of different types demarcated by slight differences in size and form, one very naturally regards these as forming typical successive stages of the life-history, the whole series being worked through by each developing individual.

The object of this communication is to record that recent work at the Millport Marine Station upon the Euphausidæ would appear to invalidate the belief indicated above. From observations upon *Meganyctiphanes norvegica*, it seems clear that the individual does not necessarily go through the thirty or so moults which have been assumed to demarcate definite successive larval stages. On the contrary, the suspicion is forced upon one that the act of ecdysis does not by any means form a fixed landmark in the developmental history of the individuals. Should this suspicion turn out to be correct it will obviously involve important modification of our current conceptions of arthropod development.

R MACDONALD.

Marine Biological Station,
Millport, May 19.

Abraham de Moivre.

TRAVELLING in countries where NATURE was not available in public libraries, it was not until to-day that I was able to consult the issue of April 17, in which my letter, with Prof. Pearson's comments, appears I must decline to accept responsibility for the statement attributed to me by Prof. Pearson, namely, that I spoke "as if the matter in the 1738 'Doctrine of Chances' and again in the 1756 edition was a mere translation 'except for minor changes'" What I *did* write was that a translation of the pamphlet under discussion appeared, except for minor changes, in both editions. I still believe this statement to be absolutely accurate. It is, of course, true that after this translation there are in the 1756 edition of the "Doctrine" 'Remarks,' and other material. Prof. Pearson regards the Remarks as of great historical importance. I am glad that in this connexion my letter drew forth his further comments on the history of statistics

May I add that my letter was written with a photographic copy of the pamphlet before me, as my reference to the *Isis* article indeed suggested Typographic considerations, which Prof. Pearson suggests, would scarcely lead me to his conclusion. But in the light of Moivre's positive statement that the contents of the pamphlet were first "made public" in 1738, it does not appear to me possible to consider the earlier pamphlet, "communicated to some Friends," as a second supplement to the "Miscellanea" of 1730.

I closed my last letter with the sentence, "It would be interesting to learn if any other copy of Moivre's original pamphlet is in existence." I have here found another copy in the Preussische Staatsbibliothek, bound in with the "Miscellanea" Are there other copies ?

R. C. ARCHIBALD.

Berlin, June 2.

The Taxation of Research.

IN "News and Views" of NATURE of June 19, p. 866, it is stated that there is a "semblance of overstatement" in our letter on the above subject published in the same issue. In justice to the Chemical Society we think this remark "requires some slight modification"

The published balance sheet of 1925 is quoted as illustrating the financial position of the Society, but had the balance sheets for previous years been examined as well, it would have been found that the *actual* deficits on the years' workings were as follows: 1920, 2853*l*.; 1921, 1104*l*.; 1922, 584*l*.; 1923, 1628*l*.—a total of 6169*l*. in four successive years, despite the raising of the subscription from 2*l*. to 3*l* in 1921. It was only by drastically cutting down published papers—even to the point of unintelligibility—that we were able to obtain a credit balance of 210*l*. in 1924 and another of 466*l*. in 1925, the latter including, however, a grant of 350*l*. from the Government Publications Grant

It is clear that in these circumstances "solvency and bankruptcy" are closely related to "surplus and deficit" on the year's working, and that even the substantial sum given as invested capital cannot long withstand depletion at the rate illustrated above.

Frictional Forces in Liquid Surfaces.

MR. CHASE in NATURE of May 22, p. 724, deals with a phenomenon which probably many have noticed. The effect produced is, I think, due entirely to the surface tension of the liquid acting on the wire where it breaks the surface.

Unless the liquid surface be of large extent a resultant force is in general set up on the wire in the plane of the surface, and if the axis of rotation of the moving system does not meet the surface in the same point as the wire, free rotation is impeded.

This form of apparatus gives a great deal of trouble in use, for the forces set up may be comparatively large. It is of course theoretically possible to find the neutral point in the surface and to adjust the axis of rotation and the suspended wire so that they both pass through it, but these adjustments are difficult to maintain, and observations made with the apparatus are liable to a very uncertain source of error.

L. H. G. DINES.

The Light-Quantum Theory.[1]

By Dr. C. D. ELLIS.

IT is well known that the wave-theory of light fails to explain certain phenomena, and so much has been written on this subject already, that it seems at first sight unnecessary to emphasise this point. But although the main problem has not altered and no solution has been found, yet the general attitude towards this question is slowly changing, and several important new experiments have been carried out. Recently a new theory was put forward by Bohr, Kramers and Slater which would have removed many of the difficulties, but experiments by Geiger and Bothe quickly showed it to be incorrect. This theory and its refutation were not without their effect, and now the attitude is frequently held that the light-quantum theory is not merely a crude picture of certain facts, but is an important theory no further from the truth than the wave-theory. The wave-theory itself cannot be correct, but except for its greater age it has no greater claims than the light-quantum view.

These two theories give entirely different pictures of the nature of light, as is expressed by their names. The wave-theory pictures the radiant energy as spreading out in all directions from the source, filling every portion of the surrounding space, so that the propagation may be imagined to be a handing on of the energy from point to point. It is an essential feature that except in special cases the intensity of the forces in the light wave diminish rapidly with increasing distance. Any theory will predict that the average energy density will diminish with the inverse square of the distance, but the law of variation of the forces is peculiar to each theory. The triumphs of the wave-theory scarcely need emphasis. By its means all the intricacies of interference and diffraction problems can be explained in the smallest detail, and in every problem involving direction this theory is in complete agreement with experiment.

It is only when we consider the interchange of energy between radiation and single atoms that the wave-theory breaks down, and the completeness of this breakdown is best seen by considering the photoelectric effect. To take a definite case, suppose X-rays are incident on a plate of some material, then it is found that electrons are ejected from the plate with considerable velocities. The number of electrons depends on the intensity of the X-rays and diminishes in the usual way as the plate is moved farther from the source of X-rays. The velocity or energy of each electron, however, does not vary but depends only on the frequency of the X-rays. The electrons are found to have the same energy whether the material from which they come is close to the X-ray bulb or whether it is removed away to any distance.

This is a result which is quite incompatible with the ordinary wave-theory of radiation, because as the distance from the source increases the radiation spreading out on all sides becomes weaker and weaker, the electric forces in the wave-front diminishing as the inverse square of the distance. The experimental result that the photoelectron always picks up the same amount of energy from the radiation could only be accounted for by giving it the power either to collect energy from a large volume or to collect energy for a long time. Both of these assumptions are unworkable, and the only conclusion is that the radiated energy must be localised in small bundles.

This is the basis of the light-quantum theory. Light of frequency ν is considered to consist of small bundles or quanta of energy all identical and of magnitude $h\nu$, h being Planck's constant. These quanta travel through space, being unaffected by each other, and preserving their own individuality until they make a suitable collision with an atom. Then if the quantum is absorbed the whole energy is transferred to the atom and an electron will be ejected. It can be seen that this hypothesis is so designed that the velocity of the photoelectrons is accounted for, first in the dependence on frequency, since the energy given up is always just one quantum, which bears the correct proportionality to the frequency; and secondly in its independence on the distance from the source, since although when the source is distant fewer quanta will arrive, those that do arrive will still give up the same invariable amount of energy to the atom.

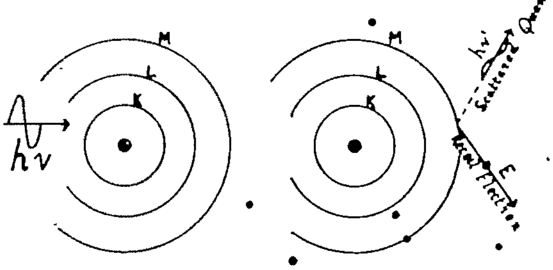

FIG. 1.—Diagrammatic representation of the mechanism of the scattering of X-rays in accordance with the relation $E + h\nu' = h\nu$.

This theory is also capable without further modification of accounting for the Compton effect. Compton found that X-rays suffered a change of wave-length when they were scattered. Now, scattering on the light-quantum hypothesis means a deflexion of the quantum, and since this quantum with its energy $h\nu$ will have momentum $h\nu/c$ where c is the velocity of light, this means further that the electron which deflects it will receive an impulsive blow. Fig. 1, in which the orbital electrons of the atom are represented by concentric rings, illustrates such a process. The left-hand picture is supposed to represent the quantum just about to collide with an electron in the M ring. The right-hand picture indicates how the quantum is deflected and sends off sideways the electron with which it collides. If, as the hypothesis demands, we consider energy to be conserved, then the energy of the scattered quantum plus the energy of the recoil electron must equal the energy of the initial quantum. In other words, the scattered quantum must have a smaller energy, which means lower frequency (since energy $=h\nu$) or longer wave-length. The theory at once suggests the simple qualitative result of Compton's experiments, and it is a striking point that the consideration of the simple dynamics of the collision lead directly to a complete quantitative agreement also.

---

[1] Substance of three lectures on "The Atom of Light and the Atom of Electricity," delivered at the Royal Institution on February 25 and March 4 and 11.

It can be seen that the light-quantum theory explains two important phenomena, but in this crude form it fails to give any explanation of diffraction and interference just as completely as the wave-theory fails to explain the photoelectric effect. These two theories are clearly incompatible, and many attempts have been made so to modify either one or the other that it might explain the rival phenomenon. We find modifications of the wave-theory which attempt, on the whole unsuccessfully, to account for photoelectric phenomena; and again, there is another class of theories which make arbitrary rules to direct the light-quanta along such paths as would be necessary to give the correct interference patterns.

The most serious theory of the first class has been proposed by Bohr, Kramers and Slater, and it must be held greatly to the credit of this theory that it was sufficiently precise in its statements to be disproved definitely by experiment. The Bohr theory took its origin from the observation that it was only in the prediction and explanation of the energy relations that the wave-theory failed, and this failure could be briefly stated by saying that on the wave-theory there is never enough energy at the right place to produce the observed changes. These authors therefore suggested that energy might not necessarily be conserved in each interchange of energy between an atom and radiation, but only when a very large number of such interchanges were considered. For example, an atom which was in a radiation stream of frequency ν could suddenly acquire energy $h\nu$ by means of the action of the radiation, although the energy density of the radiation might be so small that this amount of energy could only be found in a volume a million times greater than that of the atom and there would be no possibility of imagining any kind of collecting process. However, if a very large number of such processes were considered, then the total amount of energy abstracted from the radiation would be equal to the energy absorbed by the atoms.

The merit of this theory was that it rendered possible the calculation of the probabilities of such processes in a manner analogous to the calculations of absorption and emission on the pure wave-theory. It promised such a complete solution of the difficulty that immediately experiments were started to test its accuracy. One such experiment was carried out by Geiger and Bothe on the phenomenon of the Compton scattering, which has been referred to above. The essential features are that when X-rays are scattered the scattered radiation shows an increased wave-length and low velocity electrons are liberated from the scattering atoms. The energy relations in this process are those that would be expected if a light-quantum endowed with mass and momentum were to collide with an electron and be deflected. As a result of the collision the electron will be driven sideways, forming one of the recoiling electrons. It is clear how the light-quantum theory predicts definitely that to every scattered quantum there must occur at the same moment a recoiling electron. On Bohr's theory these two events would not occur at the same moment, there would be no detailed connexion between any one recoiling electron and any particular portion of the scattered radiation. All that is required is that, on the average, energy should be conserved. From this it may be seen that a decision between the two theories will be reached if it is possible to settle whether to each recoiling electron there corresponds a scattered quantum, or whether the scattered radiation is radiated continuously.

Geiger and Bothe directed a stream of X-rays on to a small volume of hydrogen, and on either side of this were arranged two counters. These consisted of small chambers charged to a high potential with an inner insulated electrode. When a single electron traverses the gas in such a counter there is a sudden flow of electricity to the electrode, which may be registered by a suitable instrument. One counter was open to receive the recoiling electrons, the other was to register the radiation, and was closed by a thin metal foil. On the light-quantum view we should say that the quanta incident on the foil will sometimes eject an electron into the counter, which will then register it. Since every recoiling electron must be accompanied by a scattered light-quantum there should be a detectable number of coincidences between the indications of the two counters. On Bohr's theory the scattered radiation comes off in a continuous stream, and passing through the metal foil on the face of the counter, will from time to time liberate electrons. Although on this theory there should be just as many electrons liberated as on the previous theory, the important point is that now the secondary electrons will have no direct connexion with the recoiling electrons, and there would be no reason to expect coincidences between the indications of the two instruments.

The result of this experiment was decisive; undoubted coincidences were found to occur between the indications of the electron counter and the radiation counter. This could not be accounted for on Bohr's theory, which consequently had to be abandoned. But at the same time it provided additional support for the light-quantum view, although it certainly is not a proof of its correctness.

Bothe has recently carried out a further experiment on similar lines which is specially interesting, since in this case Bohr's theory would predict coincidences whereas the light-quantum theory would not. A small piece of iron foil was placed between two 'radiation' counters and radiated with X-rays so that it emitted its own characteristic radiation. If this radiation consisted of localised quanta, then it is clear that any one quantum could go into either one counter or the other, but it could not possibly be absorbed in both counters at the same time, and there should be no coincidences between the indications of the two counters. On the other hand, if the characteristic radiation from the foil spreads out in a spherical wave, this wave will pass through both counters at the same time, and occasionally will stimulate an absorption act in both counters simultaneously, so that on this theory coincidences should be found. Experiment again decides definitely against the theory of Bohr, Kramers, and Slater, and gives the result that would be expected on the light-quantum view. This is the fate of the most serious theory which has attempted to solve the fundamental difficulty by preserving the wave-theory but altering our pictures of the absorption and emission of energy by atoms.

There is another group of theories which postulate that radiation consists of discrete quanta. Thus they explain automatically the photoelectric effect and the Compton scattering, and then attempt to account for diffraction and interference by laying down rules which shall determine the paths these quanta shall follow. The light-quantum theory accounts for all the effects once the quanta are got to the right place, but in its crude form it gives no suggestion of the quanta moving in anything but straight lines, and it is only the wave-theory which predicts successfully the directions in which light travels. Hence theories have been proposed which provide 'tramlines' along which the quanta move, and these 'tramlines' are so arranged that in a system of interference bands 'tramlines' only lead to the bright bands and none to the places of zero intensity. To be more precise, the 'tramlines' are supposed to be the paths of the Poynting vector of a virtual radiation field emitted by the atoms, and the probability of a quantum travelling along a given path is connected with the value of the Poynting vector along that path. Such theories meet with many difficulties, and no one has yet been carried to the point where it can be tested by experiment.

This has been discussed in detail recently by Prof. G. N. Lewis in an article in NATURE (February 13, p. 236), in which he also puts forward an original view on the whole problem. It is a striking fact that while all the theories are directed towards explaining the propagation of light, one theory suggesting that it occurs in the form of waves, the other in the form of corpuscles, yet light has never been observed in empty space. It is quite impossible to observe light in the course of propagation; the only events that can ever be detected are the emission and absorption of light. Until there is some atom to absorb the radiation we must be unaware of its existence. In other words, the difficulty of explaining the propagation of light may be because we are endeavouring to explain something about which we have no experimental evidence. It might be more correct to interpret the experimental facts quite directly and to say that one atom can transfer energy to another atom although they may be far apart, in a manner analogous to the transference of energy between two atoms which collide. Prof. Lewis says: "I shall make the contrary assumption that an atom never emits light except to another atom, and that in this process, which may rather be called a transmission than an emission, the atom which loses energy and the atom which gains energy play co-ordinate and symmetrical parts."

On this view the fringes in an interference system are to be regarded as forming one system with the source in the sense that the atoms which absorb the light at the bright fringes are in 'virtual' contact with the atoms in the source, whereas those in the dark fringes or any place where the light does not go are not in virtual contact. On this view there would never be any discussion as to where radiation goes, but only as to which pair of atoms could make up an emitting and absorbing couple.

The foregoing shows clearly that there is at present nothing approaching a complete theory of light, but yet it must be remembered that it is an important practical achievement that a complete description can be given by means of two theories, providing the appropriate theory is used for each phenomenon. Both these theories have more than justified the care and trouble spent on their elaboration by the help they have given to experimental work, and also on the theoretical side they represent an important advance in our knowledge of light. It would not be right to deduce that both theories are necessarily incorrect; it might be closer to the truth if we were to compare them to the plan and elevation of an engineering drawing. The wave-theory and the quantum-theory may be just the plan and elevation of the true theory of light, and the marked contradictions between them may be due to the language we use to describe the experimental results, just as the differences between a plan and elevation reflect our attempt to describe in two dimensions a three-dimensional object.

The Origin of Petroleum.

By HENRY B. MILNER.

EVERY branch of natural science possesses its quota of time-honoured problems awaiting solution; these serve to maintain an essential stimulus to contemporary thought and to animate that discussion from which progress alone is possible. Controversy, however, unless confined within legitimate bounds of clear issues, is prone to irrelevancies and digressions to an extent that, proverbially, the 'forest' of significant observations tends to be blurred by the 'trees' of individual conjecture and detail: thus is truth obscured and explanation postponed. So it is with the science of petroleum; the problem of its genesis remains paramount, partly because there are more hypotheses than even plausible solutions based on fact, mainly for the reason that the real perspective of the problem is being lost in the maze of accumulated detail and argument. It was not only appropriate but essential that, to avoid further confusion, some one should see round rather than into the problem of mineral oil origin, that the ground should be cleared by correlation of definite data of constructive theories, thus propounding a unified hypothesis from which future research could trend with some hope of positive results. It is from this viewpoint that Mr. Ernest Clark has surveyed his subject, and his thesis (presented to the Institution of Petroleum Technologists on May 25) more than justifies his entry into this difficult field of debate, chiefly by his careful analysis of the situation, by his elimination of the unessential, and by his attempt (entirely successful) to point the way.

At the outset the author tacitly discards all theories of inorganic origin of petroleum, so that we are saved the boredom of recapitulation of text-book paragraphs. He takes his stand on organic theories, and in this the majority is undoubtedly with him. We have to realise that oil formation is as much a definite and normal phase of sedimentation as that of coal, and that no curious mechanism or exceptional process has to be invoked to explain its existence. Thus, just as in studying coal our attention is directed mainly to its mother-substance and the biochemical changes whereby that substance has been made to assume its present form, so with petroleum the problem of genesis is essentially one of the nature and deposition of mother-substance and the subsequent chemical and biological reactions involved in its metamorphosis.

Those classes of organisms which, by their nature and abundance, are potentially favourable as constituents of the mother-substance of oil, belong both to the animal and vegetable kingdoms; of the latter, algæ, diatomacea, and bacteria comprise the planktonic forms, though benthonic forms contribute, such as the seaweeds; water ferns (rhizocarps), terrestrial, fresh-water, and salt marsh grasses may be similarly contributive. Of the animals, foraminifera, corals, mollusca, and fish are mainly concerned in the supply of requisite materials; planktonic, vagrant benthonic, and normal benthonic foraminifera are alike prolific and significant; corals are sedentary benthonic forms of warm marine habitat, possibly of less importance; molluscs favour a shallow water, often a muddy environment, and are accordingly suggestive, while fish, being both marine and fresh-water nekton, are abundant in shallow seas and continental shelves, significant also in their pursuit of essential planktonic food. Thus we perceive the existence of proteins, fats, and carbohydrates in varying proportions in the mother-substance of oil, carbohydrates (cellulose, etc.) characteristic of plant contribution, proteins and fats of animal ingredients. Restriction of any one form, either animal or vegetable, is, as the author shows, dependent on environment, though from a chemical viewpoint fats, either of foraminiferal or algal origin, are conceivably the most important sources of mother-substance.

Decomposition of such organic matter implies mainly oxidising reactions; the rate of oxidation varies necessarily with the available supply of oxygen in the aqueous environment, and here we perceive a selective factor capable of segregating matter of similar chemical composition from a chemically heterogeneous organic mass; some foundation of uniformity in certain important constituents of petroleum may possibly be traceable to this. Again, abundance of marine life depends largely on adequate supply of planktonic food as well as on sufficiency of oxygen; thus conditions creative of or sympathetic to high organic mortality (hence plentiful supply of mother-substance), tend to favour rapidity of oxidation of the organic matter. “The association of prolific micro-organic remains with strata which are believed to have produced petroleum is of very frequent occurrence, and due significance should be attached to this fact.”

In the matter of organic deposition, gulf and inland sea conditions seem to be most favourable, evidenced by a study of many Tertiary oil-fields. These environments often imply rapid and fluctuating sedimentation, sometimes with restricted oxidising influences. Though in this connexion the author did not consider the circumstances of palæozoic deposition, instanced by the great oil-fields of North America, these occurrences do not imply manifestly dissimilar environments, if visualised on a sufficiently large scale; the nature and process of organic contribution are certainly parallel.

The association of petroleum with brine is almost universal, and this ‘indication’ has to be stressed. The theory that such brines represent partially altered connate waters would seem to be nearest the truth, especially when it is remembered that compaction of the salt-water saturated sediment and implied orogenic movement would cause circulation of such connate fluid, afterwards diluted by meteoric fresh-water infiltration, a factor to the migration or removal of oil and gas.

The data of chemical change of organic matter to petroleum are yet obscure, despite the mass of experiment. Putrefaction by bacterial influence is at least a reasonable starting-point; thereafter the reactions would seem to be largely micro-biochemical. A simple pressure-heat distillation as a process is untenable, at least as a general mechanism, in view of observed facts, such as the absence of a common vertical gradation of oils in the field. The necessary reactions might be expected to take place at low temperatures, not above 150° C., possibly much lower; but throughout, some kind of bacterial control would seem to be strongly indicated, quite apart from the influence of extraneous geological circumstances, such as type of sedimentation, presence and potency of colloidal matter, and so on.

Ultimate composition of a crude petroleum thus becomes a function of the initial nature of the mother-substance, its environment and mode of deposition, and the chemical reactions which transform this material into petroleum hydrocarbons, also to some extent of the changes occasioned by the contact of the oil with different rock-types and with subterranean waters. From this point of view the author defines the essential directions of future research; these involve careful investigation of sediments forming at the present time, detailed knowledge of lithology and palæogeography of petroliferous sediments, also of the controlling factors to the movements of oil, gas, and brine in such sediments; from these results it is contended that chemical problems would probably be outlined. It would seem to be unnecessary, however, to await the result of geological investigations before defining or studying the chemical problems, since these, at least, are equally formidable. Clearly the work is that of biochemists and bacteriologists, quite apart from the other specialists envisaged, and the sooner such co-operation is brought about, the sooner will emerge critical data. We have more than once stressed the value of such collaboration with geologists engaged on these ‘border-line’ problems; while the author's work marks a step forward in disposing of irrelevant theory and useless detail, and in focussing attention on the essential organic origin of petroleum, it does equal if not greater service in clearing the ground for a corporate effort from which a true solution to this fascinating problem alone can spring.

Obituary.

Sir William B. Leishman, K.C.M.G., C.B., F.R.S.

The death of Sir William Leishman after a brief illness is one that will be widely and keenly felt in many circles, scientific and military, and not least by the corps to which he had given a lifelong devotion and to whose headship he had attained by sheer merit and force of personality three years before his death. His decease also breaks the circle of Service officers whose labours have opened up new ground in tropical medicine.

A medical graduate of Glasgow, Leishman entered the medical service of the army in 1887, but it was not until ten years later that the call to the laboratory life came to him and we find him installed at Netley at the feet of Sir Almroth Wright and Sir David Semple. With Semple's removal to India in 1900, Leishman became assistant professor of pathology, and in 1903, with the disbandment of the Netley laboratory, he came to London to be professor of pathology at the Royal Army Medical College, a post he retained until 1913. The War gave Leishman abundant scope for his administrative qualities, particularly in the organisation and supervision of bacteriological services in France, which proved such indispensable units in the general scheme of military medicine and hygiene. When the Director-Generalship of the Army Medical Service became vacant in 1923, it was pleasant news to many that one whose reputation rested on his achievements as a scientific worker and teacher had been raised to this important post, which, we believe, Leishman was filling with great acceptance when the end came.

It is appropriate here to refer mainly to Leishman's scientific labours, two at least of which have made his name a household word in medical science. These were his modification of the Romanowsky staining procedure in 1901 and his description for the first time in 1903 of the Leishman-Donovan bodies, the specific protozoal agent of kala-azar and tropical sore and other forms of leishmaniasis which have since become known.

The method of Romanowsky staining, now so indispensable an aid to parasitological and hæmatological technique, was, when first introduced, a cumbrous and perhaps somewhat uncertain procedure. Leishman conceived the idea of securing in one stain the product obtained by the interaction of methylene blue and eosin and dissolving that product in methyl alcohol. This solution both fixed and stained the preparation at the same time, and by the addition of distilled water at a certain stage in the process, a picture was obtained in which the chromatin material present took up the characteristic Romanowsky tint.

Leishman's stain gained wide fame and use and is still largely employed, though for certain purposes modifications such as that of Giemsa are preferred. It was admittedly the use of Romanowsky staining in the form modified by himself which enabled him to obtain a clearer picture of the structural details of the curious bodies the real nature of which had perplexed him for three years. These bodies he had observed first in spleen smears from a fatal case of obscure splenomegaly invalided from Dum-Dum, near Calcutta, to Netley. That they were protozoal parasites he had no doubt when he finally published his description of them in 1903, and he hazarded the opinion, based on observations of the forms assumed by trypanosomes in the blood and organs of rats which had died of experimental Nagana infection, that the bodies pointed to the presence of trypanosomiasis in India—or at least some form of trypanosomiasis in which the fully-developed trypanosome might only rarely make its appearance in the blood stream.

The description by Leishman appeared in May 1903, and in July came an announcement from Donovan confirming Leishman's observations in certain cases of obscure splenomegaly in Madras. Shortly afterwards was reported the finding of similar bodies in tropical sore (Delhi boil) and in the disease known as kala-azar in Assam. Kala-azar, in fact, was proved, by the finding of the parasite, to have other foci outside its main home in Assam.

The writer of this notice may be pardoned for alluding to the finding of these bodies by Marchand and him in the organs of a German soldier returned from the Boxer campaign who died in a Leipzig hospital in December 1902. In their description by Marchand in March 1903, the only opinion that was hazarded was that the bodies might represent some unique form of nuclear degeneration of spleen cells in the obscure symptom-complex known as splenic anæmia—an opinion that was promptly revised when the communications of Leishman and Donovan came to their knowledge later in the year. The Leipzig case pointed to the presence of kala-azar in China, since then a well-recognised centre.

Leishman's view that the Leishman-Donovan bodies represented some form of trypanosomiasis had much to be said for it, and the subsequent discovery by Rogers that flagellate trypanosome-like forms developed from the L.-D. bodies in artificial culture, appeared to lend considerable support to the contention. The view, however, of Ronald Ross, expressed in November 1903, that the Leishman bodies represented a new genus of parasites and not a species or phase of trypanosome, proved the correct one as time went on. Leishman himself in September 1904 directed attention to the similarity of the flagellate forms found in culture of the L.-D. bodies with the herpetomonas known to be present, for example, in the intestinal tract of the house-fly. Though this interesting connexion of the L.-D. bodies in cultural phase has been kept in view for more than twenty years, it is only within recent months that the problem of transmission seems in a fair way to solution, the most probable insect vector being a species of sand-fly.

Leishman made other important contributions to tropical medicine, particularly in connexion with tick fever and the granular changes which take place in the spirochætes within the body of the tick after an infective feed. The precise significance of these "infective granules" is not yet completely understood.

The association of Leishman with Sir Almroth Wright at Netley in the closing years of the nineteenth and the early years of the twentieth century was the means of introducing him to the great problem of antityphoid vaccination, a measure now so potently vindicated by the experience of the War. In 1902 Leishman described a method of estimating quantitatively the phagocytic power of the leucocytes in infection with the view of supplementing the bactericidal tests which had been hitherto mainly employed as criteria of acquired immunity. The technique formed the basis of the method employed by Wright and Douglas (1903) in their analysis of the factors which determine the phagocytosis of micro-organisms in the presence of normal serum. The appointment by the Army Council in March 1904 of the Antityphoid Committee "to investigate the practical prophylactic and therapeutic value of current methods of immunisation against enteric fever," gave Leishman and his enthusiastic band of collaborators abundant opportunity for experimental investigation during many busy years. Questions such as the preparation and standardisation of the vaccine, the relative efficiency of vaccines prepared in different ways, their keeping quality, the antibody response to them in the inoculated, and many other cognate questions were submitted to experiment both in man and animals. Thus when the War came, all was *en train* for the prompt institution of this beneficent preventive measure.

When the War closed, Leishman became the first Director of Pathology at the War Office, a post which he held until his appointment in 1923 to be Director-General of the Army Medical Service. The influence of Leishman as a teacher and scientific worker was an asset of incalculable value to his corps, and that influence will, we trust, go on to further fruition. The fellowship of the Royal Society came to him in 1910, and many distinguished orders thereafter. His outside interests were many, and of committee and commission work he took his full share. He was a polished and ready speaker, ever a helpful and courteous colleague, and in his little leisure he found time to indulge his love of art and music and the pleasure of tending his Croydon garden.

J. C. G. L.

SIR FREDERICK MOTT, K.B.E., F.R.S.

PSYCHIATRY has suffered a very grievous loss by the death of Sir Frederick Mott on June 8. To the last he was occupied by his researches, and in spite of advancing years he was a leader of scientific thought in the allied provinces of physiological psychology and psychiatry.

The earlier work of Mott on the physiology of the central nervous system belongs to that period when there was still much to be done by the successors of Fritsch and Hitzig in the field of cortical localisation, and his researches with Schäfer are among the foundations of our knowledge of cerebral physiology. From the motor cortex he turned to the study of sensory representation, and his work with Sherrington on the apæsthetic limb was a great contribution to our knowledge of the sensory component of motor activity. His brilliant studies on the anatomy of the spinal encephalic system and the thalamic connexions of the fillet led up to the classical work on the architecture of the cerebral cortex.

Mott's interest in the pathology of the nervous system was determined by his appointment as pathologist to the London County Council Mental Hospitals in 1898. When working in the Central Laboratory, then situated at Claybury, he had access to the enormous amount of pathological and clinical material furnished by the whole group of London mental hospitals. His first great work in this field was to study the pathology of general paralysis, the one psychosis that was then recognised to be associated obviously with concomitant bodily change. Although the syphilitic origin of general paralysis had been pointed out by Krafft-Ebbing, this etiology was only accepted by a small minority of psychiatrists in Great Britain. These were the days before the Wassermann reaction, and Mott set himself definitely to prove Krafft-Ebbing's thesis by a close study of a great mass of pathological data and by clinical observations. As a result of his epoch-making research the syphilitic origin of general paralysis was proved beyond all cavil, and this paper was followed by studies on the relation of syphilis to other forms of insanity and to tabes. The whole of this work was published in the first volume of the *Archives of Neurology*, which he founded.

From his work on general paralysis Mott became firmly impressed by the idea that bodily changes are to be found in all types of psychosis, but he recognised that it was not probable that the functional disturbances of the majority of the psychoses would be shown by the relatively coarse methods of investigation practised in the pathological histology of the nervous system. He turned his attention, therefore, to the bodily mechanisms which exhibited the organic resonance to emotion in the hope that disturbances of the affective states would be sufficiently pronounced at a period of the disease when the higher centres were less affected. Dementia præcox offered the most promising field of study, and in a series of papers on the pathology of the gonads and other endocrine organs and the vegetative nervous system in this disease, he was able to demonstrate with certainty the existence of a widespread degenerative change preceding the far slighter evidences of degeneration that could be detected in the central nervous system in advanced cases. In other psychoses similar though less marked pathological changes were encountered. Mott, however, was a profound disbeliever in the attempts to relegate the psychoses into sharply-defined classes. He considered that though the signs of structural impairment were most obvious in dementia præcox, there was not clinically or pathologically any hard-and-fast line between this and other psychoses. He was well aware that the methods of pathological anatomy could only furnish evidences of relatively gross changes, and he turned to the study of the biochemistry and physics of the central nervous system.

Though Mott later greatly modified the conclusions that he drew from the attempts which he made with Halliburton to demonstrate the existence of products of nervous degeneration in the cerebral spinal fluid, this work, which he published in his Croonian Lectures, was important as the starting-point of many subsequent investigations into the chemical pathology of the nervous system.

As a consultant neurologist to a clearing hospital for war neuroses Mott's attention was diverted for a time from the psychoses to the neuroses. A study of the previous histories of the various sufferers from war neurosis convinced him that in the overwhelming majority of the cases there was definite evidence of the pre-existing functional instability of the nervous system. He predicted that an investigation into the physiological activity of the mechanisms of the motor system in such cases would reveal functional abnormalities, and work done in his laboratory from the point of view of the physiological psychologist certainly tended to support this view. Mott considered, then, that a neurosis was the response of an abnormally constituted organism to environmental stress which could be safely encountered by the normal individual, and he looked for such abnormalities of function rather in the emotional mechanisms and the various glandular organs that subserve them than in the higher nervous strata.

These views on the pathogenesis of the psychoses and neuroses are only now beginning to make themselves felt. At the time at which they were published, students of psycho-pathology, owing to a curious confusion of thought, seemed to have regarded the formulation of the anatomical and physiological disturbances found in the psychoses as an attempt to translate thought into terms of nervous mechanism. The real importance of this work is that it enables us to build up a pathology for the psychoses on the lines that have already been firmly established for the various toxæmic psychoses and for syphilitic insanity.

In the actual study of disorders of conduct Mott followed the methods of the less extreme school of behaviourism. He thoroughly distrusted the results of the various schools of psycho-analysis on methodological grounds, but he did not consider that his discoveries on the pathology of the nervous system had any direct bearing on the admissibility of their views. He considered that the majority of the pathological changes he had discovered in insanity are congenital, and instituted a very extensive inquiry into the genealogy of the cases in the London mental hospitals. As one of the fruits of his investigation he enunciated the "Law of Anticipation," in accordance with which the onset of the psychotic symptoms appears earlier in the successive generations of a degenerate family, and thus ultimately, owing to the production of infertile juvenile psychotics, the tainted stock disappears. He had more faith in the efficacy of this natural method for the elimination of the mentally unfit than in segregation or sterilisation. He pointed out that in the earlier generations of an insane family the psychosis is as a rule not evident until after much damage has been done by the breeding of tainted progeny.

Mott's work in the field of hospital hygiene is less widely known, but it is in a great measure due to his energy and teaching that dysentery in mental hospitals is almost a thing of the past.

The great work that Mott did for the teaching of the scientific aspects of psychiatry constitutes one of his greatest services to society. He was fortunate in possessing the esteem and friendship of a great clinical psychiatrist, Dr. Henry Maudsley, and when Maudsley proposed to found a hospital for the investigation and treatment of the early forms of mental disease, it was in order that it should be under the supervision of Mott that he gave the necessary endowments to the London County Council. After many years of difficulty, the Maudsley Hospital for Early Mental Diseases was opened at Denmark Hill, and the Central Pathological Laboratory was transferred there from Claybury. It was here in the concluding years of his service as pathologist to the London Mental Hospitals that Mott instituted a school of psychiatrical medicine, one of the functions of which is to prepare the younger psychiatrists for the examination for the Diploma of Psychological Medicine, which has been instituted thanks to his efforts. Mott continued to teach enthusiastically in the Maudsley Hospital to the end, and acted as the director of a similar school of psychiatry in Birmingham, and he was on a visit thither when he had the cerebral seizure from which he died.

Mott was at the disposal of any one who sought his advice, and did much to assist younger men by suggestions and criticism. He was possessed of a sturdy common sense and preserved to advanced years a keen scientific acumen combined with a phenomenal receptivity for new views and facts. He was a man of wide culture, and his great kindliness and sincerity endeared him to all.

SIR HENRY MORRIS, BART.

SIR HENRY MORRIS, who did more than any man of his time to open up the field of renal surgery, died in London on June 14 in his eighty-third year. On February 11, 1880, when he had become full surgeon on the staff of Middlesex Hospital, he removed a stone from the kidney of a patient, this being the first time that a deliberate operation had been performed for such a purpose. The operation was successful, and has become the type of a procedure now adopted by surgeons all the world over. When he gave Hunterian Lectures at the Royal College of Surgeons in 1898, he was able to cite the results he had obtained from 367 operations carried out on the kidney. It is true that Gustav Simon of Heidelberg performed the first operation for the removal of a diseased kidney in 1869, and that this operation had been frequently and successfully repeated before 1880, but it was Morris who demonstrated that one of the commonest of disorders from which the human kidney suffers—the presence of renal concretions—can be safely cured by surgical procedure.

Sir Henry Morris was, however, a general surgeon in the best sense of the term and contributed to all branches of surgical art. He came of Welsh ancestry; his grandfather was a surgeon in Oswestry, and his father in Petworth. He was dark in hair and complexion, and massively framed in head, body and limbs, a good exemplification in the flesh of the type which Mr. "Punch" has chosen to represent as "John Bull." He was a man of decided opinion, resolute in his policy, never afraid of opposition, and public-spirited to a high degree—often seeking the columns of the *Times* to guide opinion in educational, medical, social and political matters.

Epsom College and the University of London provided the opportunities of Sir Henry Morris's education, and he repaid both by giving them his unstinted services; he took an abiding interest in the welfare of

Epsom College, acting as its treasurer for many years. His medical education was obtained at Guy's Hospital, but his life's work was spent in the wards of Middlesex Hospital, to which he became assistant surgeon in 1871. There he did much to direct attention to the urgent need of research into the nature of cancer, and took an active part in founding the Imperial Cancer Research Fund.

Sir Henry Morris was also an anatomist. He lectured on human anatomy in the Medical School of Middlesex Hospital, and in 1893 edited a very successful "Treatise on Human Anatomy." An earlier work on the "Anatomy of Joints" is still a book of reference; it contains many original observations.

In 1893 Sir Henry was elected to the council of the Royal College of Surgeons of England, serving as president for three years, 1906, 1907, 1908, a baronetcy being conferred on him then. He delivered the Hunterian Oration in 1909, in which he compared the respective merits of the inductive and deductive methods of philosophy. He served on the General Medical Council, becoming treasurer to that body, and in 1910 was elected president of the Royal Society of Medicine. He was one of the outstanding figures in modern surgery, and a leading authority on medical education.

WE regret to announce the following deaths:

Prof. E. Babák, professor of physiology and general biology in the Masaryk University and Veterinary School in Brno, known for his work on the regulation of respiratory movements and also on the influence of endocrine glands on amphibian metamorphosis, on May 29, aged fifty-three years.

Prof. J. J. Flather, head of the department of mechanical engineering at the University of Minnesota and vice-president in 1902 of Section D of the American Association for the Advancement of Science, on May 14, aged sixty-three years.

Dr. C. Hering, a pioneer in electro-chemistry, who was one of the founders of the American Electrochemical Society in 1902 and in the same year began a movement which resulted in the foundation of *Electrochemical Industry*, on May 10, aged sixty-six years.

Prof. A. Magnin, formerly professor of botany and director of the Botanic Garden, University of Besançon, and a gold medallist of the French Geographical Society, aged seventy-eight years.

Prof. W. F. Shanks, professor of physiology in the University of Leeds since 1923, and formerly lecturer in physiology in the University of Glasgow.

Prof. V. A. Steklov, professor of mathematics at the University of Leningrad and vice-president of the U.S.S.R. Academy of Sciences, on May 30, aged sixty-one years.

News and Views.

SITTING in committee on the Finance Bill on June 21, the House of Commons rejected a clause moved by Mr. Withers (University of Cambridge) providing that a university, a college, or hall in a university, a public school, and any educational institution receiving a Government grant, should be exempt from income-tax in respect of any profits forming part of its income which were applicable to educational purposes only. The Chancellor of the Exchequer opposed the motion, though he stated that he was not satisfied with the present state of the law on the subject of the exemption of 'charities' exempt from income tax. The motion arose on the decision recently given by the House of Lords that a public school making a surplus is liable to taxation as earning profits, but the general question is closely related to the letter from the president and the treasurer of the Chemical Society which appeared in our issue of June 19 and their further letter in this present issue.

THOSE engineers who hold that the concentration and standardisation of electrical power supply in Great Britain is the best policy to adopt, and are weary of the somewhat fruitless discussions on points of administration taking place during the Committee stage of the present Government Bill, will now be able to point to the ever-growing electrification of Germany in support of their views. Plans have already been made for the inter-connexion of the existing power stations in Germany by overhead 'feeders' on a gigantic scale. In the past the production of electrical power in Germany has developed on individualistic lines. The largest power works belong to the Reich, which produces more than a thousand million units per annum solely for profit. There are very many stations, however, of much smaller size which are very uneconomical. In some cases they burn peat fuel, and supply only a few hundred consumers. Owing to the great distances involved, it will be necessary to use very high pressures, and experiments are proceeding with insulators for use on lines with transmission pressures of 220 and 380 kilovolts.

Two main schemes for electrification in Germany have been planned. The first proceeds from the water-power stations at the Vorarlberg in South Germany to Hamburg, and the second from the same source through the Central German lignite fields and Berlin to East Prussia. A length of about 100 kilometres from the Goldenbergwerk to the Wesel is now working at 110 kilovolts, but double this pressure will probably become the standard. As chains of insulators are used there is no difficulty about insulation. With these high pressures it is necessary to use overhead wires of large diameter, otherwise brush discharges—the so-called corona—appear on the wires and lead to a serious loss of power. The conductors therefore are generally made of aluminium and are hollow. Some of the cable manufacturers make the conductors of copper, the outer cylindrical shell being supported by a helix of copper tape wound inside the hollow. In California, 220-kilovolt transmission over 243 miles has been in successful operation for the last two years. The cables are of aluminium with a steel core and are supported by chains consisting of twelve insulators.

REPORTS have appeared recently in some of the newspapers of a new steel, described as 'F' steel, which was stated to have great advantages for structural work, a saving of 40 per cent. in weight and 30 per cent. in cost as against ordinary mild steel being claimed. No particulars were given, but the manufacturers were said to be the Freund Smelting and Machine Manufacturing Co., of Berlin, the patent having been acquired from the Swiss metallurgist Bosshardt. A paper in *Stahl und Eisen* for April 15 gives a detailed account of the steel, from which it appears that Messrs. Freund were not in any way responsible for the newspaper statements. The steel is not a new one, but is a high-silicon alloy of a kind already known to metallurgists. Neither is the Bosshardt furnace essential to its manufacture, steel of similar properties having been made in ordinary steel furnaces. Messrs. Freund have allowed the particulars to be published, an investigation of its properties having been made by them in collaboration with the Verein deutscher Eisenhüttenleute. The steels examined contain from 0·67 to 1·1 per cent. of silicon, with low carbon, about 0·10 to 0·14. This gives an increased elastic limit and breaking strength as compared with simple carbon steel, whilst the ductility is not reduced. In the interesting volume of Sir Robert Hadfield on "Metallurgy and its Influence on Modern Progress" (see NATURE, February 6, p. 187) the use of a similar steel, but with a rather higher carbon content, in the construction of the *Mauretania* and *Lusitania* in 1907, is described. The introduction of these steels into shipbuilding was due to the late Mr. John Spencer, the composition having been arrived at as the result of the original investigations on silicon steels by Sir Robert Hadfield.

WHEN certain adhesive tapes such as are used for insulating purposes are unrolled, a bright greenish luminescence appears over the region of immediate separation occupied by the suddenly extended threads of the viscous adhesive medium. A letter on this subject entitled "Bioluminescence" was communicated by Dr. J. W. French to NATURE of June 20, 1925, p. 944, the title being suggested by the resemblance to the greenish light emitted by certain insects. Only a few kinds of insulating tape exhibit the phenomenon, such, for example, as the black "Chemico" British tape and the white Italian tape. According to Prof. Elmer O. Kraemer, of the University of Wisconsin, Madison, the light is produced when the adhesive tape is separated from the ends of the film proper in camera roll films. There are, however, many types of roll film that do not act in this way. It can be demonstrated that the effect is associated with particular adhesives and not with the film itself. Similar luminescence sometimes appears when the adhesive tape is stripped from the joint of the tin in which unexposed kinematograph film is usually contained. It occurs in the adhesive between the tape and the tin.

IN some further experiments Dr. French has found that excellent results are obtainable from the use of ordinary rubber vulcanising solution, provided it is in a suitable physical condition of tackiness, which may be varied by treatment with sulphur. The adhesive threads must not be too extensible: on the other hand they must not be too short or brittle, for if the experiment is repeated with the pieces of tape which in the first instance have produced a bright light, the luminosity will be fainter and the threads shorter. If the pieces, however, are kept pressed together for a day or two, the threads will be of more normal length and the light may be as strong as before. There thus seems to be some close connexion between the rate of extension up to the breaking point and the luminosity. Prof. Eligio Perucca, Laboratorio di Fisica Sperimentale della R. Scuola di Ingegneria, Torino, who in his lectures on experimental physics includes the phenomenon in question as a type of luminescence, states that, if one of the tapes is connected to a gold-leaf electroscope, it will be found that the stripping operation produces an electrostatic charge of three or four units at a pressure of about 200 volts. In his original communication, however, Dr. French stated that the light appears undiminished in brightness when the tapes are unrolled under water or in a Bunsen flame, so it can scarcely be assumed that the electric charge is the cause of the luminosity.

THE new Pharmacological Laboratories of the Pharmaceutical Society were opened by the Minister of Health, the Right Hon. A. Neville Chamberlain, on Wednesday, June 16. The chair was taken by Mr. P. F. Rowsell, immediate past president of the Society, during the tenure of whose presidency the opening ceremony should have been performed at the beginning of May. In his speech Mr. Rowsell referred to the passage into law of the Therapeutic Substances Act and the necessity which arose for the existence of a laboratory where those manufacturers who wished could have tested the products which were placed upon the schedule of the Act from time to time. Dr. J. H. Burn, Director of the Laboratories, described in more detail the functions which it is hoped the laboratories will subserve, and laid special emphasis upon the research into methods of standardisation which will be vigorously carried on in the future. He referred also to the international importance of the work which has been carried out since the War on this subject in the laboratories of the Medical Research Council under the direction of Dr. H. H. Dale, adding that it is gratifying to realise that Great Britain has taken the lead in introducing methods for the biological standardisation of drugs. Dr. Burn also mentioned a third reason for the founding of these Laboratories, namely, in order to afford an opportunity for the training of pharmacists in methods of biological standardisation. Mr. Chamberlain, in declaring the Laboratories open, referred to the many and varied duties of a Minister of Health, all questions relating to the prevention of disease as well as to the purity of the drugs used in treating it coming within his province. Sir Humphry Rolleston, moving a vote of thanks to Mr. Chamberlain, referred to the interest taken by the late Mr. Joseph Chamberlain in the health of the British possessions in the tropics. Mr. Edmund White, chairman of the Society's Scientific Advisory Committee, seconded the vote of thanks, and Mr. Chamberlain briefly replied. After the ceremony, the company adjourned to the Laboratories, where

Dr. Burn demonstrated methods used in the standardisation of the digitalis group of drugs, and of ergot and pituitary extract.

UNDER the will of the late Sir Winthrop Hackett, first Chancellor of the University of Western Australia, the sum of 50,000*l.* was left to the University and the Anglican Church. Three-eighths of the money was to be devoted to providing scholarships; three-eighths to be invested until it accumulated to 40,000*l.* when a Winthrop Memorial Hall was to be erected, and one-quarter was left for the purpose of the erection and maintenance of an Anglican University College with a chapel attached thereto. Not content with these proofs of his devotion to the University, Sir Winthrop bequeathed the balance of his residuary estate to the same two bodies in the same proportions and in the same manner. Sir Winthrop died in 1916, and the trustee of the estate, Mr. Alfred Langler, has informed the University Senate and the Diocesan Trustees that he will shortly have paid off all liabilities and all the numerous legacies with the exception of those of the University and the Anglican Church. The University and the Anglican Church, for the purposes of the trust alluded to in Sir Winthrop's will, are now the sole heirs of the very valuable estate left by Sir Winthrop Hackett. That estate includes the principal daily newspaper in Western Australia and a weekly paper, both of which have been 'flourishing' for many years. The bequest is without doubt one of the most munificent that has ever been made to an Australian university. To Sir Winthrop Hackett is due in large measure the starting of the University of Western Australia, and it will be remembered that he, during his lifetime, endowed the chair of agriculture.

THE political significance of recent events in Poland is outside the scope of this journal, but the outcome, the election of Prof. Ignace Moscicki as the new President of Poland, is noteworthy in that Prof. Moscicki is a distinguished man of science who has also been actively concerned in industrial chemistry. We are indebted to the *Chemical Trade Journal* for some details of his career. Prof. Moscicki is best known for a process for the fixation of nitrogen by the arc method, which was elaborated while he was director of the electro-technical and electro-chemical laboratories at the University of Freiburg. In 1912 he was appointed to a similar post at the University of Lwow which he held until after the War. Since then he has been head of the Polish State Nitrogen factory at Chorzow, where the manufacture of cyanamide has been developed, the monthly output now reaching about 10,000 tons. For five years he was a student in London. Prof. Moscicki has a reputation as a scientific worker and as an administrator, and there is little doubt that the discipline of his early training will serve him well in his difficult task of guiding the fortunes of a modern European State.

A NUMBER of paintings on ivory by Winifred Brunton, with the collective title "Africa, Ancient and Modern," is now on view at the Arlington Galleries, 22 Old Bond Street. Mrs. Brunton, as those who visit this exhibition will appreciate, has devoted much time to the study of Egyptian antiquities from the artistic point of view, and is responsible for the beautiful coloured plates illustrating the "Portraits of the Kings of Egypt." In the collection now on view more than half the subjects are drawn from ancient Egypt. All show a wonderful and accurate sense of colour, which finds full play in the reproductions of personal ornaments, although "A Temple Vase" and the lotus cup from the Cairo Museum will bear comparison with any. Of the heads, "An Unknown King," reconstructed from a statue in the Cairo Museum, and "Amenemhat III." are remarkable conceptions of force of character. There are two very charming pictures of dancers, the "Wind in the Reeds" being especially pleasing in composition and colour. The paintings from South and East Africa include several subjects of ethnographic interest. The reconstruction of Rhodesian man is more convincing than some attempts that have been made to clothe this interesting relic with flesh. The exhibition was opened by Mr. Robert Mond on June 21 and will remain open until July 2.

COMMEMORATION DAY at Livingstone College, London, E.10, was celebrated on Wednesday, June 9. The Right Rev. the Lord Bishop of Chelmsford presided, and in the course of his address said that the College exists to help all missionary societies of the church and churches; that those who go forth may at least have some kind of knowledge both as to the management of their own health and of that of other people. Missionaries trained at the College are a tremendous help to the people to whom they go if one looks at it from only a humanitarian point of view. The Rev. B. T. Butcher, of the London Missionary Society, an old student of the College, referred to conditions in New Guinea. When he first went out there, there was but one cure for the loathsome disease of yaws, and in most cases it took more than a year to effect a cure; now it can be dealt with in a short course of treatment. In his opinion, yaws will be almost unknown round the coast of New Guinea in ten years' time, and Livingstone College will have played a part in making it unknown. Mr. R. L. Barclay, hon. treasurer of the College, referred to the work which had been done for the College by the late Dr. Harford, and stated that they had already received 770*l.* towards a fund of 3000*l.* which was being raised in his memory. The Principal of the College mentioned that old students are in Sierra Leone, Labrador, Siam, North Africa, and many other parts of the world; last year 103 students entered the College, including the short course and vacation course students.

IN the *Journal of the Franklin Institute* for May, Dr. C. E. K. Mees of the Eastman Kodak Company contributes an article on the colour sensitivity of photographic materials, in which he traces the subject from its very beginnings down to the present day, especially with regard to its practical aspects. Modern panchromatic plates and films enable exposures of one-fiftieth of a second to be given through the tricolour red and green filters with apertures so low as $f/4·5$, as is necessary in colour kinematography and in aerial photography with the red filters which have to be used to do away with the fogging effect of atmospheric haze. A very instructive diagram shows that in the period 1904–1919, photography of the spectrum was possible from a little over λ200 to a little beyond λ700, in 1919–1925 sensitiveness to the infra-red was extended to rather beyond λ800; while at the present time it is possible "easily" to photograph to rather beyond λ900, and "with difficulty" to photograph from practically λ100 or even λ50 to λ1000, the "difficulty" being the long exposure necessary, and the need for vacuum apparatus when using the shorter wave-lengths. The paper includes many interesting illustrations, one being of the planet Mars to show the difference between the results when an ordinary plate and when an extreme red-sensitive plate and filter are used. The latter shows detail that is invisible in the other, and shows the actual surface of the planet, while the ordinary plate shows a much larger disc due to the atmosphere that surrounds it. Dr. Mees finally refers to the work of Barnard and Gye on the cancer virus, who by using a wave-length of λ257 and a microscope with quartz lenses of numerical aperture 1·25 have obtained a resolving power of 0·11 μ instead of the visual resolving power obtainable of 0·2 or 0·16 according to the light used. It seems questionable whether there is any practical gain, especially considering the great difficulty of using the apparatus. "Barnard, however, is undoubtedly trying to get shorter wave-lengths."

THE forty-fifth annual meeting of the Society of Chemical Industry, which will be held in London during the week July 19–23, is to assume the character of a Congress of Chemists, and as such will be supported by a large number of societies connected with chemistry. On July 19, in the Mansion House, Lord Balfour will deliver the third Messel memorial lecture in the presence of the Duke of York and the Lord Mayor; earlier in the day Sir Frederic Nathan will give his presidential address to the Institution of Chemical Engineers on "Industrial Efficiency and the Elimination of Waste," and Sir Max Muspratt will open an exhibition of British chemical plant. With the exception of these two items, which will take place in the Central Hall, Westminster, and of an exhibition of chemical apparatus at the Institute of Chemistry, all the meetings and most of the social functions will be held in the Hotel Great Central, London, N.W.

THE scientific meetings in connexion with the forthcoming meeting of the Society of Chemical Industry will be open to chemists without restriction and will include discussions on corrosion, hormones, and "Chemistry House" (July 20); power alcohol, the influence of particle size in the paint and rubber industries, under the chairmanship of Sir William Bragg (July 22); fat-extraction by solvents, and solid smokeless fuel (July 23). Among the papers to be read, those on the experimental study and use of hormones, by Dr. H. H. Dale, and sugar from wood, by Dr. W. R. Ormandy, appear to be of exceptional interest. Addresses by Sir Josiah Stamp and Sir Max Muspratt are announced for July 21. There will be a large number of excursions and visits to works, and the many social functions will include a garden party in the Royal Botanic Gardens, by invitation of Sir Alfred and Lady Mond, the annual dinner of the Society of Chemical Industry, a smoking concert, dance, and conversazione. The Chemical Industry Club is offering honorary membership to all attending the Congress. Full particulars and tickets are to be obtained from the Society of Chemical Industry, at Central House, Finsbury Square, London, E.C.2.

SIR HUMPHRY ROLLESTON, Bart., Regius professor of physic in the University of Cambridge and lately president of the Royal College of Physicians, has been awarded the Gold Medal of the British Medical Association.

FURTHER details of Miss Garrod's discovery of a skull, presumably of Mousterian age, at Gibraltar, tend to confirm the first impressions of its importance. In addition to the frontal bone another large piece of bone was found, but owing to the hardness of the matrix in which it is imbedded it is impossible yet to say whether it is the parietal or the occipital. Decision on this and other points must wait until it has been cleared. The hardness of the matrix has by no means been entirely a drawback, as it has ensured the recovery of the fragments in pieces of considerable size.

IT is announced that the Medical Research Council, on behalf of the Rockefeller Foundation, has made the following awards of medical fellowships provided by the Foundation and tenable in the United States of America during the academic year 1926–27: Dr. G. Bourne, St. Bartholomew's Hospital, London; Mr. H. W. B. Cairns, London Hospital; Miss R. E. Lucas, Maudsley Hospital, London; Mr. R. D. Mackenzie, University of Edinburgh; Mr. C. F. A. Pantin, Marine Biological Laboratory, Plymouth, Dr. A. F. B. Shaw, University of Durham; Dr. J. C. Spence, Royal Victoria Infirmary, Newcastle-on-Tyne; Mr. H. E. C. Wilson, University of Glasgow.

THE research steamship *William Scoresby* is now being fitted out at the Humber Dock, Hull, and is expected to be ready for sea at an early date. She is a small vessel of the whale catcher type, her principal dimensions being: length, 125 ft.; breadth, 26 ft.; depth, 14½ ft.; draught, 13½ ft. The *William Scoresby* will be employed, in conjunction with the R.R.S. *Discovery*, and will operate principally in tropical and antarctic regions. Her duties will consist generally in the marking of whales, steam trawling and other marine biological investigations. The ship's company will include two scientific workers, the master, four officers, and fourteen petty officers and men. The whole cost of the vessel will be met from the funds of the *Discovery* Expedition which are derived from the revenues of the Falkland Islands Dependencies.

THE part enacted by the house-fly as a carrier of disease organisms and the necessity for efficient measures preventing the breeding of this insect are facts of prime importance from the point of view of public health. We therefore welcome the appearance of a second edition of the illustrated brochure on this insect which has been recently issued by the British Museum (Natural History). The author, Major E. E. Austen, has revised and expanded the text of the first edition and has brought the pamphlet thoroughly up-to-date Its full title, "The House-Fly, its Life-History, Importance as a Disease Carrier, and Practical Measures for its Suppression," sufficiently explains its scope. It may also be added that the author deals with the insect under other conditions besides those met with in the British Isles, and has incorporated the results of experience gained through the operation of sanitary measures in the War. The pamphlet is obtainable either from the Natural History Museum, South Kensington, or through booksellers, price 1s.

Applications are invited for the following appointments, on or before the dates mentioned:—A demonstrator in the Department of Inorganic and Physical Chemistry, Bedford College for Women—Secretary, Bedford College, Regent's Park, N.W.1 (July 3). Part-time lecturer in sociology, Bedford College for Women—Secretary, Bedford College, Regent's Park, N.W 1 (July 3). Research chemists for the Fuel Research Station, East Greenwich—Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (July 3). Analysts for work in connexion with the Physical and Chemical Survey of the National Coal Resources of Great Britain—Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S W.1 (July 3). Half-time assistant in the Department of Mathematics, University College of Swansea—Registrar, University College, Swansea (July 9). Two junior scientific officers at the Royal Aircraft Establishment—Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (July 10). Assistant lecturer in physics, University College of Wales—Secretary, University College, Aberystwyth (July 13). Lectureship in chemistry in the University of Durham—Registrar, Armstrong College, Newcastle-upon-Tyne (July 17). Assistant agricultural chemist in the Department of Science and Agriculture, Barbados—Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (July 31). Senior laboratory assistant in the Department of Entomology, London School of Hygiene and Tropical Medicine—Secretary of the School, 23 Endsleigh Gardens, W.C.1 (July 31). Head of the Chemistry Department, Borough Polytechnic Institute—Principal, Borough Polytechnic Institute, Borough Road, S.E.1. Several inspectors of agriculture for the Sudan Government—Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1.

Our Astronomical Column.

Recent Solar Activity.—For several weeks there has been an absence of very large sunspots, although smaller ones, averaging half-a-dozen daily, have been of interest to observers with moderate telescopic means In addition, faculæ at both limbs of the sun have been present on most days, some of the areas being of considerable extent. Traces of the faculæ related to the great spot of last December and January in north latitude 22° were seen about a fortnight ago. On June 21, a group of spots, the development of which had been watched since June 16, was of sufficient size to be a naked-eye object on the disc. The group consisted of a roughly circular spot as leader closely followed by a close cluster of small spots, which on some days linked up with one another to form a composite companion to the leader On June 15, Mr. Newbegin, observing with his spectroscope at Sutton, Surrey, noted a metallic prominence (that is, one having a spectrum containing metallic lines) at position angle 63°, which corresponds almost exactly with the position of the newly forming spots then at the sun's east limb. This prominence, of the 'rocket' or 'splash' type, appeared as if the gases were being expelled from a common centre. Such prominences, according to Evershed and other observers, are very frequently found connected with sunspots, either during their active development, or at other times when great changes are taking place.

Particulars of the large spot are given below:

No.	Date on Disc	Central Meridian Passage.	Latitude.	Area.
7	June 16-(28)	June 22·0	25° N.	1/1400

(Area expresses the proportion covered of the sun's hemisphere.)

Neptune's Satellite.—Prof. Eichelberger's and Mr Arthur Newton's exhaustive researches on this satellite have already been mentioned in Nature. Their paper is printed in the March issue of *Mon. Not. Roy. Ast. Soc.*, and deserves a further note. It is curious that though no certain markings have been seen on Neptune's surface, we now know the position of its axis nearly as accurately as that of Mars. The position of its north pole is given as R.A. 295°·2, N. Decl 41°·3 (equinox 1900·0): the pole of the satellite's orbit describes a circle of radius 20°·1 in 585 years, the annual motion being 0°·62. The observations indicate a considerably greater motion for the major axis of the satellite's orbit, from 1°·5 to 3°·0 per annum. It moves in the opposite direction to the node, as it should, but the observed motion is probably too great. Owing to the very small eccentricity, about 0·005, it is very much more difficult to determine the position of the apse than of the node. Dr. J. Jackson deduces 1/66 and 19 hours as the probable values of the compression and rotation period of Neptune.

Temperature of Mars.—*Astr. Nach.* No. 5448 contains an article by W W. Coblentz comparing the measures made by Lampland and himself at the Lowell Observatory with those made by Pettit and Nicholson (100-inch at Mt. Wilson). It is noted that the receiver used by the latter covers a Martian area 50 per cent. larger than that used by the former; this would make the measures more nearly average ones for the whole surface, and less affected by the particular regions in view. The measures show that dark areas are hotter than bright, and that the afternoon side of the planet is hotter than the morning side; the latter point is not so plainly indicated in the measures of Pettit and Nicholson, but terrestrial analogy makes it reasonable. Radiation near the east and west limbs was found to be respectively one-third and one-half of that at the centre The article closes with a note of satisfaction that the two sets of observations are on the whole accordant.

Research Items.

English Gypsy Folk Medicines.—Mr. T. W. Thompson, in the *Journal of the Gypsy Lore Society* (Ser. 3, Vol. 4, Pt. 4), publishes some notes on the remedies used by gypsies for both human beings and horses, which are of some interest in view of the reputation which this people has long held for their skill in the art of healing. The information was obtained mainly from members of the Smith and Boswell families. Generally speaking, medicines made from herbs are preferred, and the list given includes forty-seven wild plants held to be efficacious for various diseases. Among them are hemlock and foxglove, which were recognised as dangerous plants, as also were monkshood and nightshade, and only used in weak infusions. Of the fungi, those growing in woodlands were regarded with suspicion, but of those growing in the open several varieties were sometimes eaten. One informant had a preference for simples; another preferred a number of ingredients. Though some of the herbal remedies can be justified in the light of modern knowledge, others rest on the doctrine of signatures which attested that plants and minerals indicated by their external characteristics the diseases for which Nature intended them as remedies. This applied also to the animal kingdom, *e.g.* hedgehog's fat was used for earache or a slight deafness, the skin of a supple eel for stiff joints. Other remedies provide examples of a symbolic transference or rebirth. For asthma the sufferer caught a trout alive, breathed three times into its mouth and put it back into the water. A spider was hung in a bag around the neck of a sufferer from ague, and as the spider died the ague left him. Hair from the cross on a donkey's back, skeleton feet of hedgehogs and moles, pieces of red cotton and wool are among the prophylactics against various diseases.

Californian Archæology.—The results of an examination of relics of the Indian tribes formerly inhabiting the Southern San Joaquin Valley, California, by E. W. Gifford and E. Egbert Schenck, have been published as Pt. 1 of vol. 23 of the *University of California Publications in American Archæology and Ethnology*. The geographical features of the Valley which have determined the character and extent of human occupation have been the lakes Tulare and Buena Vista. The general aridity of the valley and the variable water level which, at any rate in Tulare, ranges from 220 feet to absolute dryness, not only determined the site of occupation, but also in all probability prevented any very extensive or dense occupation. Presence of the Spaniards in other areas added fugitives to the population, and this and other causes have effected an extensive mixture of race and culture. The relics obtained from surface finds and excavation of burial- and camp-sites represent a great variety of artefacts, of bone and horn, steatite, chipped stone, ground stone, unworked stone, textiles and cordage, pottery and wood. Forty human crania were obtained which belonged to two types: the San Joaquin sub-type of the Californian type, short-faced and broad-nosed, and the Buena Vista type, relatively long-faced and narrow-nosed. The southern part of the San Joaquin Valley lies in an area the cultures of which have not yet been described. There is a generic resemblance between the culture of the San Joaquin area and the Santa Barbara area, but the two centres of the San Joaquin Valley, the Alpaugh and the Lake regions, have certain points of resemblance to the Santa Barbara culture which are mutually exclusive. This suggests independent lines of transmission, the Alpaugh possibly representing an earlier phase of the Santa Barbara culture. Certain features, such as the bags, the ceremonial use of human hair cordage, and of ground crescentic stones for girls' puberty ceremonies, point to Southern California.

Intestinal Parasites of Ruminants.—M. J. Triffitt records (*Protozoology*, No. 2, Jan. 1926) the results of examining the fæces of certain ruminants in the London Zoo. She found in the sable antelope from South Africa, and in a pair of common waterbuck from East Africa, an Entamœba which closely resembles and is probably specifically identical with *E. ovis*. Both active forms and cysts were present. Uninucleate cysts of some hitherto undescribed species of Entamœba are recorded from the fæces of an eland. The author also describes sporozoan parasites found in the intestinal wall of Bennett's wallaby. Two of these are closely allied to or identical with *Ileocystis macropodis* and *Lymphocystis macropodis* respectively, which the author considers should be ranged under the genus Globidium. One of the other parasites is an Eimeria (*E. macropodis*), the various stages of which are described.

Flagellates in the Latex of Asclepias.—*Herpetomonas elmassiani* is the only species of latex-inhabiting herpetomonad in the United States, and it has been found in great numbers in the common milkweed, *Asclepias syriaca*, in Maryland and New Jersey. Further studies on the relations of the flagellate to its plant host have been carried on by F. O. Holmes (*Biol. Bull.*, 49, 1925). He shows that the flagellate is confined to the latex system and that the Herpetomonas is intracellular but not intracytoplasmic. The latex is secreted into the general cell vacuole of the latex duct and it is in this that the flagellates occur. No other cells were found to be infected. A red and black hemipterous insect, *Oncopeltus fasciatus*, is suspected of being the insect host of *H. elmassiani*, and the flagellates were found in the trilobed salivary glands of this insect, chiefly lining the lumen of the dorsal lobe; a few were present in the anterior lobe, but none in the ventral lobe. Search for the flagellates in the intestine of the insect gave negative results.

Tidal Data for the Antarctic.—A reprint has reached us of the reduction by Dr. A. T. Doodson, The Tidal Institute, University of Liverpool, of the tide gauge records made at Cape Evans, in the Antarctic, by Mr. Nelson during 1921–22 (June–January). The reprint appears to be an excerpt from a volume collecting the results of the expedition, but bears no indication of its origin and gives no mention even of the name of the expedition. This was the third expedition wintering on Ross Island, and comparison is made of the amplitudes and phases of the principal tidal constituents (S_2, M_2, K_1, O_1) derived from the three expeditions, the others being those of the *Discovery* (1902) and the *Nimrod* (1907), all of which had their stations within a few miles of one another. The three sets of results are in very satisfactory agreement, and the tides in this small region of the Antarctic may be considered adequately known.

Hydrographical Conditions in the Baltic.—A survey of the hydrographical conditions in the northern part of the Baltic has been carried out during the summers of 1922, 1923, and 1924 by Finland and

Sweden working in co-operation, the region at the entrance to the Gulf of Bothnia having received the greatest attention. The results are recorded in the following publications recently received: Havsforskningsinstitutets Skrift. No. 30: *Thalassologische Beobachtungen im Ålands- und Schärenmeer im Juli 1922 und Juli 1923.* Herausgegeben von Rolf Witting und Hans Pettersson. Pp. 39. 7 Fmk. No. 32: *Talassologiska vårexpeditionen 1924. Referat: Die thalassologische Terminfahrt im Jahre 1924.* Av Risto Jurwa Pp. 27. 4 Fmk No. 34: *Regelmässige Beobachtungen von Temperatur und Salzgehalt des Meeres im Jahre 1923.* Von Gunnar Granquist. Pp. 54. 10 Fmk. No. 36: *Dagliga vattenståndsuppgifter 1923. Referat: Tägliche Wasserstandsangaben 1923* Av Henrik Renquist. Pp 46. 8 Fmk. (Helsingfors: Statsrådets Tryckeri, 1925.) Continuous measurements for several days were made by means of current meters at a number of positions where the physical conditions of the water, including the rate of evaporation and the change in water level, together with the meteorological conditions, were also observed. Currents of ¼ to ½ mile per hour were met with in the neighbourhood of the Aland Isles, running usually northward into the gulf and apparently not dependent upon the winds during the period of the survey. A south-going stream ran along the Swedish shore. No conclusions are drawn from the numerous data and no review of the conditions met with are included in the published records.

THE BATH SPRINGS.—Dr R. H. Rastall in the *Geol Mag.* for March 1926 reprints his interesting article on the geology of the Bath springs from "The Book of Bath," 1925. The temperature of the waters is about 70° F. above that of normal spring water, indicating that the ultimate source must be at least 5000 feet below the surface. This deduction, and the saline character and radioactivity, lead to the conclusion that the Bath and similar thermal springs in other countries are fed by deep-seated sources of igneous origin. The uprise of such waters involves the existence of pronounced fractures, and in the case of Bath it is not difficult to account for the existence of suitable fractures. The east and west lines of folding and fracture of the highly disturbed Mendip region and the similar north and south lines of the Malvern disturbances cross in the neighbourhood of Bath, thus producing lines of particularly easy penetration through the older rocks. The fractures, however, were produced before the Triassic and Jurassic beds were deposited, and the clays of the latter system seal up the water to some extent. Borings which have passed through the Rhætic clays encountered red sands from which hot water flowed. Thus the exact points of outflow at the present surface must be determined by the presence of small faults or fissures of later origin in the clays which underlie the city itself.

THE ANGLES OF CRYSTALS DURING GROWTH.—Miers has suggested that the formation of vicinal faces in crystals is due to the difference in the density of packing of the molecules in a crystal and those in a saturated solution. Further, it is considered that owing to the greater density of packing of the former the molecules of the solute separating from the solution find difficulty in compressing themselves into the closer packing of a simple crystal face. Experiments by E. S. Hedges described in the *Journal of the Chemical Society* for April 1926 support this view. By very slow growth of a crystal of sodium chlorate, single perfect cube faces have been obtained, since under such conditions the solute molecules can more easily take up their correct positions in the crystal face.

MAGNESIUM ELECTRODES IN SPECTRAL ANALYSIS.—The advantage of magnesium electrodes in cases where only small amounts of the material to be investigated are available are described by M. E. Dureuil in the *C. R. Acad. Sci.*, Paris, of April 26. Cylinders 1 cm. in diameter were employed as electrodes, the substance to be examined being placed in a cavity of about 1 mm. diameter in the positive electrode. They can be used either for arc or for spark spectra; in the former case the current should not exceed 1 ampere, to avoid ignition of the magnesium. The spectrum of magnesium is a simple one, with only about fifty lines, and in the region between 7000 and 3580 Å.U. there are only about ten strong lines; these do not come in the way of the characteristic lines of the other elements. Even with commercial magnesium the lines due to the impurities copper, iron, manganese, silicon, calcium, sodium, aluminium and carbon are weak, and would only cause difficulty in cases where these elements have to be investigated. The use of these electrodes has been found particularly valuable in the case of the platinum metals, the alkalis and alkaline earths, and especially for non-conducting minerals which resist the action of fused carbonates. This is probably due to the strong reducing action of magnesium, which at the high temperature of the arc or spark displaces the metals from their compounds, so that they give their dissociation spectra in the most favourable conditions.

THE ELECTRONIC STRUCTURE OF THE BENZENE MOLECULE.—In the *Journal of the American Chemical Society* for May 1926, L. Pauling discusses the electron-orbit-sharing theory of chemical bonds in connexion with the electronic structure of the benzene molecule. The carbon and hydrogen atoms are in the same plane at the corners of two concentric regular hexagons, and the manner in which they are connected by the shared bonds is described. Pauling extends this theory to naphthalene and anthracene, and shows that it accounts for the properties of these substances.

VITAMINS IN HEAT-STERILISED FOODS.—In view of the lack of direct evidence on the vitamin content of foods sterilised by heat and the conflicting results of earlier workers, C. M. Dugdale and R. J. Munroe have started a number of experiments on this subject. The first of the series, described in the *Journal of the Society of Chemical Industry* of May 21, deals with the presence of vitamins in meat preparations and shows, in the form of curves, the effects of various samples on the growth of rats reared on a vitamin-free diet. It is concluded that meat has a higher vitamin value than is usually supposed, and the heat processes used to sterilise it on a commercial scale affect the vitamins only slightly.

THE REACTION BETWEEN ETHYLENE AND CHLORINE.—Norrish studied the reaction between ethylene and bromine in a glass vessel and in glass vessels covered with wax, cetyl alcohol and stearic acid, and concluded that the reaction took place on the glass but not on the paraffined surface. Stewart and Edlund found that the reaction was of the second order, taking place entirely on the walls of the glass vessel containing the mixture. In the *Journal of the American Chemical Society* for May 1926, Stewart and Fowler describe the reaction between ethylene and chlorine in the presence of dry air. They state that this is also a second-order reaction taking place at the glass surface at approximately one-tenth of the speed the reaction between ethylene and bromine.

South-Eastern Union of Scientific Societies.

THE thirty-first annual Congress of the South-Eastern Union was held at Colchester on June 9-12, under the presidency of Mr. Reginald A. Smith, of the British Museum, in succession to Sir John Russell, director of the Rothamsted Experimental Station. In his address Mr. Smith dealt with "Essex in pre-Saxon Times," and pointed out that Essex is particularly rich in remains of the Early Iron Age, or Hallstadt period. Before the arrival of the Romans, Colchester was the capital of the most advanced of the British tribes. With the aid of the lantern, phases of pre-Saxon civilisation were illustrated. The gradual degradation of the British gold coin, founded on the Macedon stater, was shown, and the introduction of that on which there came to be shown an ear of corn, the origin of which still remains a mystery. A point of interest dealt with was the origin of the Red Hills, so called, although they are but raised platforms of burnt earth. The president's view was that they are the débris from the preparation of the ground for the construction of salt-works, the base of the pans with its growth of vegetation being burnt over, and the material then being scraped together and deposited in such a way as to form platforms, which may have been used as refuges by workers against sudden irruption of the tide. Workers were invited to inquire as to the finding of currency bars of iron, as at present none have been found in Essex.

Mr. Chas. E. Benham contributed a paper in which he dealt with "Colchester's greatest Citizen," Dr. William Gilbert, whose monumental work "De magnete," founded on actual experiment, laid the foundations of inductive science. He showed thus early that the earth is a magnet, and that the phenomena of the compass with its varying dip and declination all conform to that principle. Gilbert's terellæ and his other early instruments were bequeathed to the College of Surgeons, but they were all unfortunately destroyed in the great fire of 1666. The arms of the borough of Colchester constitute a story in themselves, and are associated with the legendary story of St. Helen. King Cole reigned at Colchester at the end of the third century, and was her father. He was the merry King Cole of the nursery rhyme. On his coming to terms with the Roman general Constantius, he gave the general his accomplished daughter Helena in marriage. The story is recorded in the ancient records of Colchester, which date from about 1350, so that historic accuracy cannot be claimed for it.

Dr. E. J. Salisbury's paper on "Plant Communities of the Seashore" was of special interest in view of the proximity of the town to wide stretches of estuarine flats, and an excursion to Mersea Island and the Strood enabled botanists to examine and collect specimens of the flora dealt with by Dr. Salisbury. The Strood is interesting as being a causeway of Roman foundation, connecting the island with the mainland. In the Pyefleet, running north from the Strood, are the chief oyster-beds belonging to the Colchester Corporation, and here as elsewhere constant warfare is being waged against the slipper-limpet, specimens of which were collected along the coast when a geological ramble was made to the cliffs at Walton-on-the-Naze. Tons of the slipper-limpet are annually dredged up by the corporation dredgers and destroyed, but the pest continues to increase.

No other town, said Dr. Mortimer Wheeler, possesses a local museum surpassing that of Colchester as a collection of Roman antiquities. He spoke in the great quadrangle of the castle, and described Camulodunum (Colchester) as the royal seat of the Trinobantes under the king Cunobelinus It was evident that the tribal community endeavoured to assimilate Roman culture and fashions It was the intention of the Romans to make Colchester the capital of Britain, an intention that was afterwards frustrated by geographical and other considerations. The Balkerne Gateway was the largest gateway erected by the Romans in Britain.

A paper by Mr. E. C. Stuart-Baker dealt with "Some Curious Aspects of Evolution" in bird-life and was illustrated by excellent lantern slides. Examples were given among the pheasants and other birds of the direct effect of environment on variations. One of the best-known and most widely accepted factors in evolution is the atmospheric condition of humidity. Excessive humidity acts upon the pelage or plumage and causes great darkness or brilliant colouring. A moderate amount of humidity generally results in a dull neutral tint, dark or pale in proportion to the amount of humidity being above or below normal. The absence of all humidity causes white or very pale coloration. The lecturer asked his audience to remember that when they were told that the various forms of pheasants shown can be produced in captivity by hybridisation, environment no longer exists in captivity, and man, by the selection of suitable individuals for the creation of the form which he desires to reproduce, takes upon himself the privileges and powers of environment.

Mr. Hazzledine Warren's paper on "The Correlation of the Lower Palæolithic" gave rise to considerable discussion, in view of the opinions which he expressed as to the age of Strepyan implements, and the distinctive characteristics and duration of Chellean and Acheulian cultures. In Mr. Edward A. Martin's paper on "Break-names in Geological History," he showed that while doubt exists as to the proper correlation for passage-beds, bone-beds and newly discovered strata, it would meet a want if names were allotted to the breaks between the recognised systems, to which such strata could be allocated at least tentatively. These names he proceeded to allot, all of which would be derived from the names of geologists, examples being 'Lapworthian' for the break between Ordivician and Silurian, and 'Whitakerian' for the break between Cretaceous and Eocene. These names would at once be recognisable from those of systems, since they are all personal names. In the discussion that followed, it was agreed that the subject deserved the attention of geologists.

In a paper by Mr. J. H. Owen, of Felsted, which was illustrated by very fine photographs by the author, the matter of the cuckoo and its foster-parents was dealt with in a masterly manner, and it was shown that the young cuckoo made use of its rump and tail rather than its back for the ejection of young birds and eggs from the nest. It would climb up backward the side of the nest, with the youngster on its back, and then by a final flick of its rump eject the unwanted one.

Regional survey subjects were dealt with by Mr. Alexander Farquharson on "The Social Constitution of a County"; by Mr. Geoffrey E. Hutchings on "The Choice of Maps for Regional Surveys."

In connexion with the Congress a volume has been published entitled "Essex: an Outline Scientific Survey," a concise statement of scientific research in the county, written by members of the Essex Field Club and others.

Mechanism of Oxidation in Living Tissues.

THE isolation of glutathione by F G. Hopkins in 1921 threw a fresh light on the processes of oxidation and reduction in living tissues, since the compound appeared to be of a simple constitution and not an enzyme, to which class of bodies the substances producing oxidation in the living organism were, in the majority of cases, considered to belong. Since then its constitution as a dipeptide of cysteine and glutaminic acid has been definitely proved, especially by its synthesis by Stewart and Tunnicliffe. It owes its activity in promoting oxidations to its property of acting either as a hydrogen donator, when it is present in the reduced (or cysteine) form, or as a hydrogen acceptor, when it is in the oxidised (or cystine) form: which form is present, depends on the conditions of its environment. Further details of its activity in promoting oxidations have recently been given by its original discoverer (F. G. Hopkins, *Biochem. Journ.*, 1925, vol. 19, p. 787). The paper deals with the oxidation of fats and proteins; at present the relationship, if any, between glutathione and carbohydrate utilisation has not been worked out.

Unsaturated fatty acids such as linoleic and linolenic are oxidised in the presence of the reduced form of glutathione (GSH), but the actual mechanism appears to be somewhat different at different hydrogen ion concentrations. At *p*H 3·0-4·0 large amounts of oxygen are taken up by the system: presumably a peroxide is formed by two thiol groups and the oxygen then passed on to the fatty acid, so that the reaction is catalysed by the GSH; it may be represented by the equation

$$AO_2 + 2B \longrightarrow A + 2BO,$$

where A = GSH and B = the fatty acid. On the other hand, at *p*H 7·4-7·6 less oxygen is taken up; in fact it is found that the amount is almost exactly twice that necessary to oxidise the GSH to the oxidised form (G_2S_2); in other words, the oxidation is a coupled reaction, according to the equation

$$AO_2 + B \longrightarrow AO + BO.$$

When the behaviour of the glycerides of the unsaturated fatty acids in the form of pure linseed oil was studied, different results were obtained. At *p*H 3·5-4·0 a latent period occurs before the oxygen uptake sets in; at *p*H 7·4-7·6 the equipartition of oxygen between GSH and the fatty acid is not seen, but after a high initial uptake the oxygen consumption falls off to a steady linear rate until nearly all the fat is oxidised. The point of inflexion on the curve corresponds to the time when nearly all the GSH has been oxidised, and unless there is a certain definite concentration of GSH present at the commencement, the oxidising system fails to become established. The cause of these variations is not yet known, but the establishment of the oxidising system in alkaline emulsions of linseed oil does not appear to be due to the presence of minute traces of iron.

For the investigation of the oxidation of the proteins the author has utilised certain pure preparations as well as a muscle powder obtained from the tissue by extraction with boiling water, and with alcohol and ether to remove lipoids, followed by drying and powdering. Such a muscle preparation in Ringer's solution at *p*H 7·6 and in the presence of oxidised glutathione (G_2S_2) takes up oxygen to the extent of 2000 c.mm. per gm. This oxidation occurs only in a solution of an alkaline reaction, and only when the protein is present as a solid phase, and also gives a positive nitroprusside reaction; that is, when it itself contains an -SH group. This 'fixed' -SH group of the protein is not oxidised by molecular oxygen, but can be by G_2S_2 even in the absence of oxygen. In this case the surrounding solution acquires a positive nitroprusside reaction owing to the reduction of the G_2S_2. The fixed -SH can be restored by contact with GSH; but it is not removed by simple washing of the tissue, nor is it a question of the adsorption of GSH to the tissue, but the fixed -SH appears itself to undergo alternate oxidation and reduction according to the conditions of its environment. It is probably the only reducing factor in the thermostable muscle residue.

It is to be noted that the amount of oxygen necessary to oxidise this fixed -SH group is only one-tenth of that taken up by the system in the presence of G_2S_2. Moreover, when the uptake of oxygen has ceased, restoration of the group by exposure of the powder to GSH will enable a further quantity of oxygen to be taken up with further oxidation of the protein: up to the present, an amount of oxygen equalling 10·0 c.c. per gm. of powder has been observed to be taken up, by renewing the fixed -SH group at intervals, and even this is not a maximum.

Pure proteins are not so active as the muscle powder. It is of interest to note that a protein which gives no nitroprusside reaction may be caused to react positively by denaturation. If GSH is added to the protein instead of G_2S_2, the initial oxygen uptake is quicker and the total oxygen uptake is greater by an amount which is nearly equal to that which would be required to oxidise all the GSH to G_2S_2; so that in both cases the oxidation of the protein proceeds with only minute amounts of -SH in solution.

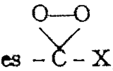
To sum up, the oxidation of fat and protein depends on the hydrogen-ion concentration of the solution and on the fact that GSH is oxidised quickly in an alkaline, but only slowly in an acid, medium. At *p*H 7·6 protein alone is oxidised, and since GSH is quickly oxidised to G_2S_2, the fixed -SH of the protein molecule must be intact to ensure the presence of -SH in the solution. At *p*H 6·0 both protein and fat are oxidised, the latter owing to the fact that the GSH is maintained at a higher concentration in the more acid solution. At *p*H 3·8 fat alone is oxidised; and the process is slower in the presence of G_2S_2, since its reduction to GSH is slow.

The question has been examined from a different point of view by J. H. Quastel (*Biochem. Journ.*, 1926, vol. 20, p. 166). Investigating the dehydrogenations produced by resting bacteria, he was struck by the great variety of substances which were capable of acting as donators or acceptors of hydrogen: moreover, closely related compounds behaved differently in the presence of *B. coli* and methylene blue; one might be oxidised and the other not. It seems scarcely possible that the organisms possess enzymes capable of acting on each different compound; on the other hand, there is good evidence that the change in the molecule of a compound which enables it to undergo oxidation or reduction takes place at the outer surface of each organism, though possibly in some cases at a surface in the interior of the cell.

Recent work has shown that molecules are orientated in a surface, so that it may be considered as a mosaic composed of the different molecules arranged singly or in groups in a definite pattern, which is characteristic for each cell, but varies slightly with its growth and activity. This molecular arrangement will lead to the existence of varying electric fields scattered over the surface of the cell, and the author considers that a molecule is 'activated,' and so becomes susceptible to oxidation (or reduction), when it comes under the influence of one of these electric fields, which causes a shift of electrons from one atom to another of the molecule. Thus the group $-CH=CH-$ becomes $-\check{C}-CH_2$. The movement of the proton will be determined both by the shift of the electrons and also by the electrical condition of the molecule itself. Thus if a radicle is one electron short of its full number it will, replacing an atom of hydrogen in the molecule, turn its positive end towards the carbon atom with which it combines, and so tend to repel a positive charge. The opposite effect occurs if the replacing radicle has one electron more than its full complement. $-OH$, $-NH_2$, and $-CH_2COOH$ repel positive electricity, whilst $-COOH$, $-CONH_2$, and $-COCH_3$ attract it. Thus on activation, $R-CH=CH-COOH$ becomes $R-\check{C}-CH_2-COOH$, and $R-CH=CH-CH_2-COOH$, $R-CH_2-\check{C}-CH_2-COOH$.

The theory therefore offers a possible explanation of the well-known β-oxidation of fatty acids in living animals. The author has examined a large number of compounds in the light of his theory and finds that his experimental results can all be explained by it. It offers a satisfactory reason why closely related compounds should differ in their behaviour as hydrogen donators in the presence of resting organisms, and obviates the necessity of postulating the existence of large numbers of enzymes which have never yet been extracted from these cells.

The author considers it probable that the $-SH$ group, as it exists in glutathione, is one of the means whereby oxygen is activated so that it becomes a hydrogen acceptor. In other cases this may be due to small traces of iron or to the development of a peroxide at an activated carbon atom; *e.g.* $-\check{C}-X$ becomes



$$-\overset{O-O}{C}-X,$$

so that the process which activates the hydrogen donator may result at the same time in the activation of oxygen

The Royal Society Conversazione.

THE Royal Society usually holds two conversaziones annually. The first of these gatherings was cancelled owing to the general strike, and the second was held on June 16 last. Many of the exhibits arranged in the Society's rooms have already been referred to in our columns. Limitations of space forbid more than passing notice of some of the remainder.

The Department of Entomology, British Museum (Natural History) (Mr. F. W. Edwards and Dr. P. A. Buxton) exhibited specimens of a submarine Chironomid. This is the first insect species known to spend its whole life in the sea, and was discovered by Dr. P. A. Buxton in Samoa, where it was found associated with other Chironomid flies having normal air-living adults. Mr. T. S. P. Strangeways and Dr. H. B. Fell showed microscope preparation of the development *in vitro* of the isolated eye of the embryonic fowl. Fowl embryos of 64-70 hours' incubation were used. An eye is dissected out and explanted into a medium composed of fowl plasma and embryonic tissue extract; here it grows and differentiates in a surprisingly normal way.

The Soil Physics Department, Rothamsted Experimental Station (Dr. B. A. Keen and Dr. W. B. Haines), exhibited a new combination of apparatus for measuring soil resistance, which has marked advantages over the usual type of dynamometer. It is light and portable, and gives a continuous record of the draught, and a time scale, on a celluloid strip, which has great advantages over paper for outdoor work under varied weather conditions.

Lieut.-Col. F. J. M. Stratton and Mr. C. R. Davidson showed a number of photographs of the solar eclipse of January 14 last, taken at the expedition sent to Benkulen, Sumatra. The expedition obtained good photographs of the corona, the spectrum of the chromosphere, and also of the corona both with slit spectroscope and prismatic cameras, from a discussion of which it is hoped that fresh knowledge may be gathered as to the condition and constitution of the solar atmosphere. From the spectrograms of the corona it will be possible to obtain accurate wave-length measurements of the lines of the coronal spectrum of unknown origin.

Prof. O. W. Richardson showed an apparatus for the investigation of soft X-rays which are produced by the electronic bombardment of solids. The tube is of transparent silica, and is exhausted to a pressure of about one ten-millionth of a millimetre of mercury. The presence of the X-radiation is demonstrated by the photoelectric emission which it produces from a copper-plate enclosed in the tube.

The National Physical Laboratory had two interesting exhibits. The vector colorimeter (Mr. Guild and Dr. Perfect) enables a colour to be specified by *qualitative* measurements involving colour matches only. Two colour matches are made. In one the test colour is matched by a mixture of spectrum red with monochromatic light of suitable wave-length; in the other by a mixture of spectrum blue with another suitable monochromatic constituent. These matches determine the two vectors, and their intersection determined the position of the colour on the colour chart. A modified manometer for the determination of the vapour tensions of molten cadmium and zinc was also shown (Mr. C. H. M. Jenkins). This is measured by the pressure of nitrogen required to level the two liquid surfaces of the metal of a specially shaped manometer. The closed end of the manometer can be flooded by rotation of the apparatus, and foreign gases can also be removed by a similar rotation accompanied by a reduction of pressure.

Mr. W. M. Mordey showed some experiments demonstrating the possibility of getting a powerful rotation, in multiphase alternate current fields, of magnetic materials which are either non-conducting in themselves or are made so by being reduced to fine powder and then made up into solid discs or cylinders with some binding material, such as glue or shellac, which insulates the particles from one another. Such discs or cylinders, which form miniature induction rotors without windings and with non-conducting cores, can be made up of powdered magnetic materials such as hard cast-iron dust, hard steel grit, nickel, cobalt, and of the magnetic minerals magnetite and pyrrhotite; in such bodies no appreciable eddy currents are produced, the rotation being due entirely to hysteresis. An interesting item in the exhibit was a small alternate-current electric fan, the rotor of which consisted simply of a piece of pyrrhotite rock with no winding on it, revolving freely in the field of a small model multiphase magnet. Loose powders of any of these materials rotated in such multiphase fields in a direction opposite to that in which solid masses of the same materials rotate, a reversal of direction due to a rolling action of the particles. No eddy currents are induced in any of the conducting materials when powdered. Dr. W. H. Eccles and Dr. Winifred Leyshon showed a neon tube and tuning fork combination for producing electrical oscillations of harmonic frequencies suitable for calibrating wave-meters. The neon tube is connected in parallel with a condenser and in series with a resistance and a battery; it then gives an intermittent luminous discharge and the current can be used to keep a steel tuning-fork in continuous vibration. The current in such a circuit has many high harmonics, and therefore induces an oscillatory current of any chosen harmonic frequency in a neighbouring circuit tuned to that frequency.

Sir Robert Hadfield, Bart., exhibited a number of specimens of alloy steels for special purposes. These included a rotor in 'ERA/ATV' steel used in the construction of exhaust gas turbines. These rotors are driven by the exhaust gases from internal combustion engines; they work continuously at a temperature of from about 800° to 950° C., and run up to the very high testing speed of 53,000 revolutions and working speeds of about 30,000 revolutions per minute. A tuning-fork of high nickel-chromium alloy steel was shown which has constant frequency under varying temperature. For this purpose the metal must have a very low temperature coefficient of the modulus of elasticity.

University and Educational Intelligence.

Birmingham.—The new buildings for the Department of Oil Engineering and Refining (which have been in use during the past session) were formally opened on June 19 by Sir John Cadman. The department is remarkably well equipped for the training of students in the science and practice of oil technology. There is special provision for experimental research in the production of synthetic liquid fuels and for high-pressure work on the Bergius process. There is a three-year course leading to the ordinary B.Sc. degree and a four-year course for an honours degree in the subject. There is in addition a post-graduate school open to honours graduates of approved universities who have taken engineering or chemistry as principal subjects.

Cambridge.—The late Mr. W. W. Rouse Ball, Trinity College, who died on April 4 of last year, has left to the University a sum of 25,000*l.* on condition that a professorship or readership of or directly connected with mathematics should be founded, and a further 25,000*l.* for a professorship or readership of some branch or branches of modern English law. He expressed a hope that these professors or readers should include in their lectures historical and philosophical aspects of their subjects. He further left a sum of 10,000*l.* the income from which is to be used for the benefit of, or toward the expense of maintaining, the University library.

In connexion with the celebration of the Bacon tercentenary by Trinity College in October next, it is proposed to confer the honorary degrees of LL.D. on Prof. W. S. Holdsworth, of the University of Oxford, and of Sc.D. on Sir Ernest Rutherford, Trinity College, Cavendish professor of experimental physics and president of the Royal Society.

It is announced from Magdalene College that elections to the Donaldson and Charles Kingsley Bye-Fellowships for the encouragement of research will be made early in July, applications to be made to the Master, Magdalene Lodge, before June 30.

Edinburgh.—The bicentenary of the institution of the Faculty of Medicine was celebrated on June 10 and 11, when representatives of many famous schools of medicine at home and abroad took part in the commemoration. At the special graduation ceremonial the honorary degree of LL.D. was conferred on the following alumni of Edinburgh: Dr. Andrew Balfour, Director of the London School of Hygiene and Tropical Medicine; Prof. Robert Howden, professor of anatomy, University of Durham; Prof. W. T. A. Jolly, professor of physiology, University of Cape Town; Sir George Newman, Ministry of Health; Prof. Alexander Primrose, professor of clinical medicine, University of Toronto; Sir John Robertson, professor of public health, University of Birmingham; Prof. Ralph Stockman, professor of materia medica, University of Glasgow; Dr. A. Logan Turner, president of the Royal College of Surgeons, Edinburgh; Sir Norman Walker, treasurer of the Royal College of Physicians, Edinburgh; Prof. J. T. Wilson, professor of anatomy, University of Cambridge.

After the graduation Sir George Newman gave an address in which, beginning with the primitive school of medicine at Salerno and later considering the schools in Bologna, Padua and Leyden, he traced the influences which led to the founding of the Edinburgh School. He emphasised the great influence exerted by Boerhaave upon Alexander Monro, who was the founder of the Medical Faculty in Edinburgh, and upon John Rutherford, who introduced clinical teaching in Edinburgh upon the Leyden model. This bedside teaching, with its subsequent developments of clerking and dressing, became one of the characteristic features of the Edinburgh School, which has been copied all over the world. Sir George referred to some of the discoveries associated with the Edinburgh School and remarked that, like all discoveries, they were but stages in the pursuit of truth—they did not begin nor were they completed in Edinburgh, but all of them were substantially advanced there, and of two of them—Simpson's work on the anaesthetic action of chloroform and Lister's antiseptic surgery—it might be said they had entered into the history of mankind.

The reconstructed Surgery Department was formally opened by Sir John Gilmour, Secretary for Scotland. The cost of the reconstruction has been largely met by a generous gift from Mr. T. S. Thomson, brother of the late professor of surgery, Alexis Thomson.

At the meeting of the University Court on June 14, intimation was received from Dr. Harold Robinson, reader in natural philosophy, of his intention to resign, as from the end of the academic year, on his appointment to the chair of physics in the University College of South Wales and Monmouth, Cardiff.

Leeds.—Mr. B. A. McSwiney has been elected to the chair of physiology, vacant through the death of Prof. W. F. Shanks. Mr. McSwiney is a graduate of the University of Dublin in arts and medicine, and after the War was appointed assistant professor of physiology at Trinity College, Dublin. In 1919 he became lecturer in experimental physiology at Leeds and in the following year at Manchester, a position which he still occupies. He is secretary of the Section of Physiology of the British Association.

Dr. Richard Douglas Passey has been elected to a new chair of experimental pathology and as director of cancer research. Dr. Passey, who is at present lecturer in pathology in the Welsh National School of Medicine, Cardiff, has been engaged in cancer research for some years past, and has published a number of papers on the subject.

Contemporary Birthdays.

June 25, 1859.	Prof. Sydney John Hickson, F R.S.
June 26, 1869.	Sir John Flett, K.B E, F.R S
June 27, 1855.	Admiral Sir A. Mostyn Field, K.C.B., F.R S.
June 28, 1851.	Sir Alfred Hopkinson, K C, M P
June 29, 1868.	Dr. George Ellery Hale, For. Mem. R.S
June 29, 1844.	Sir Francis Fox, M. Inst. C.E
July 1, 1840.	Mr. Edward Clodd

PROF. HICKSON is a Londoner. He was educated at University College School, and Downing College, Cambridge. In his early career he was some time assistant to Prof. H. N Moseley, at Oxford. Since 1894 Prof. Hickson has occupied the chair of zoology in the Victoria University, Manchester.

Sir JOHN FLETT, director of H.M. Geological Survey since 1920, was born at Kirkwall, Orkney. He was educated at Watson's College, and at the University of Edinburgh, coming there under the guidance, in geological work, of Prof. James Geikie. Before his present official post he was assistant to the director of the Geological Survey of Scotland In 1902, jointly with the late Dr. Tempest Anderson, he investigated, at the desire of the Royal Society, the volcanic eruption of the Soufrière, in St. Vincent, West Indies, publishing a voluminous report in the *Philosophical Transactions*. Sir John was awarded the Bigsby medal of the Geological Society in 1909.

Sir MOSTYN FIELD, who has carried out highly important marine survey work, was hydrographer to the Admiralty from 1904 until 1909.

Sir ALFRED HOPKINSON, who was born in Manchester, was educated at Owens College in that city, and at Lincoln College, Oxford Principal of Owens College from 1898 until 1904, he was vice-chancellor of Victoria University of Manchester in 1900–13. Sir Alfred is member of Parliament for the combined English Universities. He is Hon. LL.D. of Glasgow and Aberdeen.

Dr. HALE, distinguished for his researches in solar and stellar spectroscopy, and joint editor of the *Astrophysical Journal*, was born at Chicago. Organiser, and then director of the Yerkes Observatory of the University of Chicago, from 1895 until 1905, he afterwards took up the directorship of Mount Wilson Observatory, Pasadena, California. In 1904 the Royal Astronomical Society awarded its Gold Medal to Dr. Hale for his spectroheliograph method of photographing the solar surface and other astronomical work.

Sir FRANCIS FOX, whose father was Sir Charles Fox, the distinguished engineer of early Victorian times, was born in London. One of the engineers of the Mersey Tunnel, Sir Francis, jointly with his brother, the late Sir Douglas Fox, were constructors of two underground railways. The development of railway schemes in South Africa also engaged his attention. Sir Francis has given unstinted assistance to the authorities of various English cathedrals concerning subsidence problems.

Mr. CLODD was born at Margate and educated at Aldeburgh Grammar School. It means and expresses much to say that he was among those in Huxley's circle of intimates in "the Marlborough Place days." Fifty-four years ago Mr. Clodd published "The Childhood of the World," the precursor of many studies concerning evolutionary foundations.

Societies and Academies.

LONDON.

Royal Society, June 17.—Sir Arthur **Schuster**: A review of Mr. George W. Walker's magnetic survey (1915). Recent magnetic surveys seem to show that the components of magnetic force cannot be completely represented by a potential function, but indicate electric currents cutting the surface of the earth with current densities that are far greater than those obtained from direct measurement. Examination of Mr. Walker's magnetic survey suggests the careful examination of a comparatively small area, rather than an extensive survey of districts so large as those into which the country was divided by Walker in order to test the reality of these currents. If observations are taken at four stations, two of which lie in the meridian and two on a circle of latitude, each station being at a distance of 1·8 miles from the central point, the density of the earth-air current may be determined with a probable error of 0·1 ampere per square kilometre, on the assumption that the difference between the magnetic components at two of the stations can be determined with a probable error of 3γ in a single comparison, and that the observations are repeated 25 times The mean current density derived from Mr. Walker's survey of eight separate districts is 0·24 Lord **Rayleigh** The continuous spectrum of mercury vapour in relation to the resonance line 2536·52. The continuous spectrum can be produced without the resonance line, by fluorescent excitation with the aluminium spark, as originally observed by Wood. Under these conditions the continuous spectrum ends at 2535·9 Å.U. and the resonance line appears dark on the continuous background. The band at 2540 also appears sharply reversed on this background. The same continuous spectrum can be obtained in absorption. In this case the measured limit was 2535·5 By lowering the density of the vapour the spectrum with aluminium spark excitation is completely reversed, the resonance line 2536 52 Å U. and the band 2540 Å U now appearing bright on a comparatively dark background. The same effect is obtained by electric discharge in fairly dense vapour, if the exposure is not too heavy —O W. **Richardson**: Structure in the secondary hydrogen spectrum (iv.). A more detailed examination of the spectrum has shown that there are a number of other lines which belong to the same system as Fulcher's bands. It is proposed to rearrange these lines so that S_3 to S_{-1} form a Q branch, S the first line of an associated R branch to which there is a corresponding P branch, S_6 and S_{-2} the first two lines of an associated Q' branch, and S_7 the first line of an associated R' branch to which there is a corresponding P branch. This holds throughout the first five of the six red bands. Four similar bands occur in the green and five in the blue; but the branches in those regions which would correspond to the dashed letters have not yet been located with certainty. There is a combination such that $R(m) - P(m+1)$ has the same value for corresponding lines of corresponding bands in the red, the green, and the blue The quantum structure of the bands can be represented by terms of integral and semi-integral type. The emitter of this band system is the neutral hydrogen molecule H_2 formed and excited by the combination of the ionised hydrogen molecule H_2^+ with an electron.—W. L. **Bragg** and J. **West**: The structure of beryl, $Be_3Al_2Si_6O_{18}$. Beryl has the composition of a metasilicate, the ratio of silicon to oxygen atoms being one to three, though silicon is surrounded everywhere by four oxygen atoms arranged tetrahedrally, resembling the arrangement in orthosilicates, such as olivine, monticellite, and garnet. The group SiO_4 shares an oxygen atom with each of two neighbouring groups, thus attaining the correct ratio of silicon to oxygen. The hexagonal beryl has a structure like a honeycomb, hexagonal axes passing down empty channels at the centres of cells, the walls of which are formed of densely packed oxygen atoms grouped around beryllium, aluminium, and silicon atoms No atomic centre is closer than 2·55 Å U. to a hexagonal axis The analysis of the structure, which has seven parameters, is carried out by quantitative measurements of intensity of reflexion —**A P. Laurie**. On the change of refractive index of linseed oil in the process of drying and its effect on the deterioration of oil paintings. The tendency of the modern oil picture to lower in tone is partly due to the yellowing of the oil film and partly to changes in refractive index The inquiry took two directions; (1) The examination of certain pigments by grinding them in liquids of various refractive indices, higher than linseed oil, noticing the change of tone and examining under a microscope so as to classify them in order of translucency. (2) In order to test change of refractive index, an oil film was painted out on the glass of a Smith refractometer and observed from time to time During drying the index rose from 1·480 to 1·490. Since then the film has been observed for some eight or nine months, and the index is now greater than 1·500, a change which produces a visible effect on white-lead and pale yellows. This slow change of refractive index no doubt continues for many years Light is thus thrown on the method of painting in oil by the fifteenth-century painter, who laid down a scheme in black-and-white or brilliant colour in a medium of low refractive index, and glazed over this with thin oil paint, thus securing that as the pigments became more translucent more light would be reflected from the painting below, thereby keeping up tone and brilliancy in his pictures

Royal Microscopical Society, May 19.—**James C. Mottram** A note on the effects of β-radiation on *Colpidium colpoda* as seen in stained specimens In view of the presence of macro- and micro-nuclei in Infusoria, and of the different functions which these appear to control, the macro-nucleus controlling asexual cell division, and the micro-nucleus syngamy and sexual division, exposures to radium were made to discover whether the nuclei would exhibit any differences in sensitiveness to β-radiation No histological changes were observed in the micro-nucleus. The macro-nucleus, however, was affected by relatively short exposures. Stained specimens also showed another early effect In this species, rod-shaped mitochondria lying close to the surface are arranged in lines running longitudinally; after irradiation, the microchondria are distributed at random, and instead of being rod-shaped, and of approximately the same size, they are seen to be irregular granules of various sizes.—**Miss Joyce F. Raves**: Mitosis in *Anacylus Pyrethrum* The chromosome number is 18, a number in accordance with the chromosome number series of the Anthemideæ, the cardinal number of this series being 9 In the prophase stages of nuclear division there is observed a parallel banding of the spireme, similar to that seen in telophase, and the following division always occurs at right angles to the direction of this banding There is some evidence that when one daughter nucleus is to divide in a plane at right angles to that of the former division, it revolves through a right angle while in the telophase condition, before it is completely rounded off as a new nucleus, so that the next division may also be at right angles to the direction of the spireme banding. This suggests that the nuclear material never changes its position during the resting stage.

EDINBURGH.

Royal Society, June 7.—**F H Edgeworth**: The development of the cranial muscles of Protopterus and Lepidosiren The main facts in the development of the mandibular skeleton as described by Agar are confirmed, but a separate ascending process of the pterygoquadrate, with typical relations to the first division of the fifth nerve, is described The cranial muscles of the Dipneumona are very similar to those of Ceratodus. They are more primitive in that external gill-muscles are present In other respects they are similar to, or show slight modifications of, those present in Ceratodus.—**G. W. Tyrrell** and **M. A. Peacock**: The petrology of Iceland; Part I, The basic tuffs, by **M. A. Peacock** The Pleistocene basic tuffs of Iceland are either sideromelan-tuffs or palagonite-tuffs. Sideromelan is basaltic glass which is produced in the fragmented condition by subglacial extrusions; the drastic chilling thus suffered by the extruded liquid renders the product translucent, due to the inhibition of ore-separation Palagonite is the hydro-gel of sideromelan. Palagonitisation results from the action on sideromelan either of hot springs, or of cold sea-water.—**E. Prawochenski** and **B. Kaczkowski**: Observations on the fragment of a horse skull from interglacial deposits near Pulawy, Poland. The Vistula horse belonged to the group of small European horses, probably to the Tarpans (Gmelin), or to the ponies of the "plateau type" (Ewart)—the group which included Celtic and Arab ponies, characterised by slender limbs, and only two of the eight callosities found in horses of the forest type. The Veglia (Adriatic) pony, though hitherto regarded as descended from the Tarpan, really belonged to a forest type. The wild horse (*E. przewalskii*) of Mongolia belonged to "the heaviest type of the primitive equidæ"—an interesting conclusion, because some authors who studied the skulls of modern heavy breeds, came to the conclusion that in all probability the Clydesdales and Shires included steppe horses among their ancestors —**J Cossar Ewart**: The coat of the Lapland wolf In some mammals the coat consists almost entirely of simple fibres made up of a solid cortex and of a cuticle, *i.e.* of wool fibres; in others the coat consists of fibres containing pith cells separated by spaces, thus forming a discontinuous pith or medulla, *i e.* fur fibres; in other mammals there is a continuous medulla, and these are known as true hair fibres. In the wolf the coat consists of bundles of fur fibres, all the fibres of each bundle occupying a single pit or follicle. In the Lapland wolf there are long coarse fibres, forming an outer coat, and fine and intermediate fibres forming an inner coat The inner portion of the long fibres has the structure of fur, the outer portion has the structure of true hair, the middle portion differs but little from fur proximally but resembles hair distally. The short fine fibres of the inner coat are typical fur fibres The inner portion of the intermediate fibres has a discontinuous medulla, the outer portion a continuous medulla as in the long outer coat fibres. Instead of all the fibres of a bundle occupying one pit or follicle, the root of each fibre is lodged in a separate follicle, there is a large follicle for the long outer coat fibre, and underlying the large follicle fifteen or more slender follicles for the fine and intermediate fibres of the inner coat. In some dogs there are, in addition to wool fibres and fur fibres, numerous fibres the inner half of which has the structure of wool, the outer of true hair. Sometimes the inner third resembles wool, the middle third fur, and the outer third true hair.—**Y. Tamura** and **F. A. E. Crew**. The effect of uncomplicated vasectomy and epididymo-differentectomy in the mouse. Definite degeneration of the germinal epithelium is induced by both procedures, but its onset and progress are much more rapid after epididymo-deferentectomy.

PARIS.

Academy of Sciences, May 17.—**André Blondel**: The initial conditions of the disturbed régime of currents.—**R. de Forcrand**: The thermochemistry of thallium alcoholates and salts.—**M. Biernacki**: Some theorems of algebra.—**Leonida Tonelli**: The quadrature of surfaces.—**Gaston Julia**: The polynomials of Tchebichef.—**W. S. Fédoroff**: The representation of analytical domains and functions.—**Stefan Kempisty**: The differentials of the ensemble function.—**J. L. Routin**: A new synchronous induction motor starting automatically, and capable of being worked by Hertzian waves, with reference to the problems of teleindication and television.—**C. G. Bedreag**: The arc spectrum of copper.—**F. Darmois**: The salt effect and rotatory power.—**A. Zimmern** and **Maxime Coutin**: The production of polarising surfaces by the deposit of herepathite upon vertical plates.—**Pierre Auger**: The yield of fluorescence in the domain of the X-rays.—**René Dubrisay**: Researches on adsorption.—**P. Brun**: The properties of ternary liquid mixtures. Studies of the physical properties of mixtures of water and ethyl alcohol with a third alcohol. For the third alcohol the three cases studied were propanol, entirely miscible, isobutanol, fairly miscible, and isoamyl alcohol, slightly miscible. Curves are given for the case of isoamyl alcohol.—**B. Bogitch**: Concerning the granulation of scoria and of metals. The usual method of pouring into water from a height occasionally gives rise to explosions. If compressed air is forced into the bottom of the water vessel, below the point of fall of the liquid jet, the risk of explosion is removed. The dimensions of the water vessel can be reduced, and a smaller height of fall for the liquid jet is possible.—**N. Bezssonoff**: The rapid preparation of mono-molybdophosphotungstic acid, a reagent for polyphenols and vitamins. The purification is based on the insolubility of the complex acid in 30 per cent sulphuric acid.—**J. Bougault**: An example of a hydrated ketone ether oxide. A correction of some results given in earlier communications.—**Mme. Pauline Ramart**: The alkylation of the nitriles of the fatty series. The preparation of di- and trialkylacetonitriles. Aliphatic nitriles, treated with sodium amide, give sodium derivatives, and these when treated with alkyl halogenides give the α-alkylnitriles.—**R. Marquis**: The oxidation of acenaphthene. Acenaphthene can be directly oxidised to acenaphthenol by lead dioxide in acetic acid solution.—**J. H. Hoffet**: The age of the limestones of Crete.—**P. L. Mercanton**: The magnetisation of Australian volcanic rocks. From the magnetisation of the rocks examined it is concluded that the inclination of the earth's magnetic field in Australia was at one time in the opposite sense to that at the present day.—**Lucien Mayet**: A summary anthropological examination of the fossil men of Denise, near Le Puy-en-Velay. These remains represent the oldest human documents discovered in France, coming between *Eoanthropus Dawsoni* and *Homo neanderthalensis*.—**F. Roman**: The discovery of a fauna of mammals of the Pontian stage at Libros (Province of Teruel, Spain).—**A. Demolon**: The absorption and mobilisation of the potassium ion in clay colloids.—**Edmond Sergent** and **H. Rougebief**: The antagonism between drosophils and moulds.—**Claude Fromageot**: The oxidation-reduction potential of reversible oxidising systems, and the oxidation of organic molecules by these systems.—**H. Barthélemy**: The action of glycogen and of white of egg of the fowl on the spermatozoids of *Rana fusca*.—**Robert Weill**: A special category of nematocysts common to hydra, gymnoblastids and siphonophores.—**Ch. Porcher**: The action of heat on the complex caseinate of lime plus calcium phosphate. The greater sensibility of the phosphatic particles.—**Georges Bourguignon**, **Max Courland** and **Mlle. Renée Déjean**: Variations of chronaxy in lesions of the retina and of the retro-bulbar segment of the optic nerve.

ROME.

Royal National Academy of the Lincei, April 11.—**Leonida Tonelli**: Quadrature of surfaces.—**G. A. Crocco**: The possibility of super-aviation. Although it may be possible by the ordinary means of aviation to attain sub-acoustic velocities, hyper-acoustic velocities would require a new moto-propulsive method such as that of the reaction propulsor. In such a case, if the weight remains constant, the quantity of fuel necessary for a certain horizontal, uniform flight is inversely proportional to the product of the velocity of flight and the velocity of egress of the propulsive jet.—**A. Angeli**: Supposed priority with regard to the conductivity of unsaturated chains.—**Antonio Colucci**: An assumed property of symmetrical determinants of the sixth order.—**Luigi Fantappiè**: Determination of groups with a parameter of linear functionals.—**Guérard des Lauriers**: Spaces geodetically applicable beyond Dini's case.—**Gaetano Scorza**: Apiristic resolution of binomial congruences and Lagrange's interpolation formula.—**E. Bompiani**: The geometry of surfaces considered in ruled space.—**Mauro Picone**: The duration of small oscillations of the most general curvilinear pendulum.—**Vasco Ronchi**: Zonal gratings as interferometer objectives.—**Luigi Rolla** and **Giorgio Piccardi**: Ionisation potentials of certain elements of the rare earth group.—**Giorgio Piccardi**: The affinity of the iodine atom for the electron.—**Giulia Lugaro**: Bismuthinite from St. Agnes (Cornwall).—**F. Stella Starrabba**: Two different diagrams for the eruptivity of Japanese volcanoes.

VIENNA

Academy of Sciences, May 6.—**L. Moser** and **K. Schmidt**: Determination and separation of rare metals from other metals (vii). Determination of tungsten compounds and of metallic tungsten by distillation in a current of carbon tetrachloride vapour. The addition of chlorine to the tetrachloride checks dissociation and reduces the concentration of nascent chlorine. By the addition of air, carbon is oxidised and more nascent chlorine liberated. Tungsten, tungstates, tungsten minerals were completely decomposed and tungsten chlorides obtained in the distillate, and either precipitated with benzidin or evaporated to dryness with nitric acid. Since iron is also volatilised, a method was worked out for heating an iron-tungsten mixture with ammonium bromide at 300°, which volatilised iron only. Tungsten wire has proved very resistant to chemical attack. It was oxidised in an oven by oxygen to WO_3, and even this oxide was resistant in carbon tetrachloride. The WO_3 was reduced by hydrogen to amorphous tungsten, which could easily be volatilised in carbon tetrachloride. Various oxides remain behind. This quick method of analysing tungsten wire is likely to be useful in the incandescent lamp industry.—P. T. **Schwarz**: Influence of thermometer exposure on the observed results of temperature in Kremsmunster.—H. V. **Ficker**: Direction of wind and clouds in Teneriffe.—F. **Kerner-Marilaun**. Harmonic analysis of the temperature in the South Atlantic current circuit. Diagrams were drawn on the Seewarte-Atlas dividing the main line of the current into 24 equal portions. The points of this division were transferred to the isotherm chart. Diagrams were drawn for the yearly warmth transition at each point, and hence equations were obtained.—F. **Werner**: New or little-known snakes in the State Museum of Natural History at Vienna.—L **Hajek** and F. **Scheminzky**: Low-frequency amplifiers in phonograph construction.—G. **Luft**: Distribution of saponins and tannins in plants.—P. **Fantl** and M. **Kabos**: Zinc-dust distillation of cholesterin.

FRIDAY, JULY 2.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—J. A. Steers Orford Ness: A Study in Coastal Physiography.—L Richardson and W. F. Fleet. On Sandstones with Breccias below the Trias in South Warwickshire.—George Slater: Glacial Tectonics as reflected in Disturbed Drift Deposits. Part I. Preliminary Considerations.

SATURDAY, JULY 3.

BRITISH MYCOLOGICAL SOCIETY (Phytopathological Meeting) (at Harpenden)

PHYSIOLOGICAL SOCIETY (at Oxford).

CONFERENCES.

JULY 1 TO 2.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS (at Glasgow)—Dr. A. S. M. Macgregor, J. Taylor, and others: Discussion on the Provision for the Care of Non-Pulmonary Forms of Tuberculosis—Sir Robert Philip, Dr. L. Cox, and others: Discussion on the Actual Place and Function of the Tuberculosis Dispensary in the Tuberculosis Scheme.

JULY 2 AND 3.

INTERNATIONAL FEDERATION OF EUGENICS (at Paris)

Supplement to NATURE

No. 2933 JANUARY 16, 1926

Wordsworth's Interpretation of Nature.[1]

By Prof. WALTER GARSTANG, University of Leeds.

WORDSWORTH'S childhood and youth were spent with unusual freedom amid the sights and sounds of Nature, among hills and dales where inexhaustible variety of object and incident, grim as well as beautiful, is combined with an orderly repetition of conspicuous changes against a background of hard immutability. He revelled unchecked amid them all, "fostered alike by beauty and by fear."

His delight in Nature was closely akin to that which has inspired many famous naturalists, and his early sympathy with science was so clearly indicated that a slight turn of Fortune's wheel at the critical period of his life might well have made a naturalist of him instead of a poet. In 1785, when a happy schoolboy of fifteen, he eulogised from his Lakeland home

those Elysian plains
Where, throned in gold, immortal Science reigns,

and where Truth teaches

the curious soul
To search the mystic cause of things
And follow Nature to her secret springs;

and he records that two years later, when an undergraduate at Cambridge, with rooms over the College kitchens at St. John's, nightly from his pillow he could see beneath the stars

The antechapel where the statue stood
Of Newton with his prism and silent face,—
The marble index of a mind for ever
Voyaging through strange seas of thought, alone.
(The Prelude, III.)

His activities at Cambridge, however, remind one of Darwin's:

We sauntered, played or rioted; we talked
Unprofitable talk at morning hours;
Drifted about along the streets and walks,
Read lazily in trivial books, went forth
To gallop through the country in blind zeal
Of senseless horsemanship, or on the breast
Of Cam sailed boisterously, and let the stars
Come forth, perhaps without one quiet thought.

The academic fare, indeed, seems to have been of even less interest to him than to Darwin:

I did not love,
Judging not ill perhaps, the timid course
Of our scholastic studies; could have wished
To see the river flow with ampler range
And freer pace.

A question here presents itself. Had there been a Henslow in those days to take this sensitive, sociable, aimless youth in hand, would Wordsworth and the world have gained or lost? It cannot be doubted that he was in a state of mind in which a very slight change in the course of events might have guided his contemplation of Nature into scientific rather than poetic channels.

It is undoubtedly a fact that geometry gave him great pleasure at this time as it did later:

Specially delightful unto me
Was that clear synthesis built up aloft
So gracefully;
(Prel. VI.)

and the tribute of the Sage in "The Excursion" to the happiness of the naturalist may safely be taken to represent the poet's own feelings:

Happy is he who lives to understand
Not human nature only, but explores
All natures,—to the end that he may find
The law that governs each;
Through all the mighty commonwealth of things
Up from the creeping plant to sovereign man.
(Exc. IV.)

This is exactly the spirit that animated Darwin, the curiosity that has animated the master-minds of every science. But it is as true of science as of literature, that "for the creation of a master-work . . . two powers must concur, the power of the man and the power of the moment, and the man is not enough without the moment." The conditions, themselves a chapter of accidents, which determined the play of Darwin's spirit, never fell to Wordsworth. None had realised more vividly than he the ordered character of the living as of the inanimate universe, and of the interrelations between them; but there was as yet no beginning even of a biological "synthesis" to attract his imagination. Observation of detail, which to a later age acquired intellectual value, in Wordsworth's case simply enriched his emotions :

---

[1] Presidential address to the Leeds Philosophical and Literary Society, October 20, 1925 (slightly abbreviated by the author).

> Contented if he might enjoy
> The things which others understand.
> (The Poet's Epitaph, 1799.)

So no special science was to tie him down. This nursling of the "mountains, lakes and sounding cataracts" was "ill-tutored for captivity." But, haunted by dear memories, he did not altogether forget his old nurse; and Nature, if intermittently, continued to be his teacher. Of his Cambridge days, Wordsworth writes :

> Oft when the dazzling show no longer new
> Had ceased to dazzle, ofttimes did I quit
> My comrades, leave the crowd, buildings and groves,
> And as I paced alone the level fields
> Far from those lovely sights and sounds sublime
> With which I had been conversant, the mind
> Drooped not . . .
> I looked for universal things ; perused
> The common countenance of earth and sky.
>
> . . . . . .
>
> I called on both to teach me what they might ;
> Or, turning the mind in upon herself,
> Pored, watched, expected, listened, spread my thoughts
> And spread them with a wider creeping ; felt
> Incumbencies more awful, visitings
> Of the Upholder of the tranquil soul
> That tolerates the indignities of Time,
> And, from the centre of Eternity
> All finite motions overruling, lives
> In glory immutable . . . the great mass
> Lay bedded in a quickening soul, and all
> That I beheld respired with inward meaning.
> (Prel. III.)

This vision, a development of the more generalised emotions of earlier years,—this ecstatic realisation of the "One in all," was, if I mistake not, the spring and source of Wordsworth's interpretation of Nature. The slight fence between science and poetry had been crossed, and in the Parnassian direction :

> I had a world about me—'twas my own :
> I made it, for it only lived to me,
> And to the God who sees into the heart.

From his Cambridge time onwards, humanity began to encroach upon Nature as his principal object of interest, a period of residence in London, followed by a still more important one in France during the throes of the Revolution, contributing powerfully to this result. Though indifferent at first, he was drawn into the ferment, took sides with the "patriots," and threw himself whole-heartedly into the revolutionary cause, to be dismayed in due course when he realised

> The indecision on their part whose aim
> Seemed best, and the straightforward path of those
> Who in attack or in defence were strong
> Through their impiety.
> (Prel. X.)

Robespierre was still in power when Wordsworth was recalled to London ("dragged by a chain of harsh necessity") to undergo the mortification of hearing England's declaration of war on the Republic, the first of many moral shocks he was now to undergo. He had witnessed the ushering in, through garlanded streets and rainbow arches, of a Utopia of Reason, Liberty and Light, and, while for some years cherishing his faith in the cause, saw the issue in a long-drawn welter of conflicting passions that knew no test of good and bad, of what to hope for, or of what to shun, in which every one was doomed to become "the dupe of folly or the slave of crime." With instincts and knowledge adequate enough for his guidance along the beaten tracks, now that all these were obliterated the cheerful faith with which he set out faltered ; he began to mistrust the very elevation of spirit which had linked him with

> Sage, warrior, patriot, hero ; for it seemed
> That their best virtues were not free from taint
> Of something false and weak, that could not stand
> The open eye of Reason.
> (Prel. XII.)

He sought deliberately to separate his past by a complete "gulph" from the nebulous future before him, and in the check which his emotional life had sustained, threw poetic dreams and prospects overboard :

> In such strange passion I warred against myself—
>
> . . . . . .
>
> Zealously laboured to cut off my heart
> From all the sources of her former strength.

He turned to philosophy and found himself able, as he says, "by syllogistic words"

> to unsoul
> Those mysteries of Being which have made,
> And shall continue evermore to make,
> Of the whole human race one brotherhood ;

and with remorseless logic scanned "even the visible Universe" with "microscopic view."

Simultaneously with this casting out of emotion, being "somewhat stern in temperament" and "bold to look on painful things," he made a renewed study of the whole framework of social life :

> Dragging all precepts, judgments, maxims, creeds,
> Like culprits to the bar ; calling the mind,
> Suspiciously, to establish in plain day
> Her titles and her honours ; now believing,
> Now disbelieving ; endlessly perplexed
> With impulse, motive, right and wrong, the ground
> Of obligation, what the rule and whence
> The sanction ; till, demanding formal *proof*,
> And seeking it in everything, I lost

All feeling of conviction, and, in fine,
Sick, wearied out with contrarieties,
Yielded up moral questions in despair.
(Prel. XI.)

The crisis was complete, and the upheaval of his life might well seem incapable of simple solution; yet it settled itself as quietly and insensibly as a wave of a summer sea. When Wordsworth returned to England after his two years in France, he was too deeply stirred to contemplate retirement to the country, and chose "the great City," where the general air was still agitated over the first unsuccessful attack on the slave trade. Here, as we have seen, he toiled through books and thoughts to find the solution of the problems of society which harassed him (1792–94). Finally, when he had brought himself to emptiness, hopelessness and scepticism, he turned to "abstract science" for relief and rejoined his sister Dorothy in Cumberland:

She whispered still that brightness would return;
She, in the midst of all, preserved me still
A Poet, made me seek beneath that name,
And that alone, my office upon earth;
And, lastly, . . . Nature's self,
By all varieties of human love
Assisted, led me back through opening day
To those sweet counsels between head and heart
Whence grew that genuine knowledge, fraught with peace,
Which, through the later sinkings of this cause,
Hath still upheld me, and upholds me now.
(Prel. XI.)

And this is how Nature worked:

Long time in search of knowledge did I range
The field of human life, in heart and mind
Benighted; but, the dawn beginning now
To reappear, 'twas proved that not in vain
I had been taught to reverence a Power
That is the visible quality and shape
And image of right reason; that matures
Her processes by steadfast laws; gives birth
To no impatient or fallacious hopes,
No heat of passion or excessive zeal,
No vain conceits; provokes to no quick turns
Of self-applauding intellect; but trains
To meekness, and exalts by humble faith;
Holds up before the mind intoxicate
With present objects, and the busy dance
Of things that pass away, a temperate show
Of objects that endure.

. . . .

Thus moderated, thus composed, I found
Once more in Man an object of delight,
Of pure imagination, and of love;
And, as the horizon of my mind enlarged,
Again I took the intellectual eye
For my instructor, studious more to see
Great truths, than touch and handle little ones.
Knowledge was given accordingly; my trust
Became more firm in feelings that had stood
The test of such a trial; clearer far
My sense of excellence—of right and wrong;
The promise of the present time retired
Into its true proportion; sanguine schemes,
Ambitious projects, pleased me less; I sought
For present good in life's familiar face,
And built thereon my hopes of good to come.
(Prel. XIII.)

Prof. Arthur Beatty, of Wisconsin, has recently published an elaborate study of Wordsworth's "Doctrine and Art in their Historical Relations," and makes one or two points which bear upon my topic. The poetic and doctrinal aspects of Wordsworth have frequently been regarded as hostile. Matthew Arnold, for example, "sought to establish the fame of the poet by ignoring his philosophy"; but the quotations I have given from "The Prelude" make it clear that with Wordsworth the attainment of a philosophy was essential to his poetry. In early youth he had caught the vision of the all-embracing unity of things, which was lost in France, and had to be regained before he could accomplish anything. He sought to get a true view of life as a whole, of man in relation to Nature, even as a part of Nature; and when he had acquired it, poetry was the expression of his attainment.

Philosophically, as Prof. Beatty claims, he revolted from the sentimental Rousseauist world into which he was born, or rather, into which he had strayed; and, poetically, he rebelled against the inflated language of his poetic predecessors. He was thus, in a twofold sense, a "poet of reaction," and the springs of both revolts were intimately related. His passion for reality and simplicity outside him had the same source as his love of truth and sincerity of thought within. These he himself attributed to his "education by Nature," which, as he says, from his "first dawn of childhood" did

interweave for me
The passions that build up our human soul
Not with the mean and vulgar works of man,
But with high objects, with enduring things—
With life and nature—purifying thus
The elements of feeling and of thought.
(Prel. I.)

For, having scanned,
Not heedlessly, the laws, and watched the forms,
Of Nature, in that knowledge I possessed
A standard, often usefully applied,
Even when unconsciously, to things removed
From a familiar sympathy.
(Prel. V.)

But Prof. Beatty goes into detail, and is not content to see in the poet's attitude the simple flowering of the vigorous germs implanted in his fervent youth. "In the sphere of Art," says Beatty, "he revolts against poetic diction and harks back to Milton and Shakespeare and Chaucer; in Doctrine he revolts against Rousseau and Godwin and appeals to Hartley, Locke, and the general tradition of English philosophy."

That Wordsworth followed Hartley and Locke in rejecting the doctrine of "innate ideas," and in recognising that early sensations and sense-impressions constitute the basis upon which the mind is built up by "association of ideas," Prof. Beatty has no difficulty in showing; but merely upon the evidences of this agreement, and of his frequent use of "associationist" language, to sum Wordsworth up as "the interpreter and poet of associationism" surely betrays a lack of perspective. So far as I can see, "associationism" was simply the ladder by which Wordsworth climbed out of the morass of sentimental idealism back to the point of view of his early vision: . . .

> Ye motions of delight, that haunt the sides
> Of the green hills; ye breezes and soft airs,
> Whose subtle intercourse with breathing flowers,
> Feelingly watched, might teach Man's haughty race
> How without injury to take, to give
> Without offence; . . . Ye brooks
> Muttering along the stones, a busy noise
> By day, a quiet sound in silent night;
> Ye waves . . .
> And you, ye groves, . . .
> Oh, that I had a music and a voice
> Harmonious as your own, that I might tell
> What ye have done for me. The morning shines,
> Nor heedeth Man's perverseness; Spring returns,—
> *I saw the Spring return.*
>
> (Prel. XII.)

This surely is the poet of Nature that speaks, not the poet of "associationism" or any other philosophical nostrum.

Put briefly, the argument and illustrations detailed at great length in "The Prelude" amount to this, that man is not outside Nature—the universe of law and order—but by his subtlest fabric intimately bound up with it. Divorce him in youth from free contact with external Nature and you rob him of Nature's predetermined means of conferring upon him his share of her own grandeur, modesty and tranquillity. (See "The Three Ages" below.)

In the laws of association Wordsworth thus found not only his intellectual means of escape from sentimentalism and "innate ideas," but also confirmation of his original vision. We are all members of the all-uniting whole, and the very machinery of the mind's processes is a proof of it.

Nature, indeed, was to Wordsworth a universal symphony, a harmony of infinitely varied elements, appealing to man through every sense and gateway to the heart. Some of his smaller poems, and innumerable passages in his longer works, are just so many phrases and passages isolated from the general symphony for special purposes. The musical analogy crops up incessantly:

> No sound is uttered,—but a deep
> And solemn harmony pervades
> The hollow vale from steep to steep
> And penetrates the glades.
>
> A soft eye-music of slow-waving boughs.

There are dominating themes and *motifs*; alternations, contrasts and developments of grandeur, tumult and tranquillity; but the meanest instrument has its part to play:

> To every Form of Being is assigned
> An active Principle. (Exc. IX.)

But the activity or influence of a particular thing is not regarded as something rigorously fixed and definable, as the function of an organ or a species may be defined by science. In his most exalted moods, Wordsworth has his mind concentrated on the whole, and, when he considers the parts, it is their interrelations and interactions that he is conscious of, not their boundaries or limitations.

Herein lies the essential difference between the scientific and the Wordsworthian outlook. Wordsworth is listening to the symphony, contemplating the pageant; science, closing eyes and ears to both, is engrossed in the operations of the separate instruments, in the make-up and doings of the individual agents. The reward to science is an increasing command over instruments and materials for practical purposes, as well as a growing understanding of the processes by which the symphony is rendered. But any message which the symphony, in its entirety, has to convey, is lost to the merely analytic intellect, for it appeals to emotion, and is only apprehended by emotion. Wordsworth, following the symphony "in a wise passiveness," drinks in its "thousand blended notes," is caught up, as it were, into its atmosphere of grandeur, order and beauty, experiences an exaltation of joy that defies expression, and knows that he has entered a gateway to the loftiest aspects of reality open to man:

> With an eye made quiet by the power
> Of harmony, and the deep power of joy,
> We see into the life of things.
>
> (Tintern Abbey.)

The mere analyst shrugs his shoulders before a self revelation of this order, and suggests an abnormal activity of endocrine glands. The utmost that he is entitled to say is that the emotions, like thought itself, are conditioned, and that to wise men, in intellectual and practical matters, they have proved more useful as incentives than as guides—a truth which barely touches Wordsworth's claim, namely, the value for human life of high emotion ("admiration, hope, and love") when disciplined by communion with Nature in her varied moods, and balanced, not suppressed, by knowledge and reflection:

This is the freedom of the Universe
Unfolded, still the more, more visible,
The more we know.

On the lower plane of cause and effect there is no antagonism between the two points of view, for Wordsworth's belief embraces in advance everything that science has established or may establish as to the orderly and interdependent character of the universe, whether viewed from without or from within. But on the higher plane, in the life of the emotions or spirit, the necessitarian chain simply drops away, and is seen as a mere substratum, conditioning results but not causing them. So long as imagination, or "faith," maintains itself as "feeling" in that upper level, science, at any rate, can interpose no obstacles to its flight.

Take, as a test, this slight vignette:

A humming bee, a little trickling rill,
A pair of falcons wheeling on the wing.

The matter-of-fact man will see in these two lines a mere catalogue of three disconnected and trivial things of no significance; but to the Nature-lover they call up, with superb artistry, a fragment of the great world-symphony—summer peace with its muted sounds and leisured motions. To appreciate that fragment, or, better still, its original, is to enter, through the gateway of emotion, a realm in which the proudest generalisations of science are simply irrelevant.

It may be urged, and has been urged, that our so-called peace is a delusion, and that Wordsworth cannot expect us to ignore that underneath the apparent Nature, with which he deals, is a real Nature "red in tooth and claw." This pointed phrase, as every good naturalist knows, is based on a complete misunderstanding of the nature of the "struggle for existence," and suggests that animal life is maintained at the cost of great cruelty and suffering, which is simply not true. In reality, as in appearance, animal life is essentially a world of bustling activity and wide-spread enjoyment. Sooner or later death comes to one and all, but in most cases quickly and unconsciously, as Alfred Russel Wallace pointed out long ago. Only in man, because he "looks before and after," does death necessarily entail an undercurrent of sadness and tragedy.

How death came to be a condition of life is a biological question, to which a fairly clear answer, from the point of view of cause and effect, can already be provided. That it should ever be so has troubled sensitive souls for ages, but Wordsworth's identification of divine and natural laws enabled him to face the problem with the equanimity of a modern Biologist:

Such ebb and flow must ever be,
Then wherefore should we mourn?
(Epitaphs, X., 1806.)

Our delight in the summer symphony may proceed, therefore, unchecked by any intellectual doubts as to the reality of the harmony presented to "eye and ear." That granted, no comment is needed on the supreme expression of Wordsworth's interpretation of the whole, except to notice how trouble and a richer human experience have softened the exuberance that glowed in the visionary moods of his youth:

For I have learned
To look on Nature, not as in the hour
Of thoughtless youth; but hearing oftentimes
The still, sad music of humanity,
Not harsh, nor grating, though of ample power
To chasten and subdue. And I have felt
A presence that disturbs me with the joy
Of elevated thoughts; a sense sublime
Of something far more deeply interfused,
Whose dwelling is the light of setting suns,
And the round ocean and the living air,
And the blue sky, and in the mind of man;
A motion and a spirit, that impels
All thinking things, all objects of all thought,
And rolls through all things.
(Tintern Abbey.)

At this point it is natural and relevant to refer to an element in Wordsworth's doctrine which first finds expression in this beautiful poem, and plays a large and integral part in his conception of the relations between man and Nature—his emphasis on the distinctive qualities of the "Three Ages of Man." By tracing out, and correlating, the many passages, both of prose and verse, in which Wordsworth's ideas on this point are expressed, Prof. Beatty has discharged a critical task of great service to serious students of the poet. Stated briefly, and with special reference to my own theme, the point is this, that in the individual development of mind and character three stages are passed through: animal childhood (receptive and experimental); emotional (or "sentient") youth, and reflective (or "intellectual") maturity; and that, while each stage exhibits its own distinctive features, the mind only attains its complete fullness and efficiency if the earlier stages have been allowed free scope under conditions suited to make the most of their respective qualities—"The higher mode of being does not exclude, but necessarily includes, the lower: the intellectual does not exclude, but necessarily includes, the sentient; the sentient, the animal. . . ." (Wordsworth, "Convention of Cintra," 1809.)

The recognition of this principle doubtless came to Wordsworth during the period when he was clearing his mind after its unsettlement by his revolutionary experiences, and is bound up with his adoption of Hartley's "associationism." Its discovery, with all its implications, seems to have co-ordinated and stimulated the poet's thoughts and animated his poetry, as profoundly as the theory of recapitulation affected the zoological world of a later generation. It was the idea of a necessary developmental sequence; and it not only resolved for him a number of hitherto perplexing problems, as set forth at length in "The Prelude," but also became the sheet-anchor of his perennial optimism, as exemplified in the fourth book of "The Excursion."

To it we owe not only its quintessential expression in "The Rainbow" (1802: "The Child is father of the Man"), and the sustained splendour of the famous Ode on "Intimations of Immortality" (1802–6), but also many other of the poet's most characteristic and sonorous lines:

> Dust as we are, the immortal spirit grows
> Like harmony in music. . . .
> (Prel. I.)

It is because the impressions incidentally received in childhood (*e.g.* during bathing, skating, trapping, nutting, etc.) may give so powerful a turn to the emotions of youth as to affect, for better or worse, the mind of manhood, that Wordsworth attaches so much importance to early association with Nature. The child is thus, under natural conditions, Nature's link between herself and man.

If the immortal "Ode" be re-read in the light of these remarks, it will be observed that the first four stanzas, which, according to Wordsworth himself, were written "two years at least" before the remainder, convey no sentiment at variance with this general idea. Indeed, this is just the idea which these four stanzas do so glowingly express—the identification of childhood with the glory and joy of Nature, and the more distant sympathy between Nature and manhood:

> The first diviner influence of this world,
> As it appears to unaccustomed eyes.
> (Prel. XII.)

The association of the idea of pre-existence with the "visionary gleam" of childhood was a "poetic" afterthought; and was intended, as Wordsworth himself has assured us, rather to emphasise than to explain the "dream-like" qualities of sight and feeling with which a child's mind explores the realities of the "not-self." In that case the poet very greatly overshot the mark, both by the extent to which he carried his apotheosis of the child, and by incorporating the idea in later versions of the title. Not all the poet's skill and sustained beauty of language have been able to blend the two voices speaking in this famous "Ode." In particular, as various critics have pointed out, the second group of four stanzas (v.-viii.) is, in effect, an interpolation, alien to the poet's whole philosophy of life, and inconsistent with both the opening and closing sections of the poem. By exaggerating the divinity of the child, he is compelled in those stanzas to treat the attainment of manhood in terms of loss instead of gain, whereas in the noble peroration of the "Ode," as well as everywhere else, the "years that bring the philosophic mind" are regarded as bringing with them an access of serenity and power and human sympathy which more than compensates for the loss of the "dizzy raptures" of youth.

It is remarkable that the zoological theory of "recapitulation" has undergone, and is still undergoing, the same criticism as that which has been applied to Wordsworth's "Ode," and is being steadily pruned of elements which exaggerate the ancestral significance of developmental features. In a brief criticism of the "Ode," the general result of which is not at variance with that expressed in my last paragraph, Dean Inge implies that the qualities of childhood, which Wordsworth exalts as reminiscences of its "ancestral home," may include racial instincts "which do not arise from his own (*i.e.* the child's) experience in his present life." So far as the "interpolated" stanzas are concerned, however, the reference is not just to "animal spirits," but to

> those obstinate questionings
> Of sense and outward things,
> Fallings from us, vanishings;
> Blank misgivings of a Creature
> Moving about in worlds unrealised;

and these, as is clear from the special incidents which Wordsworth recalls in his prefatory note, are not "ancestral" traits at all, but the inevitable reactions of any mind, in its first intense subjectivity, when groping its way to the perception of external reality. The more sensitive mind naturally reacts more strikingly.

From some of his more familiar poems it might be inferred that Wordsworth's attitude towards science was one of indifference, if not of contempt, *e.g.*

> Enough of Science and of Art;
> Close up those barren leaves.
> (Lyrical Ballads, 1798.)

This inference would not lack support from certain passages in "The Excursion" (Books III. and IV.).

It is equally true, however, that Wordsworth took a lofty view of the functions both of poetry and of science, and his tributes to the actual geometry and the potential biology of his time have already been quoted. In the famous preface to the second edition of "Lyrical Ballads" (1800), he tells us that the poet is as much concerned in the spread of truth as the man of science, but truth of a different and more general order, "not standing upon external testimony, but carried into the heart by passion, truth which is its own testimony, appealing to the knowledge which all men carry about with them, and to those sympathies in which, without any other discipline than that of our daily life, we are fitted to take delight."

"The remotest discoveries of the Chemist, the Botanist, or Mineralogist, will be as proper objects of the Poet's art as any upon which it can be employed, if the time should ever come when these things shall be familiar to us, and the relations under which they are contemplated . . . shall be manifestly and palpably material to us as enjoying and suffering beings."

These quotations (nearly, but not quite, *verbatim*) are enough to show that, whether Wordsworth's point of view be accepted or not, he had a vision in his mind which was not unfriendly to the development of science, even though, as he said, he would be unable to make use of science until, in its various branches, it had made some degree of progress intelligible and familiar to the common man.

Passages like that already quoted from "Lyrical Ballads," or the half-sarcastic description in "The Excursion" (Bk. III.) of the botanist and the geologist of his time, are robbed of their sting when it is remembered that Wordsworth began to write in the eighteenth century, when few of the natural sciences had given any signal proof of their value to men "as enjoying and suffering beings." It was the age of Linneus, who was still alive in Wordsworth's youth. All the sciences were still at work upon their foundations, engrossed in distinguishing gases, analysing substances into their elements, describing and classifying species generally. They wore the aspect, to all but the initiated, of elegant pastimes or harmless hobbies.

It could scarcely be expected that the poet Wordsworth, appealing to emotion with a gospel of Nature that was the refined expression of vivid experience, should find an atmosphere "in which to move his wings" in analytic researches—

> Where soul is dead, and feeling hath no place ;
> Where knowledge, ill begun in cold remark
> On outward things, with formal inference ends.
> (Exc. IV.)

Nevertheless, it was less the act of analysis than contentment with analysis that Wordsworth decried, and there are many passages in his later writings which suggest that his early appreciation of science grew stronger as time passed :

> To reinstate wild Fancy, would we hide
> Truths whose thick veil Science has drawn aside ?
> (1833.)

Explicit references to scientific discoveries are not numerous, but the following are interesting examples of Wordsworth's poetic use of them. We have already noted his admiration of Newton. In his account of the babe in his mother's arms, he characteristically refers to "gravitation" as one of the bonds "that connect him [*i.e.* the babe] with the world" (Prel. II.).

In his poem "To the Small Celandine" (1803) there is a playful comparison between the poet's "discovery" of this flower and the stir made on the "sage astronomer's" finding of a new star. The allusion is obviously to Herschel's discovery of Uranus (1781).

Similarly, as was first pointed out to me by my blind botanical friend Mr. J. G. Wilkinson, the poet's many references to the "breathing" of flowers—one of which has been quoted already (p. 4)—are probably based on the results of Joseph Priestley's experiments (1775)—"the philosophic Priestley" of Wordsworth's "Apology for the French Revolution" (1793). One of the poems which contains an allusion to "breathing flowers" is "This Lawn, a carpet all alive" (1829), and in the Fenwick note to this (1843) the poet remarks : "The beauty in form of a plant or an animal is not made less but more apparent as a whole by more accurate insight into its constituent properties and powers."

So far it has been possible to discuss Wordsworth's interpretation of Nature without considering the special use which the poet makes of particular details. We have seen, however, that while his general idea of Nature can be appropriately likened to that of a symphony, or, rather, an interacting harmony of sense-impressions generally, he also regarded each part of Nature, each "Form of Being," animate and inanimate, as discharging an "active" function. His clear, imaginative vision, and mastery of word and phrase, are never more telling than in those descriptions of Nature, scattered through all his larger works, in which the influences of natural objects are made manifest without the need of a single didactic word. As Matthew Arnold so aptly said : "Nature herself seems to take the pen out of his hand, and to write for him with her own bare, sheer, penetrating power."

When in his smaller poems Wordsworth singles out particular "Forms of Being" for special eulogy, a change of tone is at once apparent ; the poet ceases to be the perfect mouthpiece of Nature, and, allowing freer play to fancy, tends to become the conscious teacher and moralist. It is not his special interest in "life's familiar face" that betrays him. On the contrary, to reveal new charms in the common-place strengthens his claims to be Nature's own interpreter. But Nature endows all her children with distinctive charms, each admirable in its sphere ; and the false note creeps in when the moralist, with his single scale of human values, seeks to compare one flower with another, one bird with another, not from the relative efficiency with which they play their parts, but from their fancied approximation to points in the human code.

The Lesser Celandine, pleasing him at first, and naturally, as a bright harbinger of spring, becomes a type of meekness and humility in contrast to the self-advertising buttercup, "of the flaring hours" (the "little children's flower" of Browning !). On the other hand the "cheerful" Daisy is praised for its very ubiquity at every season, while Violets "in their secret mews" ("modest" for every other poet !) are dismissed with a suggestion of encouraging the "wanton zephyrs." Similarly the fiery eloquence of the nightingale is rejected on one occasion for the "pensive" cooing of the stockdove, and on another for the "pilgrim" strains of the skylark, "true to the kindred points of heaven and home."

Treatment of this kind is obviously not interpretation of Nature, but self-expression, with natural objects employed as symbols. It differs little in essence from the "emblematic" treatment of Nature by the poet's predecessors, and carries with it an artificial flavour of the domestic garden, instead of the atmosphere of Nature herself. Even in these flights of fancy and imagination, however, Wordsworth always goes directly to Nature for his emblems and types, and not to the traditional stock, and his observant eye picks out real and distinctive features on which his reflections are based or his fancy plays.

As a typical example of this latter point may be cited his poem on the familiar "Herb Robert," with its shining red stems, which enable "Poor Robin," as he calls it,

> his part to fill;
> Cheerful alike if bare of flowers as now,
> Or when his tiny gems shall deck his brow.

But best of all his smaller Nature-poems, because simply lyrical, is, to my mind, his poem on the greenfinch ("Green Linnet"), in which he makes delightful play with the bird's liveliness, protective colouring, and characteristic discontinuity of song:

> My dazzled sight he oft deceives,
> A brother of the dancing leaves;
> Then flits, and from the cottage eaves
> Pours forth his song in gushes.

In fact, as the late Sir Walter Raleigh said, "the spirit of science has found no loftier or loyaller prophet than Wordsworth," and I venture to hope that this examination of Wordsworth's message and methods by one of themselves may not be altogether indifferent to the votaries of science. With zeal as undivided as theirs he pursued the same goal, truth; in accuracy and range of observation, no less than in fidelity of description, he was as scrupulous as the best, and equally critical (but not neglectful) of speculation and romance. Indeed, though poetic to the core, he risked reputation and fame by insisting that poetic creations must be based on the facts and realities of the world "as they are," and not as unchecked fancy may depict them—an axiom of his to which NATURE pays weekly tribute:

> To the solid ground
> Of Nature trusts the Mind that builds for aye;
> Convinced that there, there only, she can lay
> Secure foundations.
>
> (Misc. Sonnets, XXXIV.)

Wordsworth's whole gospel, indeed, might be summed up in some such terms as these: Learn the order of Nature; recognise the fixity of her laws, and then conform. Do these things, however, not with a cold and formal spirit, kicking against the pricks of stern necessity, but with a "feeling intellect" that first learns to admire the grandeur and harmony of Nature's order, and then aspires to achieve them in the distracted fields of human life:

> This prayer I make,
> Knowing that Nature never did betray
> The heart that loved her; 'tis her privilege
> Through all the years of this our life, to lead
> From joy to joy: for she can so inform
> The mind that is within us, so impress
> With quietness and beauty, and so feed
> With lofty thoughts, that neither evil tongues,
> Rash judgments, nor the sneers of selfish men,
> Nor greeting where no kindness is, nor all
> The dreary intercourse of daily life,
> Shall e'er prevail against us, or disturb
> Our cheerful faith, that all which we behold
> Is full of blessings.
>
> (Tintern Abbey, 1798.)

The facts confronting the poet and the man of science are the same, Nature and man,—man the inhabitant of Nature, and Nature the environment and nurse of man,—but each acting and reacting on the other, and together building up "this transcendent universe." To understand this unity is the task of poetry and science alike. But while science sets no term to its efforts, and the life-work of a single investigator is spent upon a mere fragment or two of the ultimate edifice, the poet, when he claims his ancient rôle, feels bidden to present to his age and generation a synthesis, of which the corners have been rounded by insight and feeling, where the inductions of science are still, and may be for ever, wanting. This aim may be incapable of complete attainment, but it is neither futile nor unwelcome in the attempt, provided the poet be equipped for his task by long, close and sympathetic converse with Nature and man, and that he be one

> who looks
> In steadiness, who hath among least things
> An undersense of greatest; sees the parts
> As parts, but with a feeling of the whole.

It is precisely because he fulfilled these requirements that Wordsworth still claims our attention.

No. 2936 FEBRUARY 6, 1926

Primitive Law and Order.[1]

By Dr. B. MALINOWSKI.

SAVAGERY to most people is still synonymous with absurd, cruel, and eccentric customs, with quaint superstitions and revolting practices. Sexual licence, infanticide, head-hunting, couvade, cannibalism and what not, have made anthropology attractive reading to many, a subject of curiosity rather than of serious scholarship to others. A fuller knowledge of the so-called savages, however, has revealed "Ye beastly devices of Ye heathen" as the product of firm law and of strict tradition, due to biological, mental and social needs of human nature, rather than as the outcome of unbridled passion and unfettered excess. Law and order pervade the tribal usages of primitive races, they govern all the humdrum course of daily existence, as well as the leading acts of public life, whether these be quaint and sensational or merely important and venerable.

THE AUTOMATIC SUBMISSION TO CUSTOM AND THE REAL PROBLEM.

When we come to inquire why rules of conduct, however hard, irksome, or unwelcome, are obeyed; what makes private life, economic co-operation, public events run so smoothly; of what, in short, consist the forces of law and order in savagery—the answer is not so easy to give, and what anthropology has had to say about it is far from satisfactory. So long as it could be maintained that the 'savage' is really savage, that he follows what little law he has but fitfully and loosely, the problem did not exist. When the question became actual, when it became plain that hypertrophy of rules rather than lawlessness is characteristic of primitive life, scientific opinion casting for new bearings veered round to the opposite point: the savage was made not only into a model of the law-abiding citizen, but it also became an axiom that in submitting to all his tribal rules and fetters, he follows the natural trend of his spontaneous impulses; that in this way he glides, so to speak, along the line of least resistance.

The savage—so runs to-day's verdict of competent anthropologists—has a deep reverence for tradition and custom, an automatic submission to their biddings. He obeys them "slavishly," "unwittingly," "spontaneously," through "mental inertia," combined with the fear of public opinion or of supernatural punishment (Sidney Hartland); or again through a "pervading group-sentiment if not group-instinct" (Rivers). I have already in a previous article stated the views of such contemporary writers as Hobhouse, Rivers, Sidney Hartland and Lowie, and I have submitted them to a searching criticism and have arrived at the conclusion that neither the way in which the problem has been set forth, nor the solutions given, can be regarded as adequate.[2] I have also tried to make it clear that any shortcomings in theory or observation are due to the real difficulties and pitfalls of which this subject is so full.

The extreme difficulty of the problem lies, I think, in the very complex and diffuse nature of the forces which constitute primitive law. Accustomed as we are to look for a definite machinery of enactment, administration, and enforcement of law, we cast round for something analogous in a savage community and, failing to find there any similar arrangements, we conclude that all law is obeyed by this mysterious propensity of the savage to obey it.

Anthropology seems here to be faced by a similar difficulty as the one overcome by Tylor in his "minimum definition of religion." By defining the forces of law in terms of central authority, codes, courts, and constables, we must come to the conclusion that law needs no enforcement in a primitive community and is followed spontaneously. That the savage does break the law sometimes, though rarely and occasionally, has been recorded by observers and taken into account by builders of anthropological theory, who have always maintained that criminal law is the only law of savages. But that his observance of the rules of law under the normal conditions, when it is followed and not defied, is at best partial, conditional, and subject to evasions; that it is not enforced by any wholesale motive like fear of punishment, or a general submission to all tradition, but by very complex psychological and social inducements—all this is a state of affairs which modern anthropology has so far completely overlooked. In the following account I shall try to establish it for one ethnographic province, north-west Melanesia, and I shall show reasons why observations of similar nature to those carried out by myself should be extended to other societies in order to give us some idea about their legal conditions.

---

[1] The present article contains the substance, expanded and recast, of a discourse delivered before the Royal Institution on Friday, February 13, 1925. I wish to express my indebtedness to the Laura Spelman Rockefeller Memorial for the assistance given me in carrying out this investigation.

[2] See NATURE, August 15, 1925, p. 230, review entitled "Primitive Law."

We shall approach our facts with a very elastic and wide conception of the problem before us. In looking for 'law' and legal forces, we shall try merely to discover and analyse all the rules conceived and acted upon as binding obligations, to find out the nature of the binding forces, and to classify the rules according to the manner in which they are made valid. We shall see that by an inductive examination of facts, carried out without any preconceived idea or ready-made definition, we shall be enabled to arrive at a satisfactory classification of the norms and rules of a primitive community, at a clear distinction of primitive law from other forms of custom, and at a new, dynamic conception of the social organisation of savages. Since the facts of primitive law described in this article have been recorded in Melanesia, the classical area of 'communism' and 'promiscuity,' of 'group-sentiment' and 'clan-solidarity,' of 'spontaneous obedience' and what not, the conclusions we shall be able to draw—which will dispose of these catch-words and all they stand for—may be of special interest.

MELANESIAN ECONOMICS AND THE THEORY OF PRIMITIVE COMMUNISM.

The Trobriand Archipelago, which is inhabited by the Melanesian community referred to, lies to the north-east of New Guinea and consists of a group of flat coral islands, surrounding a wide lagoon. The plains of the land are covered with fertile soil and the lagoon teems with fish, while both afford easy means of intercommunication to the inhabitants. Accordingly, the islands support a dense population mainly engaged in agriculture and fishing, but expert also in various arts and crafts and keen on trade and exchange.

Like all coral islanders, they spend a great deal of their time on the central lagoon. On a calm day it is alive with canoes carrying people or produce, or engaged in one of their manifold systems of fishing. A superficial acquaintance with these pursuits might leave one with an impression of arbitrary disorder, anarchy, complete lack of system. Patient and painstaking observations would soon reveal, however, not only that the natives have definite technical systems of catching fish and complex economic arrangements, but also that they have a close organisation in their working teams, and a fixed division of social functions.

Thus, within each canoe it would be found that there is one man who is its rightful owner, while the rest act as a crew. All these men, who as a rule belong to the same sub-clan, are bound to each other and to their fellow-villagers by mutual obligations: when the whole community go out fishing, the owner cannot refuse his canoe. He must go out himself or let some one else do it instead. The crew are equally under an obligation to him. For reasons which will presently become clear, each man must fill his place and stand by his task. Each man also receives his fair share in the distribution of the catch as an equivalent of his service. Thus the ownership and the use of the canoe consist of a series of definite obligations and duties uniting a group of people into a working team.

What makes the conditions even more complex is that the owners and the members of the crew are entitled to surrender their privileges to any one of their relatives and friends. This is often done, but always for a consideration, for a repayment. To an observer who does not grasp all the details, and does not follow all the intricacies of each transaction, such a state of affairs looks very much like communism: the canoe appears to be owned jointly by a group and used indiscriminately by the whole community.

Dr. Rivers in fact tells us that "one of the objects of Melanesian culture which is usually, if not always, the subject of common ownership is the canoe," and further on, in reference to this statement, he speaks about "the great extent to which communistic sentiments concerning property dominate the people of Melanesia" ("Social Organisation," pp. 106 and 107). In another work, the same writer speaks about "the socialistic or even communistic behaviour of such societies as those of Melanesia" ("Psychology and Politics," pp. 86 and 87). Nothing could be more mistaken than such generalisations. There is a strict distinction and definition in the rights of every one, and this makes ownership anything but communistic. We have in Melanesia a compound and complex system of holding property, which in no way partakes of the nature of 'socialism' or 'communism.' A modern joint-stock company might just as well be called a 'communistic enterprise.' As a matter of fact, any descriptions of a savage institution in terms such as 'communism,' 'capitalism,' 'joint-stock company,' or what not, borrowed from present-day economic conditions or political controversy, cannot be but misleading.

The only correct proceeding is to describe the legal state of affairs in terms of concrete fact. Thus, the ownership of a Trobriand fishing canoe is defined by the manner in which the object is made, used and regarded with reference to the group of men who produced it and enjoy its possession. The master of the canoe, who acts at the same time as the head of the team and as the fishing magician of the canoe, has first of all to finance the building of a new craft, when the old one is worn out, and he has to maintain it in good repair, helped in this by the rest of his crew. In this they remain under mutual obligations to one another, to appear each at his post, while every canoe is bound to come when a communal fishing has been arranged.

In using the craft, every joint owner has a right to a certain place in it and to certain duties, privileges, and benefits associated with it. He has his post in the canoe, he has his task to perform, and enjoys the corresponding title, either of 'master' or 'steersman,' or 'keeper of the nets,' or 'watcher for fish.' His position and title are determined by the combined action of rank, age, and personal ability. Each canoe also has its place in the fleet and its part to play in the manœuvres of joint fishing. Thus on a close inquiry we discover in this pursuit a definite system of division of functions and a rigid system of mutual obligations, into which a sense of duty and the recognition of the need of co-operation enter side by side with a realisation of self-interest, privileges, and benefits. Ownership, therefore, can be defined neither by such words as 'communism' or 'individualism,' nor by reference to 'joint-stock company' system or 'personal enterprise,' but by the concrete facts and conditions of use. It is the sum of duties, privileges, and mutualities which bind the joint owners to the object and to each other.

Thus, in connexion with the first object which attracted our attention—the native canoe—we are met by law, order, definite privileges, and a well-developed system of obligations.

THE BINDING FORCE OF ECONOMIC OBLIGATIONS.

To enter more deeply into the nature of these binding obligations, let us follow the fishermen to the shore. Let us see what happens with the division of the catch. In most cases only a small proportion of it remains with the villagers. As a rule we should find a number of people from some inland community waiting on the shore. They receive the bundles of fish from the fisherman and carry them home, often many miles away, running so as to arrive while it is still fresh. Here again we should find a system of mutual services and obligations based on a standing arrangement between two village communities. The inland village supplies the fishermen with vegetables: the coastal community repays with fish. This arrangement is primarily an economic one. It has also a ceremonial aspect, for the exchange has to be done according to an elaborate ritual. But there is also the legal side, a system of mutual obligations which forces the fisherman to repay whenever he has received a gift from his inland partner, and vice versa. Neither partner can refuse, neither may stint in his return gift, neither should delay.

What is the motive force behind these obligations? The coastal and inland villages respectively have to rely upon each other for the supply of food. On the coast the natives never have enough vegetable food, while inland the people are always in need of fish. Moreover, custom will have it that on the coast all the big ceremonial displays and distributions of food, which form an extremely important aspect of the public life of these natives, must be made with certain specially large and fine varieties of vegetable food, which grow only on the fertile plains inland. There, on the other hand, the proper substance for a distribution and feast is fish. Thus to all other reasons of value of the respectively rarer food, there is added an artificially, culturally created dependence of the two districts upon one another. So that on the whole each community is very much in need of its partners. If at any time previously these have been guilty of neglect, however, they know that they will be in one way or another severely penalised. Each community has, therefore, a weapon for the enforcement of its rights: reciprocity.

This is not limited to the exchange of fish for vegetables. As a rule, two communities rely upon each other in other forms of trading and other mutual services as well. Thus every chain of reciprocity is made the more stringent by being part and parcel of a whole system of mutualities.

RECIPROCITY AND DUAL ORGANISATION.

I have found only one writer who fully appreciates the importance of reciprocity in primitive social organisation. The leading German anthropologist, Prof. Thurnwald of Berlin, clearly recognises "die Symmetrie des Gesellschaftsbaus" and the corresponding "Symmetrie von Handlungen." "Die Symmetrie von Handlungen aber nennen wir das Prinzip der Vergeltung. Dieses liegt tief verwurzelt im menschlichen Empfinden—als adäquate Reaktion—und ihm kam von jeher die grösste Bedeutung im sozialen Leben zu." ("Die Gemeinde der Bánaro," Stuttgart, 1921, p. 16). Throughout his monograph, which by the way is perhaps the best account of the social organisation of a savage tribe extant, Prof. Thurnwald shows how the symmetry of social structure and of actions pervades native life. Its importance as a legal binding form is not, however, explicitly stated by the writer, who seems to be aware of its psychological foundation "in human feeling," rather than of its social function in safeguarding the continuity and adequacy of mutual services.

The old theories of tribal dichotomy, the discussions about the 'origins' of 'phratries' or 'moieties' and of the duality in tribal subdivisions, never entered into the inner or differential foundations of the external phenomenon of halving. The recent treatment of the "dual organisation" by the late Dr. Rivers and his school suffers badly from the defect of looking for recondite causes instead of analysing the phenomenon itself. The dual principle is neither the result of "fusion" or "splitting" nor of any other sociological cataclysm. It is the integral result of the inner symmetry of all social transactions, of the reciprocity of services, without which no primitive community could exist. A dual organisation may appear clearly in the division of a tribe into two 'moieties' or be almost completely obliterated—but I venture to foretell that wherever careful inquiry be made, symmetry of structure will be found in every savage society, as the indispensable basis of reciprocal obligations.

The sociological manner in which the relations of reciprocity are arranged makes them yet more stringent. Between the two communities the exchanges are not carried out haphazard, any two individuals trading with each other at random. On the contrary, every man has his permanent partner in the exchange, and the two have to deal with each other. They are often relatives-in-law, or else sworn friends, or partners in the important system of ceremonial exchange called *kula*. Within each community again, the individual partners are ranged into totemic subclans. So that the exchange establishes a system of sociological ties of economic nature, often combined with other ties, between individual and individual, kinship group and kinship group, village and village, district and district.

Going over the relations and transactions previously described, it is easy to see that the same principle of mutuality supplies the sanction to each rule. There is in every act as well as at the basis of every status a sociological dualism: two parties who exchange services and functions, each watching over the measure of fulfilment and the fairness of conduct of the other. The master of the canoe, whose interests and ambitions are bound up with his craft, looks after order in the internal transactions between the members of the crew and represents the latter externally. To him each member of the crew is bound at the time of construction and ever after, when co-operation is necessary. Reciprocally, the master has to give each man the ceremonial payment at the feast of construction; the master cannot refuse any one his place in the boat; and he has to see that each man receives his fair share of the catch. In this and in all the manifold activities of economic order, the social behaviour of the natives is based on a well-assessed give-and-take, always mentally ticked off and in the long run balanced. There is no wholesale discharge of duties or acceptance of privileges; no 'communistic' disregard of tally and ear-mark. The free and easy way in which all transactions are done, the good manners which pervade all and cover any hitches or maladjustments, make it difficult for the superficial observer to see the keen self-interest and watchful reckoning which runs right through. To one who knows the natives intimately, nothing is more patent than this. The same control which the master assumes within his canoe, is taken within the community by the headman who is, as a rule, also the hereditary magician.

Law, Self-interest, and Social Ambition.

It scarcely needs to be added that there are also other driving motives, besides the constraint of reciprocal obligations, which keep the fishermen to their task. The utility of the pursuit, the craving for the fresh, excellent diet, above all, perhaps, the fascination of what to the natives is an intensely fascinating sport—move them more obviously, more consciously even, and more effectively than what we have described as the legal obligation. But the social constraint, the regard for the effective rights and claims of others is always prominent in the mind of the natives as well as in their behaviour, once this is well understood. It is also indispensable to ensure the smooth working of their institutions. For in spite of all zest and attractions, there are on each occasion a few individuals, indisposed, moody, obsessed by some other interest—very often by an intrigue—who would like to escape from their obligation, if they could. Any one who knows how extremely difficult, if not impossible, it is to organise a body of Melanesians for even a short and amusing pursuit requiring concerted action, and how well and readily they set to work in their customary enterprises, will realise the function and the need of compulsion, due to the native's conviction that another man has a claim on his work.

There is yet another force which makes the obligations still more binding. I have mentioned already the ceremonial aspect of the transactions. The gifts of food in the system of exchange described above must be offered according to strict formalities, in specially made measures of wood, carried and presented in a prescribed manner, in a ceremonial procession and with a blast of conch-shells. Now nothing has a greater sway over the Melanesian's mind than ambition and vanity associated with a display of food and wealth. In the giving of gifts, in the distribution of their surplus, they feel a manifestation of power, and an enhancement of personality. The Trobriander keeps his food in houses better made and more highly ornamented than his dwelling huts Generosity is the highest virtue to him, and wealth the essential element of influence and rank. The association of a semi-commercial transaction with definite public ceremonies supplies another binding force of fulfilment through a special psychological mechanism: the desire for display, the ambition to appear munificent, the extreme esteem for wealth and for the accumulation of food.

We have thus gained some insight into the nature of the mental and social forces which make certain rules of conduct into binding law. Nor is the binding force superfluous. Whenever the native can evade his obligations without the loss of prestige, or without the prospective loss of gain, he does so, exactly as a civilised business man would do. When the "automatic smoothness" in the run of obligations so often attributed to the Melanesian is studied more closely, it becomes clear that there are constant hitches in the transactions, that there is much grumbling and recrimination and seldom is a man completely satisfied with his partner. But, on the whole, he continues in the partnership and, on the whole, every one tries to fulfil his obligations, for he is impelled to do so, partly through enlightened self-interest, partly in obedience to his social ambitions and sentiments. Take the real savage, keen on evading his duties, swaggering and boastful when he has fulfilled them, and compare him with the anthropologist's dummy who slavishly follows custom and automatically obeys every regulation. There is not the remotest resemblance between the teachings of anthropology on this subject and the reality of native life. We begin to see how the dogma of mechanical obedience to law would prevent the field-worker from seeing the really relevant facts of primitive legal organisation. We understand now that the rules of law, the rules with a definite binding obligation, stand out from the mere rules of custom. We can see also that civil law, consisting of positive ordinances, is much more developed than the body of mere prohibitions, and that a study of criminal law alone among savages misses the most important phenomena of their legal life.

It is also obvious that the type of rules which we have been discussing, although they are unquestionably rules of binding law, have in no way the character of religious commandments, laid down absolutely, obeyed rigidly and integrally.[3] The rules here described are essentially elastic, adjustable, and they leave a considerable latitude within which their fulfilment is regarded as satisfactory. The bundles of fish, the measures of yams, or bunches of taro, can only be roughly assessed, and naturally the quantities exchanged vary according to whether the fishing season or the harvest is more abundant. All this is taken into account and only wilful stinginess, neglect, or laziness are regarded as a breach of contract. Since again, largesse is a matter of honour and praise, the average native will strain all his resources to be lavish in his measure. He knows, moreover, that any excess in zeal and generosity is bound to be sooner or later rewarded.

We can see now that a narrow and rigid conception of the problem—a definition of 'law' as the machinery of carrying out justice in cases of trespass—would leave on one side all the phenomena to which we have referred In all facts described, the element or aspect of law, that is, of effective social constraint, consists in the complex arrangements which make people keep to their obligations. Among them the most important is the manner in which many transactions are linked into chains of mutual services, every one of them having to be repaid at some later date. The public and ceremonial manner in which these transactions are usually carried out, combined with the great ambition and vanity of the Melanesian, adds also to the safeguarding forces of law.

THE RULES OF LAW IN RELIGIOUS ACTS.

I have referred so far mainly to economic relations, for civil law is primarily concerned with ownership and wealth among savages as well as among ourselves. But we could find the legal aspect in any other domain of tribal life. Take, for example, the most characteristic acts of ceremonial life—the rites of mourning and sorrow for the dead. At first we perceive in them, naturally, their religious character: they are acts of piety towards the deceased, caused by fear or love or solicitude for the spirit of the departed As ritual and public display of emotion, they are also part of the ceremonial life of the community.

Who, however, would suspect a legal side to such religious transactions? Yet in the Trobriands there is not one single mortuary act, not one ceremony, which is not considered to be an obligation of the performer towards some of the other survivors. The widow weeps and wails in ceremonial sorrow, in religious piety and fear—but also because the strength of her grief affords direct satisfaction to the deceased man's brothers and maternal relatives. It is the matrilineal group of kindred who, according to the native theory of kinship and mourning, are the people really bereaved. The wife, though she lived with her husband, though she should grieve at his death, though often she really and sincerely does so, remains but a stranger, by the rules of matrilineal kinship. It is her duty towards the surviving members of her husband's clan, accordingly, to display her grief, to keep a long period of mourning and to carry the jaw-bone of her husband for some years after his death. Nor is this obligation without reciprocity. At the first big ceremonial distribution, some three days after her husband's death, she will receive from his kinsmen a ritual payment, and a substantial one, for her tears; and at later ceremonial feasts she is given more payments for the subsequent services of mourning. It should also be kept in mind that, to the natives, mourning is but a link in the lifelong chain of reciprocities between husband and wife and between their respective families.

---

[3] Examples of scientific opinions, which ascribe to primitive law in general such a semi-religious character, are given in the review entitled "Primitive Law," referred to above.

THE LAW OF MARRIAGE.

This brings us to the subject of marriage, extremely important for the understanding of native law. Marriage establishes not merely a bond between husband and wife, but it also imposes a standing relation of mutuality between the man and the wife's family, especially her brother. A woman and her brother are bound to each other by characteristic and highly important ties of kinship. In a Trobriand family a female must always remain under the special guardianship of one man—one of her brothers or, if she has none, her nearest maternal kinsman. She has to obey him and fulfil a number of duties, while he looks after her welfare and provides for her economically even after she is married.

The brother becomes the natural warden of her children, who therefore have to regard him and not their father as the legal head of the family. He in turn has to look after them, and he has to supply the household with a considerable proportion of its food. This is the more burdensome since marriage being patrilocal, the girl has moved away to her husband's community, so that every time at harvest there is a general economic *chassé-croisé* all over the district.

After the crops are taken out, the yams are classified and the pick of the crop from each garden is put into a conical heap. The main heap in each garden-plot is always for the sister's household. The sole purpose of all the skill and labour devoted to this display of food is the satisfaction of the gardener's ambition. The whole community, nay, the whole district, will see the garden produce, comment upon it, criticise, or praise. A big heap proclaims, in the words of my informant: "Look what I have done for my sister and her family. I am a good gardener and my nearest relatives, my sister and her children, will never suffer for want of food" After a few days the heap is dismantled, the yams carried in baskets to the sister's village, where they are put up into exactly the same shape in front of the yamhouse of the sister's husband; there again the members of the community will see the heap and admire it. This whole ceremonial side of the transaction has a binding force which we know already. The display, the comparisons, the public assessment impose a definite psychological constraint upon the giver—they satisfy and reward him, when successful work enables him to give a generous gift, and they penalise and humiliate him for inefficiency, stinginess, or bad luck.

Besides ambition, reciprocity prevails in this transaction as everywhere else; at times, indeed, it steps in almost upon the heels of an act of fulfilment. First of all, the husband has to repay by definite periodic gifts every annual harvest contribution. Later on, when the children grow up, they will come directly under the authority of their maternal uncle; the boys will have to help him, to assist him in everything, to contribute a definite quota to all the payments he has to make. His sister's daughters do but little for him directly, but indirectly, in a matrilineal society, they provide him with his heirs and descendants of two generations below.

Thus placing the harvest offerings within their sociological context, and taking a long view of the relationship, we see that every one of its transactions is justified as a link in the chain of mutualities. Yet taking it isolated, torn out of its setting, each transaction appears nonsensical, intolerably burdensome and, sociologically, meaningless, also no doubt "communistic"! What could be more economically absurd than this oblique distribution of garden produce, where every man works for his sister and has to rely in turn on his wife's brother, where more time and energy is apparently wasted on display, on show, on the shifting of the goods, than on real work ? Yet a closer analysis shows that some of these apparently unnecessary actions are powerful economic incentives, that others supply the legal binding force, while others again are the direct result of native kinship ideas. It is also clear that we can understand the legal aspect of such relations only if we look upon them integrally without over-emphasising any one link in the chain of reciprocal duties.

The real reason why all these economic obligations are normally kept, and kept very scrupulously, is that failure to comply places a man in an intolerable position, while slackness in fulfilment covers him with opprobrium. The honourable citizen is bound to carry out his duties, though his submission is not due to any instinct or intuitive impulse or mysterious 'group-sentiment,' but to the detailed and elaborate working of a system, in which every act has its own place and must be performed without fail. Though no native, however intelligent, can formulate this state of affairs in a general, abstract manner, or present it as a sociological theory, yet every one is well aware of its existence, and in each concrete case he can foresee the consequences.

THE RULES OF CUSTOM DEFINED AND CLASSIFIED.

If we designate the sum total of rules, conventions, and patterns of behaviour as the body of custom, there is no doubt that the native feels a strong respect for all of them, has a tendency to do what others do, what every one approves of, and, if not drawn or driven in another direction by his appetites or interests, will follow the biddings of custom, rather than any other course The force of habit, the awe of traditional command and a sentimental attachment to it, the desire to satisfy public opinion—all combine to make custom be obeyed for its own sake. In this the 'savages' do not differ from the members of any self-contained community with a limited horizon, whether this be an Eastern European ghetto, an Oxford college, or a Fundamentalist Middle West community. But love of tradition, conformism, and the sway of custom account but to a very partial extent for obedience to rules among dons, savages, peasants, or Junkers.

Limiting ourselves strictly to savages once more, there are among the Trobrianders a number of traditional rules instructing the craftsman how to ply his trade. The inert and uncritical way in which these rules are obeyed is due to the general 'conformism of savages' as we might call it. But in the main these rules are followed because their practical utility is recognised by reason and testified by experience. Again, other injunctions of how to behave in associating with one's friends, relatives, superiors, equals, and so on, are obeyed because any deviation from them makes a man feel and look, in the eyes of others, ridiculous, clumsy, socially uncouth. These are the precepts of good manners, very developed in Melanesia and most strictly adhered to. There are further rules laying down the proceedings at games, sports, entertainments and festivities, rules which are the soul and substance of the amusement or pursuit and are kept because it is felt and recognised that any failure to 'play the game' spoils it—that is, when the game is really a game! In all this, it will be noted, there are no mental forces of inclination or of self-interest, or even inertia, which would run counter to any rule and make its fulfilment a burden. It is quite as easy to follow the rule as not, and once you embark upon a sporting or pleasurable pursuit, you really can enjoy it only if you obey all its rules whether of art, manner, or game.

There are also norms pertaining to things sacred and important, the rules of magical rite, funerary pomp, or what not. These are primarily backed up by supernatural sanctions and by the strong feeling that sacred matters must not be tampered with. By an equally strong moral force are maintained certain rules of personal conduct towards near relatives, members of the household and others towards whom strong sentiments of friendship, loyalty, or devotion are felt, which back up the dictates of the social code.

This brief catalogue is not an attempt at a classification, but is mainly meant to indicate clearly that, besides the rules of law, there are several other types of norm and traditional commandment which are backed up by motives or forces, mainly psychological, in any case entirely different from those which are characteristic of law in that community. Thus, though in my survey attention has naturally been mainly focussed on the legal machinery, I was not intent on proving that all social rules are legal, but on the contrary, I wanted to show that the rules of law form but one well-defined category within the body of custom.

AN ANTHROPOLOGICAL DEFINITION OF LAW.

The rules of law stand out from the rest in that they are felt and regarded as the obligations of one person and the rightful claims of another. They are sanctioned not by a mere psychological motive, but by a definite social machinery of binding force, based, as we know, upon mutual dependence and realised in the equivalent arrangement of reciprocal services, as well as in the combination of such claims into strands of multiple relationship. The ceremonial manner in which most transactions are carried out, which entails public control and criticism, adds still more to their binding force.

We may therefore finally dismiss the view that 'group-sentiment' or 'collective responsibility' are the only or even the main force which ensures adhesion to custom and which makes it binding or legal. *Esprit de corps*, solidarity, pride in one's community and clan exist undoubtedly among the Melanesians—no social order could be maintained without them in any culture high or low. I only want to enter a caution against such exaggerated views as those of Rivers, Sidney Hartland, Durkheim, and others, which would make this unselfish, impersonal, unlimited group-loyalty the corner-stone of all social order in primitive cultures. The savage is neither an extreme 'collectivist' nor an intransigent 'individualist'—he is, like man in general, a mixture of both.

It results also from the account here given that primitive law does not consist exclusively or even mostly of negative injunctions, nor is all savage law criminal law.[4] So far we have met with positive commandments only, the breach of which is penalised but not punished, and the machinery of which can by no procrustean methods be stretched beyond the line which separates *civil* from *criminal* law. If we have to provide the rules described in these articles with some modern, hence necessarily inappropriate, label, they must be called the body of 'civil law' of the Trobriand Islanders.

---

[4] Quotations of such opinions in modern anthropological literature and a criticism of them is given in the review entitled "Primitive Law," referred to above.

'Civil law,' the positive law governing all the phases of tribal life, consists then of a body of binding obligations, regarded as a right by one party and acknowledged as a duty by the other, kept in force by a specific mechanism of reciprocity and publicity, inherent in the structure of their society. These rules of civil law are elastic and possessing a certain latitude. They offer not only penalties for failure, but also premiums for an overdose of fulfilment. Their stringency is ensured through the rational appreciation of cause and effect by the natives, combined with a number of social and personal sentiments such as ambition, vanity, pride, desire of self-enhancement by display, and also attachment, friendship, devotion and loyalty to the kin.

It scarcely needs to be added that 'law' and 'legal phenomena,' as we have discovered, described, and defined them in a part of Melanesia, do not consist in any independent institutions. Law represents rather an aspect of their tribal life, one side of their structure, than any independent, self-contained social arrangements. Law dwells not in a special system of decrees, which foresee and define possible forms of non-fulfilment and provide appropriate barriers and remedies. Law is the specific result of the configuration of obligations, which makes it impossible for the native to shirk his responsibility without suffering for it in the future.

SPECIFIC LEGAL ARRANGEMENTS.

The rare quarrels which occur at times take the form of an exchange of public expostulation (*yakala*), in which the two parties assisted by friends and relatives meet, harangue one another, hurl and hurl back recriminations. Such litigation allows people to give vent to their feelings and shows the trend of public opinion, and thus it may be of assistance in settling disputes. Sometimes it seems, however, only to harden the litigants. In no case is there any definite sentence pronounced by a third party, and agreement is but seldom reached then and there. The *yakala* therefore is a special legal arrangement, but of small importance and not really touching the heart of legal constraint.

Some other specific legal mechanisms may also be mentioned here. One of them is the *kaytapaku*, the magical protection of property by means of conditional curses. When a man owns coco or areca palms in distant spots, where it is impossible to keep watch over them, he attaches a palm leaf to the trunk of the tree, an indication that a formula has been uttered, which automatically would bring down ailment on the thief. Another institution which has a legal side is the *kaytubutabu*, a form of magic performed over all the coconut trees of a community to bring about their fertility, as a rule in view of an approaching feast. Such magic entails a strict prohibition to gather the nuts or to partake of coconut, even when imported. A similar institution is the *gwara*.[5] A pole is planted on the reef, and this places a taboo on any export of certain valuable objects, exchanged ceremonially in the *kula*, while their importation on the contrary is encouraged. This is a sort of moratorium, stopping all payments, without any interference with the receipts, which also aims at an accumulation of valuable objects before a big ceremonial distribution. Another important legal feature is a sort of ceremonial contract, called *kayasa*.[6] Here the leader of an expedition, the master of a feast, or the *entrepreneur* in an industrial venture, gives a big ceremonial distribution. Those who participate in it and benefit by the bounty are under an obligation to assist the leader throughout the enterprise.

All these institutions, *kayasa*, *kaytapaku*, and *kaytubutabu*, entail special binding ties. But even they are not exclusively *legal*. It would be above all a great mistake to deal with the subject of law by a simple enumeration of these few arrangements, each of which subserves a special end and fulfils a very partial function. The main province of law is in the social mechanism which is to be found at the bottom of all the real obligations and covers a very vast portion of their custom, though by no means all of it, as we know.

CONCLUSION AND FORECAST.

I have dealt here only with one province of Melanesia, and the conclusions arrived at have naturally a limited range. These conclusions, however, are based on facts observed by a new method and regarded from a new point of view; so that they might stimulate other observers to take up a similar line of study in other parts of the world. With a wider and more elastic 'minimum definition' of law, there is no doubt that new legal phenomena of the same type as those found in N.W. Melanesia will be discovered. There is no doubt that custom is not based only on a universal, undifferentiated, ubiquitous force, this mental inertia, though this unquestionably exists and adds its quota to other constraint. There must be in all societies a class of rules too practical to be backed up by religious sanctions, too burdensome to be left to mere goodwill, too personally vital to individuals to be enforced by any abstract agency. This is the domain of legal rules, and I venture to foretell that reciprocity, systematic incidence, publicity and ambition will be found to be the main factors in the binding machinery of primitive law.

---

[5] Comp. the account of this institution in "Argonauts of the Western Pacific" (references in Index s.v. *Gwara*), also descriptions in Prof. Seligman's "Melanesians," and in the present writer's "The Natives of Mailu" (*Trans. R. Soc. of S. Australia*, vol. 39), of the *gola* or *gora* among the Western Papuo-Melanesians.

Supplement to NATURE

No. 2944 APRIL 3, 1926

Our Bookshelf

Man in the Past.

Les origines de l'humanité. Par Prof. René Verneau. (Bibliothèque générale illustrée, 1.) Pp. 80+59 planches. (Paris: F. Rieder et Cie, 1926.) 15 francs.

To summarise adequately and in popular language the present position of our knowledge of the origin and development of mankind in a compass of less than eighty pages of not very small type, is a feat which is possible only to a master of his subject with a gift of lucid exposition such as Prof. Verneau. In this little book the uninstructed reader will find all that is essential for a thorough understanding of the elements of his subject and the bearing upon it of the geological and palæontological evidence. Nor has the author hesitated to deal with matters on which the views of experts differ. Even such questions as the antiquity of the Calaveras skull and the theories of Ameghino on the antiquity of man in South America are briefly discussed and the points at issue set forth. On the question of Neanderthal man, Prof. Verneau gives a succinct and carefully argued summary of the evidence upon which is based his own view that Neanderthal man is not an aberrant and extinct form, but stands in the direct line of descent as evidenced by atavistic types such as the Australian. Prof. Verneau's exposition is greatly helped by a very full series of remarkably well produced illustrations which alone would make this little book a possession to be desired by any archæologist.

Prehistoric and Roman Wales. By Dr. R. E. M. Wheeler. Pp. 229. (Oxford: Clarendon Press; London: Oxford University Press, 1925.) 18*s.* net.

Wales is a country which presents many difficulties and many pitfalls to the student of prehistory. The evidence is often scanty and sometimes, when considered in relation to the succession of cultural periods elsewhere, entirely lacking; and both in its character and in its distribution it is frequently puzzling to interpret. In the present volume, Dr. Wheeler has essayed to weave a connected story out of this material and, within the limitations imposed by the nature of his data, he has been eminently successful. His views are sane and cautious, but at the same time inspired with an imagination which is kept under careful restraint by a keen appreciation of how far his facts are capable of carrying the proof of any suggested conclusions. As an example may be cited the skilful use of probable climatic and geographical conditions in explaining the character and distribution of the palæolithic implement in Wales, the emergence of the area as a meeting place of culture from east and west, and its final transformation into a true frontier province under the Empire. His word of caution in regard to the, perhaps, too exuberant plotting of prehistoric trade routes is timely as well as characteristic. Amid so much that is excellent, a special commendation of the valuable summary and analysis of our present knowledge of Roman Wales may not be out of place.

Mystery Cities: Exploration and Adventure in Lubaantun. By Thomas Gann. Pp. 252+32 plates. (London: Gerald Duckworth and Co., Ltd., 1925.) 21*s.* net.

Dr. Gann is well known as an explorer in the realms of Central American archæology, and needs no introduction. Those who have read his "In an Unknown Land" can have no doubt of his ability to describe his adventures in pursuit of scientific data with a graphic power and a humour which endear him to the hearts of his readers, while giving a sufficient account of his results to make his book of permanent value as a record. He here describes his journey of the season 1924–25 in British Honduras, first to explore mounds at Xunantunich and afterwards to Lubaantun, where he joined Lady Brown and Mr. Mitchell-Hedges, his fellow-concessionaires, and continued the work of a preceding preliminary reconnaissance.

One of the results of the journey, as is well known, was the discovery of the remarkable amphitheatre which has no parallel in the whole area once occupied by the Maya. It provided seating accommodation for at least 5000 people "or at a pinch possibly 10,000," and measures approximately 350 feet from east to west by 300 feet from north to south, the greater part of the space being taken up by seating and standing accommodation for the spectators of whatever was taking place in the arena. There is a pathetic interest in turning from Dr. Gann's description of the monuments of the ancient Maya to his account of their degenerate descendants of to-day, to whom he does more than justice

Aspects of Psychology.

(1) *Education as the Psychologist Sees It.* By Prof. W. B. Pillsbury. Pp. ix+342. (New York: The Macmillan Co., 1925.) 8*s.* 6*d.* net.

(2) *Old and New Viewpoints in Psychology.* By Prof. Knight Dunlap. Pp. 166. (London: Henry Kimpton, 1925.) 10*s.* 6*d.* net.

(1) Prof. Pillsbury aims at presenting a concise summary of the problems of the teacher as they appear to the psychologist. The first part deals with the statistical side of psychological research and the nature of intelligence. Then follows an account of the general psychological processes and laws helpful to the teacher, namely, instinct, habit, attention, reasoning. A chapter is devoted to feeling and emotion in relation to discipline. At the end of each chapter is a list of questions.

To the teacher with a good psychological training the book is a useful synopsis of much scattered work, but to the beginner and to the general reader, to whom the writer also wishes to appeal, it may give the entirely illusory idea that much more is known than is actually the case. There is little indication of what is hypothesis and what is theory. The interpolation of physiological details—for example, the synaptic hypothesis, to explain associated acts—does not elucidate psychological occurrences. The account of correlation is of little value to any one who already knows it and inadequate as a first introduction. If it is necessary to introduce the Freudian theories at all, then more space should have been devoted to them; casual criticism, with no indication of the data for criticism, is out of place in an elementary book. The difference between suppression and repression is not made clear.

Although somewhat stereotyped, parts of the text are interesting. Its defects are largely due to its note form.

(2) Prof. Dunlap has brought together a number of papers given by him to various societies, and, as might be expected, they are of unequal value. The first chapter, on mental measurement, is the best, being a very able review of current work on the subject. The author gives an account of the work leading up to the present-day intelligence tests; he describes the aims and methods of the tests, discusses the claims legitimate and illegitimate of workers in this field, and issues a warning against the futility of many popular expositions.

The chapters on spiritualism and on the comic are somewhat sketchy accounts of a vast field. Dr. McDougall's theory of laughter published in this journal in 1903 might help to elucidate some of the problems of the latter. The chapter on present-day schools of psychology enables the author to tilt at all the more outstanding current systems. Doubtless the most ardent Freudian would agree with the author that to "repress effectively" is the greatest asset a human individual can have: the trouble lies in the adverb attached.

As lectures they must have been very stimulating; whether they merit book form is doubtful.

Art and the Unconscious: a Psychological Approach to a Problem of Philosophy. By John M. Thorburn. Pp. xii+242. (London: Kegan Paul and Co., Ltd., 1925.) 10*s*. 6*d*. net.

Mr. Thorburn has attempted to discover how far the problems of art and the sources of its inspiration may be restated in the light of contemporary theories of the unconscious. He begins by considering a domain where we are all artists, namely, the dream life, and goes on to relate this to the problems of the nature and origin of the imagination, art and the archaic, the function of symbolism, etc. The range of subjects discussed is wide, comprising literature, architecture, painting, and music.

The author has derived much inspiration from the writings of Freud and Jung, but he does not therefore make the mistake of neglecting conscious processes in his enthusiasm for the unconscious. The book is a contribution to the interpretation of art, to philosophy, and to the psychology of the imagination. The style is not easy and in places is decidedly laboured, due obviously to the difficulty of the conceptions.

Medical Science.

Arteriosclerosis: a Summary View. By the late Rt. Hon. Sir T. Clifford Allbutt. Pp. viii+108. (London: Macmillan and Co., Ltd., 1925.) 5*s*. net.

Intended for the busy practitioner, this summary of a larger work contains added material which makes the essay an admirable statement of the present state of knowledge of the subject. Sir Humphry Rolleston, who saw the little work through the press, reminds the reader of additions made by the author to the science and art of medicine. "Some of these are now so thoroughly incorporated in common knowledge and practice that our indebtedness in this respect is largely forgotten, such as the invention of the clinical thermometer now in use and the description of syphilitic disease of the cerebral arteries." His distinction between hyperpiesia, or high blood pressure of obscure origin, and the hyperpiesis of renal disease, which is in one sense the kernel of the essay, will also take its place in medicine surviving the elucidation of what is now obscure. For the light shed on the difficult problems of arterial disease and its consequences the volume will have many readers. It deserves a wider public for its amazing skill in the marshalling of hosts of facts and its delightful literary style.

Lister and his Achievement: being the First Lister Memorial Lecture delivered at the Royal College of Surgeons of England on May 14, 1925. By Sir Wm. Watson Cheyne. Pp. iv+136. (London: Longmans, Green and Co., 1925.) 7*s*. 6*d*. net.

The First Lister Memorial Lecture was a compression of a short history of Lister's work. Both are here printed together; the first occupies the opening thirty-eight pages of the volume and the second the remainder as an appendix. Without consideration of the necessity of such an arrangement if the lecture is to be given permanence in its original form, the plan is nevertheless not a perfect mode of presentation. At the same time no one who is genuinely interested in the development of surgery and in the life of its great English exponent would sacrifice any one of the glimpses which Sir Watson Cheyne has given of his great teacher. It may be said, however, that the earnest championship of the whole technique and nomenclature of Lord Lister's practice met with in these pages as against the newer 'improvements' is now receiving much more support than formerly from many surgeons, and we may still see a revival of *antiseptic* surgery.

Natural History.

(1) *The Monkeyfolk of South Africa.* By F. W. Fitzsimons. Second edition. Pp. xiv+172+48 plates. (London: Longmans, Green and Co., 1924.) 10*s*. 6*d*. net.

(2) *Chats on British Mammals: Ungulates, Carnivores, and Insectivores.* By Dr. Jas. J. Simpson. Pp. 122+4 plates. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1924.) 2*s*. 6*d*. net.

(1) In his preface Mr. Fitzsimons says: "I am a strong advocate of books being written in simple language, because they are then easily comprehended

by learned men and women, as well as the most ignorant schoolboy or girl." That sentence may not be a model of tactful expression, but it shows consideration for the learned, and that, alas! is far from general. The author also says, very truly, that: "In the degree that a writer is able to interest the mind of the reader, so just in that degree will he succeed in impressing the cells of the grey matter of the brain. Unless the teacher succeed in arousing the intelligent interest of his pupil, he can make but little headway." There is, however, a right and a wrong way of doing this, and most certainly Mr. Fitzsimons has followed the latter. Apparently imagining it to be impossible to give a direct and at the same time an interesting account of the monkeys of South Africa and their habits, he has chosen to play the part of a talkative and most irritatingly well-informed monkey. Many a moralist, no doubt, has used such a device for the conveyance and gilding of his philosophic pills; but the naturalist should remember that he is dealing with lilies and refined gold.

(2) A glimpse of the right way to arouse and secure the "intelligent interest" of a pupil in his natural surroundings may be got from Dr. Simpson's "Chats on British Mammals," an early one of a series of little books containing the admirable "ten-minute" talks on natural history broadcast by the author from the Cardiff Station.

M. A. C. H.

Animal Life in the Sea. By R. J. Daniel. Pp. 119+4 plates. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd, 1925.) 5*s.* 6*d.* net.

Mr. Daniel gives a popular account of marine creatures from microscopic plants to fishes and whales, finishing with descriptions and explanations of various legendary sea serpents. It is a well-planned book, simply written, and will serve admirably for a first step towards interesting untrained observers in all that is to be found in the sea, the habits of the animals living in it, and the various phenomena connected with them, besides simple discussions of physical and chemical conditions from the surface to the depth of the ocean. The larger sea animals are most to the fore—fishes, whales, and giant cuttles—the illustrations being culled from many sources, including some from ancient maps and old pictures of sea monsters. Deep-sea animals are given special prominence, and the short account of conditions and life in the ocean depths is perhaps the best part of the book. In the small space of 117 pages an amount of interesting information has been included that might well have made a larger volume.

Concerning the Habits of Insects. By F. Balfour-Browne. Pp. x+169+9 plates. (London: Cambridge University Press, 1925.) 6*s.* net.

This small volume is the aftermath of the Christmas lectures, intended for a juvenile audience, which the author delivered at the Royal Institution in 1924. Its aim is to stimulate an interest in insect life and induce others to make observations in the wide field before them. In the first chapter the author utilises his own favourite studies of water-beetles as an example of what insect collecting may lead to. It is true that most of the real investigators in entomology were at one time in their lives collectors. There are also a great many folk who remain real collectors without ever becoming real entomologists. It is hoped that Mr. Balfour-Browne's book may lead to some depletion of the ranks of the latter class and, if so, retard the extinction of some of the more rare local insects.

In Chapter 2 the author describes his own delightfully simple and effective methods of observing the behaviour of some of the commoner solitary bees and wasps. The succeeding three chapters are devoted to phases of the habits of caterpillars, dragonflies, and water-beetles. All these accounts are written in a pleasing freshness of style, and there is no mistaking that the author has observed personally most of what he writes about. The book concludes with remarks on the economic significance of insects especially in relation to the transmission of tropical diseases. This apologia, as we may call it, for entomology winds up with an allusion to the possibility of a livelihood now being earned by its pursuit, although Mr. Balfour-Browne deplores any one taking up the subject with that intention.

A. D. I.

Notes on the Birds of Cley, Norfolk. By the late H. N. Pashley. Pp. 138+2 plates. (London: H. F. and G. Witherby, 1925.) 7*s.* 6*d.* net.

The late Mr. Pashley had the good fortune to live for many years on a part of the Norfolk coast which is almost unrivalled in the British Isles as a locality for rare migrants, and as a practising and well-known taxidermist he had great numbers of interesting specimens through his hands, in addition to the birds which he saw or obtained himself. The greater part of his small book—now published just after his death at the age of eighty-one years—consists of extracts from his ornithological diaries covering a period of thirty-eight years: this is a rich mine of information. There follows a systematic list in which the chief facts are conveniently summarised for each species. There are also a few pages of more general reminiscences.

One of the most interesting points which emerges relates to the changes which have taken place within the period covered. As Mr. B. B. Riviere says in his foreword, "The Shore-Lark and Lapland Bunting, which in the sixties and eighties respectively were regarded as very great rarities, are now regular winter visitors to Cley, the former in considerable numbers. The Black-tailed Godwit, no specimen of which appears to have found its way into Pashley's shop until the year 1917, has since then occurred regularly in the neighbourhood as an autumn, and occasional spring, migrant; whilst the Sandwich Tern, a rare passer-by of the eighties, now breeds in hundreds, almost within sight of Mr Pashley's windows." These are gratifying facts to set off against the depletion of our avifauna in so many other directions.

Zoological Handbooks.

Zoologisches Worterbuch. Von Dr. Erwin Hirsch-Schweigger. (Veit's Sammlung Wissenschaftlicher Wörterbücher.) Pp. viii+628. (Berlin und Leipzig: Walter de Gruyter und Co., 1925). 26 gold marks.

This short zoological dictionary is intended as a 'first aid' for professional zoologists, teachers, students, and amateur naturalists, its object being to provide a means of rapid orientation, without entering into minute details. The ground covered is not restricted to zoology in the narrow sense, but includes cytology, anatomy, genetics, and theoretical biology in general.

As regards systematic zoology, the higher subdivisions down to orders and the most typical families are well represented. Brief diagnoses of these are given, together with references to some of the genera and species. The value of these diagnoses and other definitions is enhanced by numerous cross-references. Some of the systematic groups are provided with index-numbers of the "Bibliotheca Zoologica," to which the reader is referred for further information. The geographical distribution of separate forms is indicated in a similar manner, the respective regions being arranged at the end of the book in tabular form. The classification adopted is also given at the end, side by side with that of the "Bibliotheca Zoologica." A useful feature of the dictionary is the accentuation of Latin and latinised words and the etymology of these and other foreign words, given in brackets.

In a book of this type it is perhaps inevitable that certain inaccuracies will occur. Thus the Aggregataria (or Aggregatidæ) are referred to the Gregarinida instead of to the Coccidia; the causative organism of tropical malaria is referred to as *Plasmodium præcox*, without mention of the name *P. falciparum*. The retention of Hartmann's artificial group Binucleata does not accord with the view of most protozoologists. The various members of the family Filariidæ, which actually belong to different genera, are all placed in one genus, Filaria. These minor defects do not detract from the general merit of the book, which may be recommended as a useful short guide to zoological nomenclature.

C. A. Hoare.

Animal Classification and Distribution, a Précis Reference Book for Students of Elementary Zoology at Secondary Schools, Colleges, and the Universities; being a Time-saving Synopsis with Provision for a Digest of Lecture Notes and Sketches. By Douglas M. Reid. (Griffin's Scientific Text-books.) Pp. xv + 51 (every other page blank). (London: Charles Griffin and Co., Ltd., 1925.) 6*s.* net.

The purpose of this volume is expressed in the opening lines of the preface: "Experience in teaching students of zoology has shown that many who are unfamiliar with the laws and principles of classification lose much time in searching various books to determine the position of some organism, . . . and to meet this need the present synopsis is provided." It must be said at once that the volume will require many emendations and additions if it is to enable the student to determine the position of the animals he sees or collects. A number of the small subdivisions containing relatively rare forms might well have been omitted and the space so obtained devoted to a fuller definition of the main groups. Many of the definitions contain loose statements which will lead to misunderstanding; *e.g.* "epithelium absent" is given as one of the characters of Nematoda (no doubt cœlomic epithelium was intended), and Gordius is said to be free living—a statement which takes little account of the life-history; the Zoantharia are defined as having a calcareous skeleton, but the example of the order correctly cited is Actinia, which has no skeleton. The author would do well to study page 9 and ask himself how the reader will know by inspection whether certain worms "have possessed chaetae," if in all Polychæta the "head end is fitted with tentacles"; if the posterior sucker of a leech is on the posterior segment, why the leeches alone among annelids are cited as exhibiting embryonic development; if Gephyrea are hermaphrodite (see Bonellia) and the mouth and anus are at the opposite ends of the body (see Sipunculus), and why the presence of a vascular system and nephridia are noted in Gephyrea but left unnoticed in Oligochæta and Polychæta, where they (especially the vascular system) are much more typical.

We do not feel able to recommend this volume as tending to a solution of the student's difficulties in classification.

Plant Morphology.

Monocotyledons: a Morphological Study. By Dr. Agnes Arber. (Cambridge Botanical Handbooks.) Pp. xv + 258. (Cambridge: At the University Press, 1925.) 21*s.* net.

Dr. Arber has produced a very clear, learned, and admirably illustrated treatise on the monocotyledons. To be properly appreciated it must be studied in detail, since it is a carefully reasoned morphological study dealing with the study of plant organs from the point of view of their internal structural features as well as of their external. Thus the root, the axis, the foliage leaf in its various forms as represented in the monocotyledons, and the prophyll, including phyllo-clades, are fully treated. The seedling and its interpretation is also discussed at length. In the chapter on the reproductive phase the floral peculiarities exhibited are described and details of the structure of the embryo sac and ovule are given.

This is followed by a discussion on taxonomy and a very interesting chapter on parallelism in evolution. The book concludes with a full bibliography and carefully prepared index.

Dr. Arber, though a disciple and fellow-worker of the late Miss Ethel Sargent, has largely followed her own ideas in writing this book and the result is a work full of fresh light on a fascinating problem—the meaning and interpretation, especially as regards their vegetative features, of the very diverse organisms which are grouped together in the phylum monocotyledons.

Many theories have been put forward to explain the relation of the monocotyledons to the dicotyledons, the most generally accepted being that the former have arisen from the latter. Dr. Arber, however, considers that the evidence, both from the living plants and the scanty fossil records, is not sufficient to warrant acceptance of such views. She would rather maintain that the great groups of flowering plants came independently into existence, and that their immense variety of form and structure at the present day is due to reduction, fusion and degeneration. Adaptation, she holds very strongly, affords no explanation of the characters which distinguish groups.

Both text and figures deserve the careful attention of botanists and students of evolution. The book is not only one for which the author deserves very high praise, but is also a production which reflects great credit on the Cambridge University Press.

An Introduction to Plant Anatomy. By Prof. Arthur J. Eames and Prof. Laurence H. MacDaniels. (McGraw-Hill Publications in the Agricultural and Botanical Sciences.) Pp. xv+364. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 17*s.* 6*d.* net.

It is rare, indeed, that one meets a book that needs little but commendation, yet such is the case in connexion with this detailed text-book of plant anatomy. Without embarking upon general theories, the authors are merely concerned with the descriptive morphology of vascular plants. Physiological and ecological aspects of morphology, and the practical applications of this subject, are indicated incidentally to the general treatment, while comparative morphology is used only when it may help to make clear structural complexity. Although the treatment of the subject is in no way causal, yet the developmental side of morphology is well to the fore in chapters on meristems, the primary and secondary plant bodies, and in the treatment of cambial activities.

The view-point from which the organisation of the vascular tissues is developed is that these are primarily laid down on a cylindrical plan, from which various subordinate types can be traced. The treatment of this subject is as thoroughly up-to-date as the rest of the book. Lists of recent references are given at the end of each chapter, while excellent illustrations abound, notably those of different types of wood, presented by the courtesy of the United States Forest Service. The result is a well-balanced book which can scarcely fail to be of value to any botanist who uses morphological data.

Geology.

(1) *Mineralogie.* Von Prof. Dr. R. Brauns. (Sammlung Göschen, Band 29.) Sechste verbesserte Auflage. Pp. 143. 1·25 gold marks.

(2) *Geschichte der Geologie.* Von Prof. Dr. K. Hummel. (Sammlung Goschen, Band 899.) Pp. 123. 1·25 gold marks.

(Berlin und Leipzig: Walter de Gruyter und Co., 1925.)

These are recent issues of this excellent series which has been employed in Great Britain for practice in reading scientific German. The first (1) is a miniature text-book of mineralogy quite sufficient to give a sound elementary knowledge of the subject. It will be all the more welcome in Britain that Naumann's notation of crystal faces is discarded and only those of Weiss and Miller are placed before the student. The second (2) is a remarkably full but concise description of the historical development of geological science in all its branches.

Gestaltungsgeschichte der Erde. Von Dr. Leopold Kohn. (Sammlung Bornträger, Band 7.) Pp. vii+200. (Berlin: Gebr. Borntrāger, 1925.) 7·50 gold marks.

This is a readable but somewhat discursive account of the problems presented by the history of the earth. Special attention is given to the geosynclinal theory of mountain formation, which in one form or another has gained considerable support in recent years, though it has not obtained the approval of Prof. Heim. On this and other subjects the opinions of different authors are freely quoted. Altogether it is a stimulating book, and if it is somewhat inconclusive, that is largely to be attributed to the difficulties inherent in many of the questions with which it deals. A folder is included, giving a synopsis of the different stages in the earth's history.

Popular Astronomy.

A Popular Guide to the Heavens: a Series of Eighty-six Plates; with Explanatory Text and Index. By Sir Robert Stawell Ball. Fourth edition, completely revised and edited by the Rev. T. E. R. Phillips. Pp. xii+84+86 plates+13. (London: George Philip and Son, Ltd.; Liverpool: Philip, Son and Nephew, Ltd., 1925.) 15*s.* net.

After an interval of fifteen years since the publication of the third edition, this book now appears rehabilitated under Mr. Phillips's able revision. To the usual planetary diagrams, numerous lunar and stellar charts, drawings of planets and comets, a number of photographs have been added to represent the work of modern astronomical photography, together with a concise summary of such topics as methods of measuring the distances of the stars, the classification of stellar spectra, and new information on variable stars.

It is to be regretted, however, that sunspots—a source of interest to many people possessing small telescopes—are not represented by a short series of photographs, illustrating, for example, the growth of a typical stream of spots. The single plate portraying sunspots by direct photography is, we think, unwisely retained from the last edition to the exclusion of more recent and better photographs. The Stonyhurst charts might also have been mentioned as being very useful to the amateur.

It can be said with confidence that every one interested in astronomy, whether possessing a telescope or not, will be well equipped with this popular guide—a title which deservedly expresses its purpose in the fullest sense.

A Voyage in Space: a Course of Six Lectures "Adapted to a Juvenile Auditory" delivered at the Royal Institution at Xmas 1913. By Prof. H. H. Turner. Second edition, with an Addendum on Recent Discoveries. Pp. xvi+344. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1925.) 7*s.* 6*d.* net.

The first edition of this book was published during the unsettled times of 1915. The publication of a second edition comes, therefore, as a welcome reminder of these excellent lectures, which being reproduced in print are made accessible to an increasing number of hearers beyond the limits of the lecture room. To those who have heard one of Prof. Turner's discourses on astronomy, the book will require no further introduction. To others, a hearty invitation may be given to share in the good things provided for the young people (and their seniors) at the Royal Institution. A glance at the numerous illustrations, averaging at least one to every three pages of text, will show the original, simple, and often amusing manner in which the author characteristically presents his subject to his audience.

The first three lectures are concerned with the preparations for the journey: (1) The starting-point, our earth; (2) the length of our voyage and the start through the air; (3) journeying by telescope. The remaining lectures are devoted to the journey itself: (4) visit to the moon and planets; (5) visit to the sun; (6) visit to the stars. During the interval of ten years between the publication of the two editions, the great advances of astronomy call for the addendum. In forty pages it is only possible, as the author says, to give samples of these advances. Nevertheless, the reader is introduced to things appertaining to relativity, the study of the upper air, recent ideas on stellar evolution, and the measurement of the diameter of α Orionis.

Mathematics.

Nouveau traité de mathématiques générales. Par Prof. Eugène Fabry. Tome 2. Analyse: Intégrales, équations différentielles, dérivées partielles, courbure, séries trigonométriques; Mécanique: vecteurs, cinématique, statique, dynamique, résistance des matériaux; théorie des erreurs. Quatrième édition entièrement refondue. Pp. 276. (Paris: J. Hermann, 1925.) 40 francs.

PROF. FABRY's object in this volume is to give a working knowledge of elementary mathematical analysis, leading to some of its mechanical applications. In the first half, dealing with differentiation, integration, and differential equations, he sketches the more familiar processes of the calculus but generally omits any reference to the refinements which a pure mathematician now considers to be essential to the discussion. Thus the account of Fourier series covers six pages, in which it is shown how to evaluate the coefficients, and includes no mention of the validity of Fourier's expansion. Subject to such limitations, the section on analysis contains little that is actually wrong. In the compass of 120 pages the ground covered ranges from elementary calculus to partial differential equations and Stokes' theorem. A reader prepared to disregard the niceties of pure mathematics will often find that the brevity of Prof. Fabry's treatment adds interest to the topics discussed.

Passing to the second half of the book, the section on statics contains three pages about catenaries. Centres of gravity and moments of inertia are discussed more fully. In dynamics there are chapters dealing with the motion of a single particle and with that of a rigid body about an axis. The last two chapters are devoted to the resistance of materials and the theory of errors, and are followed by a collection of 276 formulæ.

Prof. Fabry's style is lucid throughout, and his treatment of the various subjects discussed is brief through his ignoration of mathematical subtleties, not through over-condensation. The book, now in its fourth edition, is of greater value to engineers using mathematics as a tool than to students: the latter will generally find the author's treatment to be inadequate.

W. E. H. B.

Modern Physics.

The Spectroscopy of X-rays. By Prof. Manne Siegbahn. Translated with the author's additions by Prof. George A. Lindsay. Pp. xii+287. (London: Oxford University Press, 1925.) 20*s.* net.

THIS is an excellent translation of Prof. Siegbahn's well-known book, and it will be widely appreciated. Prof. Siegbahn and his pupils have made the field of X-ray spectroscopy peculiarly their own, and no one is better qualified than the author to review the present position of the subject. The refinements in technique which he has introduced have led to a knowledge of X-ray spectra which approaches in accuracy that of optical spectra at no very recent date, and the imposing table at the end of the book giving the principal X-ray spectral lines is a revelation as to the extent of the field surveyed.

The book has been written throughout from the view-point of the experimental investigator. Discussions of the purely theoretical aspect have not been entered into, but just so much theory has been given as will illustrate the interest of the various experimental results. The matter has been most carefully and wisely chosen with this object in mind.

The subject naturally divides itself into two parts, dealing with technique and with the significance for atomic physics of X-ray spectra respectively. In the first part an account is given of the types of X-ray tube, of spectroscopic apparatus, and of sources of high-tension current. Here will be found many useful hints, tables of the properties of materials, and a mass of information collected and arranged. The second part describes the laws of excitation of the spectra, the *K*, *L*, *M*, and *N* series, absorption spectra, the systematic arrangement of the spectral lines and its interpretation. The last chapter gives an account of the methods, other than those of wave-length measurement, which provide a means of measuring the inner energy levels of the atom.

X-ray spectroscopy is making such rapid advances that any review of it will need constant revision. One feels very grateful to the author for having found time, in the midst of his investigations, to collect the information, and present it in an attractive and convenient form. His book is an excellent introduction to the subject and review of the present state of knowledge, and is in a form which will make it possible to bring it up-to-date in future editions. Prof. G. H. Lindsay has worked in the author's laboratory, and his translation does full justice to the simple and readable style of the original book.

A Treatise on Electricity. By F. B. Pidduck. Second edition. Pp. xiv+664. (Cambridge: At the University Press, 1925.) 21*s.* net.

THE first edition of Mr. Pidduck's valuable treatise on electricity appeared in 1916, and the important advances made in the science during the past ten years have necessitated some changes in the present edition. In the earlier part of the book the most important alteration is to be found in the mathematical introduction, the vectorial methods and notation now employed resulting in considerable improvement in the subsequent mathematical analysis. The author, however, is on his guard against abandoning Cartesian analysis for a complete symbolic calculus, and his treatment should appeal to the physicist.

In the later chapters modern work has been described in considerable detail, though the treatment of recent theories of magnetism is somewhat slight. The chapter on electric oscillations is of great interest, and we find here scientific accounts of the triode as generator, detector, and amplifier, and also a description of its use for the production of short waves having a wave-length of only 30 or 40 cm. In the chapter on electricity in gases we have an account of the nuclear theory of the atom, and the results of Aston on the composite nature of the chemical elements obtained by means of his mass spectrograph. A separate chapter has been assigned to Röntgen rays, in which is given a compact but readable summary of the diffraction of the rays by crystals and of the nature and origin of the X-ray spectra of the elements. The last chapter deals with the electrical theory of matter, including Bohr's theory of the origin of spectra, the experiments of Gerlach and Stern showing definite orientation of electron orbits in a magnetic field, and the theories of the Zeeman and the Stark effect. In its revised form this treatise should prove of great assistance to the student of advanced physics.

The Dynamical Theory of Sound. By Dr. Horace Lamb. Second edition. Pp. viii + 307. (London: Edward Arnold and Co., 1925.) 18*s.* net.

The lucidity which characterises all Prof. Lamb's writings is exemplified in a marked degree in his treatise on the dynamical theory of sound. In this respect he follows in the footsteps of his master, Lord Rayleigh, to whom he acknowledges his indebtedness. For the second edition a thorough revision has been carried out, and a number of errors have been corrected. In its new form, the book should be of the greatest value to a student beginning the serious study of the subject. It is, however, to be regretted that the accounts given of recent applications are somewhat slight. Many readers would have welcomed more detailed descriptions of the hot-wire microphone, the methods employed in sound-ranging, and the problems of physiological acoustics.

Colloid Chemistry.

The Effects of Ions in Colloidal Systems. By Prof. Leonor Michaelis. Pp. 108. (Baltimore, Md.: Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1925.) 12*s.* 6*d.* net.

The author of this volume, who is a professor of biochemistry in Japan, was invited to lecture in the United States during April and May 1924. The material of these lectures is now presented as a brief monograph. In the introductory lecture, a defence is made of the pursuit by a biochemist of a line of research in pure physical chemistry. Such a defence is scarcely necessary, since it is a well-known phenomenon that a biologist with a genius for work in physical science, having a different range of interests and of relevant data from the professional physicist or chemist, can often make a contribution of exceptional value to the progress of pure science.

In the present instance the subject selected has been "The Effects of Ions in Colloidal Systems," and in a series of eight short lectures the author has presented in a most effective manner some of the principal problems that are encountered in this field of work, although he does not find himself able, in every case, to offer a complete solution. His chief interest appears to consist in the detection and study of "electric double layers," but one of the most interesting lectures deals with the properties of charcoal as an absorbent. This familiar material, instead of being a typical absorbent, as is generally supposed, appears to be unique amongst inanimate systems, since "experience has shown that *any* substance dissolved in an excess of water is adsorbed by charcoal," which "possesses a prominent faculty for adsorbing . . . non-ionised electro-indifferent substances."

The author introduces the term "acidoid" to describe substances such as mastic which have the properties of insoluble acids, whilst insoluble amino-acids are described as "ampholytoids." Fortunately, he has not yet begun to describe silver iodide as an "electrolytoid" in order to emphasise the fact that it is almost insoluble in water, but this will doubtless follow in due course.

English readers will be interested in the book, but will regard its price as excessive.

Introduction à l'étude des colloïdes : état colloïdal et ses applications. Par Prof. W. Kopaczewski. Pp. vii + 226 + 2 planches. (Paris: Gauthier-Villars et Cie, 1925.) 16 francs.

The first 64 pages of this small work profess to give the principal facts about the colloidal state, "all hypotheses and theories . . . being passed over in silence," while the remainder is divided into two parts, dealing with its industrial applications and with the colloidal state and life. This ratio of space, which is to be found in some other recent publications and appears to be becoming specific to the subject, seems a little difficult to justify; if it is granted, the author may be said to have done his work well. Although the industrial applications cover an immense field—cellulose and its esters, artificial silk, glue and gelatin, soil, beer, are among the sub-headings—he succeeds remarkably well, on the whole, in showing how the progress of colloid chemistry has thrown light on empirical procedure, or has led directly to the invention of new processes.

In the part devoted to the phenomena of life, inordinate space is given to the work of Leduc, which, fascinating as some of the experimental results are, can scarcely be considered seriously as throwing light on what goes on in organisms. The author is a medical man, and this explains the somewhat extended treatment of subjects for which the general reader is not prepared, like anaphylactic shock; whether a book of the present kind is the place for a somewhat surprising and emphatic condemnation of blood transfusion may also seem doubtful.

The book will no doubt give a number of readers the impression that 'there is something' in colloid chemistry, and may induce a few of them to seek something more than a mere bowing acquaintance with the discipline.

Chemical Analysis.

The Theory of Quantitative Analysis and its Practical Application. By Dr. Henry Bassett. (Twentieth-Century Chemistry Series.) Pp. viii + 308. (London: G. Routledge and Sons, Ltd., 1925.) 15*s.* net.

DR. BASSETT has produced a most interesting and valuable book. It is not a treatise on analysis; it is rather an exposition of modern ideas in physical chemistry, copiously illustrated by reference to detailed accounts of good analytical methods. For example, the chapter on the solubility product treats of various silver-halogen titration methods, and the determination of barium as sulphate. In connexion with co-ordination and complex ions, one finds a number of nickel-cobalt separations and the ammonium phosphomolybdate precipitation. Colloids, amphoteric compounds, electro-affinity, the composition of aqueous ammonia—such are a few of the other chapter headings.

The work is useful to the student and to the analyst alike. A careful perusal should help materially towards a knowledge of modern concepts of physical chemistry, while the criticism from a new point of view reveals the strength or weakness of the many analytical methods dealt with. A search for new methods should be assisted by an application of the principles set forth in the book, since in this way it may often be recognised at the outset that a suggested course of action is unsound and therefore not worth investigation.

The book is well produced, and very few typographical errors have been noticed. T. W. H.

Miscellaneous.

1825–1925: a Century of Stupendous Progress. By Joseph McCabe. Pp. viii + 168. (London: Watts and Co., 1925.) 5*s.* net.

MR. MCCABE presents in this very intriguing book a thesis involving two points: (*a*) "that there has been in the last one hundred years more progress in every respect than had ever been witnessed in five hundred years before, and (*b*) that this progress is due almost entirely to science." The author makes out a very strong case. Mr. McCabe is apparently moved to a defence of modern progress partly by the contributions of Bertrand Russell and Schiller in the "To-day and To-morrow" series issued by Messrs. Kegan Paul, Trench, Trubner and Co., Ltd., and partly by the persistence with which certain writers decry modern tendencies and belittle our times. Against such men the author expresses himself very vigorously. But after all this sort of cry has been common to all ages and civilisations.

However, whatever may be the promptings, Mr. McCabe has presented a very effective picture of life in 1825 at all angles in contrast with the conditions of to-day, and in the latter portion of his work he shows very forcibly the part science has played in this social and economic evolution. It may be argued that civilisation reached heights in the past in every way comparable with those of to-day, but there is much in the author's contention that a culture which did not reach or touch the common people cannot be counted as a general influence. It is from this point of view that Mr. McCabe's case derives its main strength: "From the world of the Middle Ages no reform could be expected. The five per cent. of Europe who could read and think were precisely those who profited most by the existing order of things; the ninety-five per cent., the mass of the workers, lived at so low an intellectual level that they hardly ever dreamed of changes." We feel confident that this stimulating book will find a ready public. L. B. H.

Meteorological Office: Air Ministry. British Rainfall, 1924. The Sixty-fourth Annual Volume of the British Rainfall Organisation. (M.O. 275.) Pp. xv + 266. (London: H.M. Stationery Office, 1925.) 15*s.* net.

THIS work maintains the same high order which has characterised its predecessors, although the superintendency of the British Rainfall Organisation has again changed hands, Mr. R. Corless now being responsible. In addition to the general table giving the rainfall of the individual observers at nearly 5000 stations, many details of considerable interest are given. Maps and tables show the distribution of rainfall in each month and for the year, and its relation to the average. Discussions are given of heavy falls in short periods and of the number of days with rain, as well as of spells of dry and wet weather during the year. Records are given of evaporation and percolation through the soil.

For the British Isles generally, 1924 was the wettest year since 1903, and at many stations it was the wettest year on record. For the whole area the rainfall was 17 per cent. in excess of the normal; in 1903 the excess was 27 per cent. A local downpour of 9·4 inches occurred on August 18 at Cannington, Somerset, of which at least 8 inches fell in 5 hours; this unprecedented rainfall is discussed at length in a special article by Dr. Glasspoole. Details are also given of the widespread deluge in the great thunderstorm of May 31, floods being general in western and northern districts.

In each month from April to October the rainfall was above the average, which is the longest sequence of wet months since before 1881.

Statistics are given showing the relative dryness or wetness of each month or year in the series 1881 to 1924 for England and Wales, Scotland and Ireland separately, and for the British Isles as a whole.

C. H.

Chambers's Encyclopædia: a Dictionary of Universal Knowledge. New edition. Edited by Dr. David Patrick and William Geddie. Vol. 7: Manchester to Pennywort. Pp. iv + 855. (London and Edinburgh: W. and R. Chambers, Ltd.; Philadelphia: J. B. Lippincott Co., 1926.) 20*s.* net.

SEVEN out of ten volumes of this useful encyclopædia have now appeared. The present volume bears evidence of revision and correction up to last year, and some of the articles have been completely rewritten since the earlier editions. It is no mean feat to compress such subjects as mining into seven pages, music into five, or Norway into less than six, but it appears to be done successfully in this work without sacrificing essentials and yet keeping the articles in a readable form. There are several new coloured maps.

Printed in Great Britain by R. & R. Clark, Limited, Edinburgh.

Supplement to NATURE.

No. 2948 MAY 1, 1926

The Source of Stellar Energy.[1]

By Prof. A. S. EDDINGTON, F.R.S.

IT is generally agreed that the gravitational energy released by contraction is quite insufficient to provide the heat squandered by the stars in radiation. The Helmholtz-Kelvin hypothesis of contraction leads to an age of the sun, and therefore of the solar system, which is much too low. Revision of Kelvin's calculation in the light of modern results does not materially alter his figures; the present position is that the contraction theory gives an age of the sun 46 million years, or 19 million years if we measure from the time when its photospheric temperature reached 3000°. Moreover, these figures are rather too high, because they make no allowance for energy retained in the sun as energy of ionisation, which substantially reduces the amount left available for radiation.

Physical and geological evidence seems to be conclusive that the age of the earth—reckoned from a period which by no means goes back to its beginnings as a planet—is much greater. The age of the older rocks found from their uranium-lead ratio is generally put at 1200 million years; lower estimates have been urged by Prof. Joly, but none low enough to save the contraction hypothesis. An extension of the Kelvin time-scale is also demanded by the evolution of the earth-moon system. On the astronomical side there is the evidence of the Cepheid variables; if δ Cephei has no supply of energy other than contraction, we can calculate the rate at which its density must be increasing and the consequent change of period of its pulsations. This turns out to be much greater than the observations will admit, and it is found that at least in the Cepheid stage, evolution is proceeding at not more than one-hundredth of the rate given by the contraction hypothesis. This argument, although primarily referring to the pulsatory theory, should apply also to rival theories which admit that the light-period is intrinsic in the star whether it is a period of vibration or rotation.

We seem to require a time-scale which will allow at least 10^{10} years for the age of the sun; certainly we cannot abate our demands below 10^9 years. It is necessary to look for a more prolific source of energy to maintain the heat of the sun and stars through this extended period. We can at once narrow down the field of search. *No source is of any avail unless it liberates heat in the deep interior of a star.* The crux of the problem is not merely the provision for surface radiation, but the maintenance of the star's internal heat which keeps the gravitating mass from collapsing. To keep the sun in its present condition of distension it is necessary to maintain within it a temperature-gradient climbing from 6000° at the surface to 40,000,000° at the centre; if the present gradient is not kept up the sun will contract and evolve prematurely. Clearly you cannot maintain a temperature-gradient by supplying heat at the bottom end. If this year the sun encountered a swarm of meteors which bombarded it with enough energy to furnish a year's supply of radiation, that would not add a year or even a day to the life of the sun; its internal readjustments would go on unaffected. All that would happen would be that the sun would give us twice the normal amount of radiation this year.

Since we cannot very well imagine an *extraneous* source of heat able to release itself at the centre of the star, the idea of a star picking up its energy as it goes along seems to be definitely ruled out. It follows that the star contains hidden within it the energy which has to last the rest of its life. But energy cannot be successfully hidden; it betrays itself because it has (or because it is) mass. Energy of 9×10^{20} ergs has a mass 1 gm., and this will count as part of the mass of the star determined by astronomical methods. Energy of $1{\cdot}8 \times 10^{54}$ ergs has a mass 2×10^{33} gm., which is the mass of the sun; consequently that is the sum total of the energy that the sun contains. How much of this is capable of being converted into radiation we do not know; but if it is all available, there is enough to maintain the sun's radiation at the present rate for 15 billion years. To put the argument in another form, the heat emitted by the sun each year has a mass of 120 billion tons; and if this loss of mass continued, there would be no mass left at the end of 15 billion years.

SUBATOMIC ENERGY.

This store of energy is, with insignificant exception, energy of constitution of the atoms and electrons; that is to say, subatomic energy. Granting that the Kelvin time-scale is inadequate, granting that our argument against extraneous sources of energy is valid, granting that the accepted view of the conservation of mass and energy is not erroneous, the source must be subatomic energy, for everything else has been eliminated. Most of the store is energy inherent in the constitution of the electrons and protons and cannot be set free unless they are annihilated. We have to suppose that a proton and electron run together, their electric charges cancel, and nothing is left but a splash in the ether which spreads out as an electromagnetic wave carrying off the energy. The possibility of this occurrence has long been a favourite speculation; for my own part, I first encountered it in Larmor's "Aether and Matter" (1900), where a vivid picture is drawn of the creation of a proton and electron by cutting the ether round a tube and giving it a permanent twist, and it is discreetly hinted that the tube might one day slip back. Whilst this is one alternative, a small—but perhaps sufficient—part of the store can be released by a less drastic process, namely, the transmutation of the elements. When a helium atom is formed out of protons and electrons, 0·8 per cent. of the mass, and therefore 0·8 per cent. of the energy, disappears. If this evolution of the elements is occurring in the stars, the energy so released might be the source we are looking for.

---

[1] Last of a course of three lectures delivered at King's College (University of London) on March 5.

The conclusion that an appreciable part of the energy of protons and electrons can be released without destroying them is due to Dr. Aston's researches with the mass-spectrograph in 1920. He proved that the deviations of the chemical atomic weights from whole numbers was generally due to the elements being mixtures of isotopes, and that the weights of individual atoms approximate very closely to whole numbers in terms of $O=16$; but for the hydrogen atom the small but significant deviation was confirmed, the weight being 1·008 and not exactly 1. This shows that the proton when isolated as in hydrogen has mass 1·008, but when brought into close contiguity with electrons in the nuclei of helium or higher elements, it has a combining mass 1·000. The difference no doubt represents the ordinary decrease of electrostatic energy when positive and negative charges are brought near together; and by the usual electromagnetic laws the disappearing energy (and mass) is carried away as radiation. If then helium is being formed in the stars, a supply of radiant energy is being released possibly sufficient to maintain their heat; and although mass is being radiated away, the total number of protons and electrons remains undiminished. This hypothesis was rather favourably considered by Prof. J. Perrin and the writer in 1920, but subsequent consideration has at any rate not strengthened its probability.

The further steps of evolution of higher elements release much less energy proportionately, so that not more than about 1 per cent. of the total store can be released, and that only if the material consists initially of hydrogen. In most of the work on the radiative theory it has been unnecessary to assume any particular chemical constitution of the star, except for the one proviso that there is not an excessive proportion of hydrogen; hydrogen gives widely different results from all the other elements, so that, curiously enough, the isolated scrap of information which we possess as to the chemical composition of the stellar interior bears upon this important question. I do not think we can admit more than 10 per cent. of hydrogen even in the youngest stars; it would thus appear that the evolution of the elements is far advanced in the pre-stellar nebular stage. In that case not more than one-thousandth of the total subatomic energy is releasable by transmutation; and the life of the sun past and future is brought down to $1{\cdot}5 \times 10^{10}$ years—a period perhaps not inadequate, but leaving little to spare. If we want more than this we must accept the hypothesis of annihilation of protons and electrons. The question now being put to the stars is, which of the two alternatives—transmutation or annihilation of matter—is providing the main supply of stellar energy?

Until recently the problem of the source of stellar energy was only of importance in connexion with the time-scale, and there was no pressing need for a decision between scales of 10^{10} and 10^{13} years. In 1916, when I began the studies described in the two preceding lectures, a more intimate contact with the problem seemed imminent, since some assumption must be made as to the relative distribution of the source in different parts of the interior. This distribution could be calculated definitely according to the Kelvin theory; but that theory was already obsolescent and there was no interest in working out the problem on such a basis. Progress became possible when it was realised that, within reasonable limits, the distribution of the source had only a minor influence on the results, and the question could be relegated to the stage of second approximation which we were not yet ready to undertake. It was early in 1924 that the problem was raised acutely by the conclusion that the dwarf stars are still in the condition of a perfect gas, contrary to the then accepted theory of evolution. It became clear that any new theory of evolution must be closely bound up with the laws of subatomic energy.

THE PROBLEM OF EVOLUTION.

It is well known that there is a certain statistical locus—a curve on the magnitude-type diagram—towards which the stars tend to concentrate. It was a merit of the giant and dwarf theory of evolution that it indicated this locus as the track of evolution of an average star. Any arbitrary change in the rate of liberation of subatomic energy would cause the star to move to some other position on the track, and the laws of subatomic energy were therefore only concerned in determining the *rate of progress*, *i.e.* the time-scale. They did not determine the track. The new conclusion makes this explanation of the statistical locus untenable. An arbitrary change in the liberation of subatomic energy will make the dwarf stars move off the track; we have therefore to exclude such arbitrary changes; that is to say, we have to consider the laws governing the liberation of subatomic energy if we are to understand the statistical locus.

In particular, the close dependence which we have found between luminosity and mass excludes any evolution of faint stars from bright stars unless we can admit that the mass decreases considerably during the star's lifetime. Not only in the giant and dwarf theory, but also in the theory which preceded it, evolution from the bright stars of types B and A to the faint stars of type M along the dwarf series has been a fundamental assumption. To avoid a complete upheaval of these ideas, we must admit substantial decrease of mass, and therefore the annihilation of matter. From this point of view—the aspect which concerns astronomers most practically—the hypothesis of annihilation of matter is really the most conservative; that does not necessarily make it true, but it justifies us in discussing it very seriously.

It is possible that a star might change mass in other ways than by radiation, but these other changes are probably much smaller. With fair certainty we can set an upper limit to the amount of accretion by the stars from diffuse matter in space; this turns out to be much less than the loss by radiation. The escape of matter from the stars must also be much smaller. I calculate that the sun's chromosphere would have to move outwards continuously at 100 km. per sec. in order to carry away as much mass from the sun as escapes by radiation. Needless to say, such a material outflow would be detected by the Doppler effect. I think, therefore, that the rate of loss of mass by a star can be set equal to its radiation so that it is a known quantity (independent of our views of subatomic energy), and the only question is whether the lifetime is sufficient for this loss to be a determining factor in stellar evolution. If the lifetime continues until the loss exceeds 1 per cent., the protons and electrons must be disappearing.

I suppose that most physicists will regard the subject of subatomic energy as a field of airy speculation. That is not the way in which it presents itself to an astronomer. Once it is granted that a star is evolving much more slowly than on the contraction hypothesis, so that its outflow of energy is practically the amount liberated within it, the measurement of the output of subatomic energy is one of the commonest astronomical measurements—the measurement of the heat and light of a star. Naturally the astronomer is not content to go on with these measurements indefinitely without an attempt to arrange them in some sort of coherence, to find out how they correspond with the internal temperature and density or the age of the material. If the physicist had in his laboratory unknown sources of energy, the output of which he could measure and the physical conditions of which he could determine, he would not be so backward in speculating on the causes and laws of the phenomena. The astronomical study of subatomic energy is no whit less direct than this; and although our attempts to weave the observational results into order are as yet unsuccessful, the problem is no more speculative than any other induction from experiment.

EXHAUSTIBILITY OF THE SOURCE.

Let us now examine some of the difficulties in the observational data. Consider the following:

The sun liberates 2 *ergs per gm. per sec. against* 58 *ergs per gm. per sec. by Capella.*

The sun has 620 *times the density and* 3·7 *times the internal temperature of Capella.*

Surely if density and temperature have any effect at all on the liberation of subatomic energy they must stimulate it. Density in particular brings the ingredients for any process closer together. Yet the sun, with higher temperature and density, liberates less than Capella. I think the only answer is that the sun is getting worn out; that it has, in fact, moved on to the higher density and temperature in order to stimulate a failing supply. It is admittedly an older star. We have thus an important factor forced on us, namely, exhaustibility of the supply.

Now consider the two components of Capella: a single star divided into two parts, and in accordance with the mass-luminosity law the heavier component radiates and has radiated more ergs per gm. than the light component. Consequently it has used up more of its supply. Yet the more massive star, more exhausted, at lower density, and at lower temperature, still liberates more ergs per gm. than its companion.

It may be urged that if the fission occurred within the last 100,000 years the components have not yet reached the steady state; in that case it would not be fair to equate the release of subatomic energy to the observed radiation. But the case of Capella is typical of the spectroscopic binaries in general,[1] and these are so numerous that they cannot all be of so recent a date. In most *eclipsing variables*, however, the faint component is the cooler, and its lower output of energy would thus be explicable. These are stars in which the two components are very close together—sometimes almost touching—and their formation is probably recent. *It is just those stars in which (owing to recent formation) exceptional behaviour would be pardonable which require no excuse.*

---

[1] Except that in the dwarf binaries there is no appreciable difference in the internal temperatures of the two components.

Jeans suggests that when fission occurred the heavier component would appropriate the central portion of the original star, where the heaviest elements containing the more active sources might be concentrated. To this there are two objections. First, so far as we can calculate, diffusion is unable to effect any appreciable separation of the light and heavy elements in the lifetime of a giant star. Secondly, the rotation of the star causes circulating currents which keep the material sufficiently stirred. This last conclusion rests on a theorem of Von Zeipel criticised by Jeans; but I am convinced that Von Zeipel is right. It is, therefore probable that when a star divides, the initial constitution of the two components is identical.

With regard to the latter point, some doubt may exist as to the efficiency of the stirring, owing to the likelihood that the circulation will become stratified. I understand that in a viscous liquid the vorticity has a tendency to break up into layers, so that the star might be divided into two or three shells with thorough mixing in each shell and not much mixing between successive shells. But even so I do not think that the general mixing would cease altogether. The diffusion which it has to counteract is exceedingly slow, and it would take at least 10^{13} years for the heaviest and lightest elements to separate. The age of Capella when it divided could not be much more than 10^{11} years. Moreover, although the heavy elements would tend to sink to the centre in small stars, the tendency in massive stars like Capella appears to be opposite. According to physical theory, the heaviest atoms have the highest absorption coefficients and experience the greatest radiation pressure. The interaction of the gravitational and electrical fields with radiation pressure leads to curious results; so that in Capella the heaviest elements together with hydrogen and helium would flow towards the surface, the other light elements tending towards the centre.

The Main Series.

Turn now to stars on the 'Main Series' which stretches from types O and B down the old dwarf series to type M. By far the majority of the stars are on this series, so that presumably it corresponds to the major part of a star's life. The giant stage appears to be a temporary halt during which a very active, but soon exhausted, supply of energy is being tapped; the star then goes on to the Main Series, where it remains until its chief supply is exhausted. At this stage, if at all, the energy is being derived from annihilation of protons and electrons, for the star cannot move along the Main Series unless it undergoes substantial loss of mass. We might expect the stars to continue in this stage until the end, since it is difficult to see why the protons and electrons should ever grow tired of destroying one another; apparently, however, some more refractory material is present (or is evolved) in the star, so that in some stars at least a residuum remains unburnt, which passes on to the fiercer ordeal of the 'White Dwarf' stage.

In the Main Series we find a simplicity in the laws of subatomic energy which is perhaps more embarrassing than the previous complications. As H. N. Russell has pointed out, all the stars in this stage have practically the same internal temperature. I find the central temperature on the Main Series to be 40 million degrees; Russell puts the figure rather lower.

The close uniformity of internal temperature is beautifully shown in a diagram for a considerable number of individual stars published by Russell (NATURE, August 8, 1925, vol. 116, p. 209). The following treatment may be considered supplementary to his. It is difficult to allow for the errors of observational data of individual stars and to know just how much stress should be laid on particular discordances. We propose therefore the converse problem:—Assuming a constant central temperature of 40,000,000° along the Main Series, we find the consequent relation between luminosity and spectral type and compare it with the relation indicated by the general stellar statistics.

RESULTS FOR ASSUMED CENTRAL TEMPERATURE 4×10^7.

Mass.	Bol. Mag.	Vis. Mag.	Eff. Temp.	Type.
0·182	11·94	14·5	2,550°	<Md
0·258	10·25	11·6	3,210	K9
0·512	7·26	7·6	4,540	K0
0·746	5·93	6·1	5,160	G4
1·00	4·47	4·5	6,290	F8
1·58	2·43	2·5	8,250	A8
2·56	0·52	0·9	10,520	A0
4·53	−1·38	−0·6	13,260	B7
11·46	−3·86	−2·4	17,460	B2
37·67	−6·44	−4·3	22,500	Oe
90·63	−8·12	−6	26,200	O

From the mass in the first column and the assumed central temperature we can deduce the bolometric magnitude and effective temperature by the radiative theory.[1] The reduction to visual magnitude is taken to correspond to the effective temperature. In the last column spectral types are assigned corresponding to the effective temperatures according to what I suppose to be the most generally accepted scale. Taking columns 3 and 5 of the above table, we obtain a magnitude-type relation which follows with great accuracy the central line of the Main Series as indicated by observational statistics. Without laying undue stress on the closeness of the accordance, we must conclude that the temperature in this phase of evolution is surprisingly steady.

---

[1] In the first three lines of the table a small correction has been applied to the predicted bolometric magnitudes in order to bring them closer to the empirical mass-luminosity curve. (This correction is derived from data independent of the present type-luminosity comparison.)

Whether the star requires a supply of 680 ergs/gm. sec. like V Puppis, 2 ergs/gm. sec. like the sun, or 0·08 ergs/gm. sec. like Krueger 60, it has to rise to a temperature of about 40,000,000° to obtain it. Apparently at that critical temperature the supply is *ad libitum*. Can we suppose that energy issues freely from matter at 40,000,000° as steam issues from water at 100°? I think that physicists would be hard put to it to reconcile such extraordinary behaviour with any accepted principles, yet that is what the astronomical observations taken at face value seem to insist on.

OVERSTABILITY.

Here we encounter another difficulty depending on 'overstability.' Imagine a vertical cylinder with a piston, the chamber containing hot gas. To increase the resemblance to a star we must suppose that heat is continually being admitted into the chamber and an equal amount leaks away through the walls. The piston will rest in stable equilibrium on its cushion of hot gas, and if slightly displaced will return to its equilibrium position after small oscillations. But suppose that the piston operates a valve which admits extra heat to the chamber when the piston is lowered and shuts off the heat supply when the piston is raised. Then (allowing for the leakage) the chamber gains heat at the time of compression and loses heat at the time of rarefaction—just like the cylinder of any heat engine—consequently a slight displacement of the piston will set the engine working and the piston will move up and down with increasing amplitude. I call this 'steam-engine' condition *overstability*: it is not instability (a tendency to move away from equilibrium), but a tendency to return towards equilibrium with too much impetus so that oscillations increase instead of dying out. Now it will be seen that if there is a critical temperature, the oscillations of a star work a valve just in this way: If the star is compressed it becomes hotter; a larger region is raised above the critical temperature and more subatomic energy is released. If it expands, the centre falls below the critical temperature and the heat supply stops. Consequently the star begins performing like a steam-engine. If the power of the engine is only slight, it may be unable to overcome dissipative forces and the star will remain stable; but at least in the faint stars, which normally keep only a small region at the centre above the critical temperature, overstability will result. We know of some stars—the Cepheid Variables—which, whether from this cause or some other, are overstable and consequently pulsate, but they are uncommon, and they are all giant stars or stars at the head of the Main Series; they are, in fact, just the wrong stars to suit the theory.

I have referred to this difficulty of overstability primarily as an argument against too readily accepting the idea of a critical temperature at 40,000,000°, but it is also a general difficulty. The channel between the Scylla of instability and the Charybdis of overstability turns out to be so narrow that it is difficult to devise any law of subatomic energy which will steer the star safely through it. Tentatively I am inclined to cut the knot by introducing yet another complication. I suppose that a change of temperature or density does not immediately change the rate of liberation of energy; there is a time lag of months or perhaps hundreds of years, so that short-period changes have no effect. This would happen if temperature and density controlled the rate of formation of self-destroying material which afterwards proceeded to liberate its energy spontaneously at a rate unaffected by temperature and density.[4]

It will be seen that we have already encountered a number of difficulties. I daresay that we can wriggle out of these somehow, but that kind of procedure is not very convincing. I think that a successful theory ought occasionally to predict right results at the first attempt and not invariably to guess wrong, afterwards making amends by introducing a new complication. It looks as though we have not yet the right clue in our hands for a general synthesis of the problem of subatomic energy, and we are not prepared to advocate one theory in preference to another. We shall, however, continue here to glean what facts we can from the astronomical observations.

DEPENDENCE ON TEMPERATURE AND DENSITY.

By considering the stability of a star we can show that the rate of liberation of energy increases with temperature or density or with both. Let the rate of liberation of subatomic energy be E and the rate of radiation from the star be L. In a steady state $E = L$. Now suppose that E drops below L; the star contracts (as on the Kelvin hypothesis which postulates $E=0$). But it is generally agreed that L increases as the radius decreases, so that the deficit is made worse. Further contraction ensues, with further increase of L, and the star gradually collapses. To save the star we must suppose that the increase of temperature and density by the contraction causes an increase of E, so that E becomes greater than L and drives the star back to equilibrium. The threatened instability is not catastrophic, and the collapse would occupy a time comparable with the Kelvin time-scale; but of course we must provide against such a collapse since we reject the Kelvin time-scale.

---

[4] If the annihilation of matter were due to free electrons shooting at the protons in the nucleus and destroying them by direct hits, the rate would be proportional to $\rho T^{-\frac{1}{2}}$ (subject to a dependence on the chemical composition if the protons in some nuclei are better protected than in others). As this law seems to have no support from observation, we conclude that it is not the free electrons but the bound or the nuclear electrons which perform the task. Hence arises the idea of formation of elements with a *penchant* for self-destruction.

In Jeans's theories the release of subatomic energy is supposed to be independent of the temperature and density (by analogy with ordinary radioactivity). This view is also taken by Nernst. I have felt constrained to reject it from the beginnings of the researches on radiative equilibrium, since it leaves no means by which E and L for the different stars can be brought to a balance. Prodigious changes of density are required to alter L by a factor of more than 3 or 4, and as stated in the last paragraph, the adjustment of L is most probably in the wrong direction. It seems essential that the adjustment should come about by changing E. It is true that theoretical physics opposes difficulties to the idea that stellar temperatures can appreciably affect subatomic processes; but they are difficulties which obviously must be surmounted. It has, for example, been objected that the temperature in the stars is not great enough for the transmutation of hydrogen into helium—so ruling out one possible source of energy. But helium exists, and it is not much use for the critic to urge that the stars are not hot enough for its formation unless he is prepared to show us a *hotter place*.

The assumption that E is independent of temperature and density gives a cast-iron rule into which there seems no hope of fitting the astronomical data. It requires that the energy per gram liberated and radiated by any star depends only on the age. What zero the age is to be reckoned from is not clear. In any case, study of coeval groups of stars such as the Pleiades, Hyades, Præsepe, etc., does not confirm this hypothesis.

EVIDENCE OF DECREASE OF MASS.

We now consider more particularly the theory that the mass of a star changes considerably during its evolution. As already explained, this requires the more drastic hypothesis of annihilation of electrons and protons, transmutation of the elements being unable to provide sufficient energy for the longer time-scale involved. There can be no evolution down the Main Series unless this change of mass is admitted; the star would presumably evolve rapidly until it reached the Main Series, remain unchanged for the greater part of its life, and then go on to the white dwarf stage. That means that evolution would cease to play a prominent part in astrophysics. The fact that the stars leaving the Main Series (white dwarfs) are generally of smaller mass than the stars approaching it (giants) is an argument in favour of considerable change of mass in this stage.

The statistics of giant stars also support this view. Assuming that the most diffuse condition is the earliest, the average mass of a star at or near birth can be found from the statistics of giant K and M stars. Determining the masses from the luminosities, we find that 90 per cent. of these young stars have masses between 2·4 and 5·5 × sun; whereas the average for the stars in general is less than that of the sun. This strongly suggests that most stars have lost a large part of their original mass. The result fits in well with the conclusion reached in the first lecture that the masses of the stars correspond to the critical range where radiation-pressure is gaining ascendancy. Taking the average of all the stars, say ½ to 1 × sun, radiation-pressure is between 0·007 and 0·05 of the whole pressure—clearly too low a value. But we ought rather to take the initial masses before there was any wastage; the masses 2·4–5·5 × sun give the proportion of radiation-pressure 0·17–0·35, which is just the range likely to be effective.

For this reason I conclude that stars are not usually born with mass less than 2 × sun. It might be argued that we do not observe diffuse stars of smaller mass because they condense very rapidly. But why? They are not exhausting their store of energy so fast, and ought to evolve more slowly.

COEVAL STARS IN CLUSTERS.

There is, however, an argument perhaps equally strong on the other side which we shall now try to explain. We first draw up a table showing the time taken for a star to evolve through a given range of mass or of luminosity. This can be done because $dM/dt = -L/c^2$, the mass of the outflowing radiation L ergs being L/c^2 gm. Since L can be expressed as a function of M by the mass-luminosity law, the equation can be integrated[5] to give M as a function of t

Mass (Sun = 1)	Abs. Bolometric Mag	Duration of Stage.
∞ to 35	< −5	·038 × 10^{11} years
35 „ 10	−5 to −2½	·065
10 „ 3·7	−2½ „ 0	214
3·7 „ 1·73	0 „ 2½	·93
1·73 „ 0·92	2½ „ 5	5·21
0·92 „ 0·53	5 „ 7½	36·3
0·53 „ 0·31	7½ „ 10	·281
0·31 „ 0·18	10 „ 12½	2190

---

[5] *Monthly Notices, Roy. Astr. Soc.*, 84, p. 308.

The table applies primarily to the Main Series on which the internal temperature remains constant, but can also be used with sufficient approximation for the giant stars. We see that, however large the initial mass, there cannot be more than mass 2 left at the end of a billion years. Consequently, if a cluster contains stars of mass greater than 2, that is, brighter than about $+2^m$, the cluster cannot be more than a billion years old. But looking lower down the table we see that a billion years is quite insignificant for the evolution of the fainter stars; so that if the cluster also contains stars of magnitude 5^m to 7^m, these must have been born with practically the same mass and luminosity which they now possess. It is found that many clusters contain bright and faint stars together, and our argument shows that in this case the faint stars cannot have evolved appreciably. If we have to deny the evolution of dwarf stars in clusters, is there any point in assuming evolution of dwarf stars in general? In any case it looks as though we must abrogate the idea that the stars cannot be born with masses less than 2.

Yet, although the observations of clusters appear to contradict our conclusion, we take some courage from the fact that they do so rather half-heartedly. (It is such a novel experience to find Nature taking any notice of our predictions in regard to subatomic energy, that a half-hearted denial is a cause for elation.) I learn from Hertzsprung that moving clusters such as the Hyades, Pleiades, and Præsepe certainly do not contain anything like their full quota of faint dwarfs. They stop suddenly at about $+7^m$, with few or none fainter than this limit. There appears also to be evidence that in globular clusters the dwarfs are not nearly so numerous in comparison with the giants as in the galactic system generally. Perhaps, therefore, there may be something in our argument as to the difficulty of bright and faint stars existing together in coeval systems, though we clearly have not yet got it formulated quite aright.

In the galactic system, where it is presumed that we have to do with a mixture of stars of all ages, the number of stars in any stage should be proportional to the duration of the stage. Hence the figures in the last column of the table should be proportional to the number of stars between the corresponding limits of magnitude. This prediction, however, applies only to masses below 2; the numbers corresponding to the earlier part of the table must be greatly reduced, because most stars start from masses between 2 and 5. The luminosity distribution predicted in this way is fairly well confirmed by the observational statistics.

Another test which affords some slight support for the theory of evolution by loss of mass has been applied by Vogt. It is easily seen from the table that if two stars start with widely different masses, the ratio of the masses will approach equality as time goes on. Hence in double-star systems we should expect large mass-ratios only in the early stages of evolution, and the mass-ratio should progressively approach unity for the later spectral types. This appears to be satisfactorily confirmed.

It might perhaps have been hoped that the loss of mass, through its effect on the dynamics of double-star systems, would clear up some of the problems with regard to their separations and eccentricities hitherto unexplained. This has been investigated by Jeans and Smart; but the results are disappointing, and the new theory does not bring any illumination to the outstanding problems. Nor can I glean anything particularly favourable or unfavourable to the theory from the various other discussions which have appeared.

COMPTON EFFECT.

As illustrating the close connexion between the progress of pure physics and astronomy, we may note that the discovery of the Compton effect relieved what had been a real difficulty in regard to subatomic sources of stellar energy. By the quantum theory the radiation emitted in the formation of helium from hydrogen should be of wave-length 0·00041 Å.U., and in the annihilation of a proton and electron 0·000013 Å.U. By what mechanism can this high frequency radiation be transformed down to the ordinary forms of heat energy in a star? The usual absorption coefficients fall off as the cube of the wave-length, and the second of the above quanta would probably go right through the star—and to the end of the world—without finding anything to absorb it and turn it into utilisable heat. It would be scattered fairly often, because the coefficient of scattering by electrons, although decreasing for short wave-lengths, does not fall off so rapidly; but so long as it was thought that the wave-length was unaltered by scattering, that did not help to solve the difficulty. Now the theory of the Compton effect tells us that the wave-length is increased by $0·024 (1 - \cos \theta)$ Å.U. after scattering; so that, however short the original wave-length, the first appreciable scattering reduces the radiation to ordinary γ-ray status. Most of the energy passes into a recoil electron which flies off with enormous energy; and there is then no difficulty in seeing how the energy is frittered away into ordinary molecular heat.

PENETRATING RADIATION.

The question of the origin of the penetrating radiation found in the earth's atmosphere has considerable interest in connexion with subatomic energy. An astronomical turn was given to the problem a few years ago by Kohlhörster's experiments, which claimed to show that the radiation was travelling downwards and, therefore, presumably coming from outside our atmosphere. He found also that the intensity depended on the altitude of the Milky Way, so that most radiation was received when the greatest extension of the stellar system was overhead. The altitude of the sun made no difference, showing that the sun was not the source. The penetrating power was evidently much greater than that of any known γ-rays, so that it seemed clear that the radiation could only come from some powerful subatomic source such as the transmutation of hydrogen or the annihilation of matter. Very recently Millikan has announced the results of an extensive and careful study of this radiation. He is strongly convinced that it comes from extra-terrestrial sources; and he finds that the penetrating power agrees with that of the quantum emitted in the formation of helium from hydrogen.

Being unfamiliar with the technical details and difficulties of the experiments, I cannot take sides either with Kohlhörster and Millikan or with their critics. In the earlier days it had seemed to me that the high penetrating power (which seems to be universally admitted) went far to settle the question. This indicated a concentration of energy such as could only result from drastic subatomic processes; and it was at any rate less sensational to suppose that these processes were occurring in the depths of space than to postulate them on our own planet. But I was somewhat shaken by C. T. R. Wilson's calculations as to 'runaway' electrons in thunderstorms. He showed that these could acquire sufficient energy to furnish radiation of this nature without involving subatomic processes. It would, however, be difficult to account for the downward flow of the radiation if it were originated by Wilson's electrons.

If physicists ultimately are satisfied as to the extra-terrestrial origin of the radiation, what bearing will it have on the problems studied here? The chief conclusion to be drawn from it is that the subatomic processes can occur at comparatively low temperature—less than 100,000°. All the really hot matter of the universe is securely tucked away behind walls sufficiently thick to stop and scatter the most penetrating radiation; it cannot be the source of the radiation reaching us. Our choice lies between the photospheric layers of the stars and the nebulous matter in space. The latter origin is the more probable. Unless the stars are more potent sources than the sun, the penetrating radiation from the stars will be to that from the sun roughly in the proportion of starlight to sunlight; the experiments show that no appreciable part comes from the sun, and *a fortiori* that from the stars should be negligible. The diffuse and dark nebulæ and the matter scattered through interstellar space may perhaps amount to a total mass as great as the whole mass of the stars; and, moreover, there is no screening, so that all the radiation originating from it is able to reach us.

If this is right we must draw another important conclusion—the subatomic processes can occur at extremely low density. Astronomically we welcome these conclusions. We are hard put to it to explain the occurrence of helium and other elements in the nebulæ and of rather advanced elements in the spectra of the earliest stars, unless there is a building up of the higher elements in the pre-stellar stage of low temperature and density. But the physicist may well shake his head over the problem. How are the protons and electrons to meet and cancel one another in a medium so rare that the free path lasts for years? How are 4 protons and 2 electrons to assemble together and create a helium nucleus? It is perhaps a comfort that this last occurrence is so improbable under any conditions of density and temperature that we can postulate it in the nebulæ—on the principle that we may as well be hung for a sheep as a lamb. We recall also that these conclusions are in keeping with the observational fact (so difficult to reconcile with theory) that in general it is the diffuse low-temperature stars which liberate subatomic energy most prolifically.

I should have liked to close this course by leading up to some great climax. But perhaps it is more in accordance with the conditions of scientific progress that it should fizzle out, ending with a glimpse of the obscurity which marks the frontiers of present knowledge. I do not apologise for the lameness of my conclusion, for it is not a conclusion. I wish I could feel confident that it is even a beginning.

Electrons, Atoms and Molecules.[1]

By Prof. T. M. Lowry, F.R.S.

Any one who is familiar with the state of chemistry before and after the War must recognise that, whilst chemical practice and chemical beliefs have undergone very little alteration, the foundation underlying these beliefs has been altered profoundly by recent physical discoveries. In particular, although chemists still believe in Dalton's atoms and in the molecules of Avogadro, they have been compelled to accept an entirely different picture of the structure of the atom, and to adopt a new and revolutionary conception of the nature of the forces which bind the atoms together into molecules. Whilst, therefore, chemical research still proceeds along familiar paths, and is expressed by means of familiar terms and symbols, physical research has given us a new outlook; and, since what a man does is ultimately determined by what he believes, it is certain that chemical practice as well as chemical theory must be influenced profoundly by the new ideas that have been given to us by our physical colleagues. The object of this discourse is to indicate some of the aspects of pre-War chemistry which have been transformed by the impact of post-War physics.

MOLECULAR DIMENSIONS.

The principal contribution of the physicist to our knowledge of molecules has been a numerical one. He has taught us how to count, to weigh, and to measure individual molecules, and, in the person of Sir William Bragg, he has provided us with a convenient system of units in which to express these quantities. This system is based upon Ångström's unit of length, 10^{-8} cm., which has long been used in order to express the wave-lengths of light of different colours. Bragg has, therefore, proposed[2] to measure areas and volumes in 10^{-16} sq. cm. and 10^{-24} c.c.; and although it is scarcely possible to picture the process of filling with water a vessel with a capacity of only 10^{-24} c.c., it is, nevertheless, an obvious step to make the unit of mass correspond with the unit of volume, as 10^{-24} gram.

Having got a suitable system of units, we can use them in order to express atomic and molecular dimensions. The fundamental constant in this investigation is the *Avogadro number*, which tells us the actual number of atoms in the gram-atom of any element, or of molecules in the gram-molecule of any element or compound. Unlike Loschmidt's number (which tells us how many molecules there are in 1 c.c. of a gas at normal temperature and pressure), this is a universal constant, since it is not influenced by deviations from the ideal gas laws. During the past twenty years, more than a score of attempts have been made to determine the numerical value of this constant, by the most diverse methods; but I need only quote the number finally deduced by Millikan in 1917 from a study of the movement of a rain of electrified oil-drops. This curiously indirect method has given surprisingly accurate results; indeed, it is said that the number of molecules in a gram-molecule of a pure substance is known with about the same degree of accuracy as the total population recorded in the census of a big city such as Chicago. In conformity with our scheme, Millikan's value of the Avogadro constant can be expressed most conveniently in powers of eight as $N = 0{\cdot}6062 \times 10^{24}$.

By taking the reciprocal of this number we can deduce at once that *the weight of an individual atom or molecule in Ångström units is* 1·65 *times its atomic or molecular weight*. For example, the mass of an atom of hydrogen is $1{\cdot}65 \times 1{\cdot}0075 = 1{\cdot}66$ Å.U.; and the mass of a molecule of oxygen is $1{\cdot}65 \times 32 = 52{\cdot}8$ Å.U. From these data it would be easy to calculate the linear dimensions of the molecule if we could assume that it was spherical or cubical; but, although the early experiments of Devaux supported this view, more exact measurements have proved that the dimensions of the molecule are not equal in different directions. The molecule has, in fact, a definite shape, now open to experimental investigation, which must be taken into account in calculating its dimensions. Let me indicate three physical methods used for this purpose.

(*a*) *Viscosity of Gases.*—According to the kinetic theory of gases, the viscosity of a gas is a measure of the sectional area of the molecules. This was one of the earliest methods used to calculate molecular dimensions, and (unlike the two following methods) it is independent of a knowledge of the Avogadro constant. It has been developed in recent years by Prof. Rankine, who has deduced for the *collision-areas* of various gases values such as the following:

---

[1] Compiled from lectures delivered at the Birkbeck College, London, on Jan. 25, and at Bristol on Feb. 12, 1926.

[2] *Proc. Phys. Soc.*, 1921, 34, p. 35.

TABLE I.—COLLISION-AREAS OF GASES IN ÅNGSTROM UNITS.[3]

CH_4 = 7·72 NH_3 = 6·40 OH_2 = ? HF = ? Ne = 4·17
SiH_4 = ? PH_3 = 9·11 SH_2 = 7·73 HCl = 6·76 A = 6·48
AsH_3 = 9·85 SeH_2 = ? HBr = 7·63 Kr = 7·57
SbH_3 = ? TeH_2 = ? HI = 9·26 X = 9·15

These numbers, however, do not lead directly to a knowledge of the linear dimensions of the molecules, since they merely give the average area of the molecule as viewed from every possible aspect.

(*b*) *Monomolecular Films.*—Much more detailed information is given by a study of thin films of oil on the surface of water. So long ago as 1899,[4] Lord Rayleigh explained the fact that a definite concentration of oil was required in order to diminish the surface tension of water by supposing that it was necessary to cover the water with a film of oil one molecule thick, before any effect could be produced. Since the quantity required corresponded with a film of a thickness of about 10 Å.U., he concluded that this was the approximate diameter of the molecules.

When the Avogadro number was known it was possible to compare the *thickness* of the monomolecular film with the *area* occupied by the individual molecules, and thus to get some idea of their shape. Devaux, who first made this comparison in 1904,[5] was unfortunate in that the triolein with which he worked gave a monomolecular film with a thickness of 11 Å.U., as compared with a calculated molecular diameter of 11·3 Å.U. He therefore concluded that the molecules were roughly spherical in shape, as Rayleigh had postulated; and it was left to Langmuir in 1917[6] to discover that the dimensions of the molecule are in fact widely different in different directions. Thus in Table II. the molecular area was deduced directly by dividing the total area of the film in Å.U. by the number of molecules which it contained; the width is merely the square-root of this area; but the length was calculated on the assumption that the density of the film is equal to that of the oil in bulk, and that the length of the molecule is equal to the thickness of the film.

TABLE II.—CROSS-SECTIONS AND LENGTHS OF MOLECULES.

Substance.	Formula.	Area per Molecule	Width	Length	Length per Carbon Atom.
Palmitic acid	$C_{15}H_{31}COOH$	21 Å U	4·6 Å U	24·0 Å U	1·5 Å U
Stearic acid	$C_{17}H_{35}COOH$	22	4·7	25·0	1·39
Cerotic acid	$C_{25}H_{51}COOH$	25	5·0	31·0	1·20
Tristearin	$(C_{18}H_{35}O_2)_3C_3H_5$	66	8·1	25·0	1·32
Myricyl alcohol	$C_{30}H_{61}OH$	27	5·2	41·0	1·37

To Langmuir, then, belongs the credit of discovering that, whilst the sectional area of the molecule of a saturated fatty acid or alcohol is approximately constant, corresponding with a square with a side of about 5 Å.U.,[7] the length of the chain may extend to more than 40 Å.U. As a result of these observations, Langmuir was also able to assert that the individual molecules in the film were oriented, with the acid radical immersed in the water and the hydrocarbon chain projecting outwards towards the air. The spreading of the oil into a monomolecular film could therefore be attributed to the striving of the 'hydrophilous' or thirsty 'heads' of the molecules to secure access to the water, and of the 'hydrophobic' or oily tails to escape drowning.

Most of the applications of Langmuir's conception are physical in character, as in the case of the lowering of the surface-tension of water by a film of oil. Harker, however, has recently put forward a case[8] in which the chemical properties of a compound appear to be determined by the orientation of the molecules in the surface of the liquid. Thus, he found that benzyl chloride could not be hydrolysed by dry steam, but was rapidly hydrolysed whenever there was an opportunity for liquid water to condense. This result can be explained most easily by supposing that the steam could not secure access to the active 'heads' of the molecules, since these would normally be directed towards the interior of the liquid, but that liquid water can reverse this orientation, and thus bring the chlorine into a position in which it can be attacked.

(*c*) *X-ray Analysis.*—The third method depends on investigating the distance between the mass-centres of atoms or molecules by means of X-rays. This is a reciprocal process, since our knowledge of the wave-lengths of X-rays does not yet rest on direct measurements of length, but has been deduced indirectly from the distance between the atoms of sodium and chlorine in a crystal of rock-salt, as calculated with the help of Avogadro's constant. Thus, since one gram-molecule of salt occupies 27 c.c., it is clear that the total number of atoms of sodium and chlorine in 1 c.c. of salt is $2/27 \times 0{\cdot}6062 \times 10^{24} = 0{\cdot}0452 \times 10^{24}$; but, before we can calculate the distance between the centres of these atoms, we must know how they are arranged in the crystal. A preliminary survey by means of X-rays shows that the atoms of sodium and chlorine occupy alternate points in a simple cubic lattice; we can, therefore, allot to each atom a cubic cell with a volume of $22·1 \times 10^{-24}$ c.c. (the reciprocal of the preceding number); and by taking the cube root of this number we can deduce the distance between the atoms as 2·81 Å.U. After having determined this fundamental distance, we can use a crystal of rock-salt[9] as a diffraction grating in order to determine the wave-lengths of the X-rays emitted by the elements, and we can then use these wave-lengths in order to determine the distance between the atoms or molecules in other crystals. In this way it has been shown, for example, that the distance between the carbon-atoms in a diamond is 1·52 Å U, and that the same 'atomic diameter' appears incessantly in other carbon-compounds. This diameter, indeed, is one of the most constant of the numerical properties of the element, and is the obvious basis for a modern space-chemistry of carbon compounds.

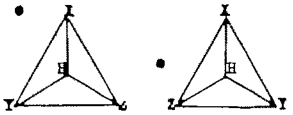
STEREOCHEMISTRY.

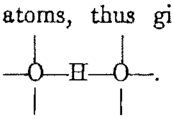
In addition to providing information as to the distance between atoms and molecules, X-ray analysis has made important contributions to our knowledge of molecular configuration or 'chemistry in space.' The first of the new chemical space-models was developed in 1874 by le Bel and Van 't Hoff, in order to account for the limited number of isomers which can be prepared of carbon compounds of various types. Thus since isomerism in derivatives of methane first appears in compounds of the type CHXYZ, these authors were led independently to postulate a *tetrahedral* configuration of the four univalent radicals around a central atom of carbon, in place of the *square* configuration of the common two-dimensional formulæ. The two opposite ways in which the four different radicals in these 'asymmetric' compounds can be arranged in space about the central atom of carbon could then be represented by alternative symbols, corresponding with the two known isomers, as follows:



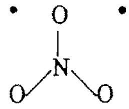
The new three-dimensional formulæ were confirmed by the experiments which led to the enunciation of von Baeyer's *Strain theory*, since it was found that a 5-atom ring with angles of 108° is more easily formed than a 4-atom ring with angles of 90°, as would be expected if the normal angle between the bonds is the characteristic tetrahedral angle, 109½°, of the solid model, instead of the right-angle of the planar formulæ.

This chemical evidence has now been confirmed by direct physical measurements. In particular, X-ray analysis has proved that the diamond is built from tetrahedrally-oriented atoms, and in such a simple manner that a child of five, if provided with a supply of rods and balls with properly adjusted sockets, could not build the model differently. A similar tetrahedral configuration of four beryllium atoms around a central atom of oxygen, and conversely of four oxygen atoms around a central atom of beryllium, has been found in basic beryllium acetate,[10] $OBe_4(O_2CMe)_6$; and the X-ray analysis of ice[11] shows four hydrogen atoms arranged in the same tetrahedral pattern about each atom of oxygen. A tetrahedral arrangement of four oxygen atoms around a central atom of sulphur has also been found in barium sulphate[12]

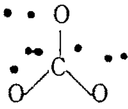
Moreover, in addition to confirming and extending the scope of Van 't Hoff's tetrahedral configuration, X-ray analysis has also indicated the existence of other configurations. Thus in ice, every atom of hydrogen is placed at the centre of a line joining two oxygen atoms, thus giving rise to a *linear* configuration,



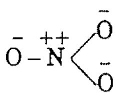
$—O—H—O—$. Again, in sodium nitrate, and in calcite and aragonite, we find a *triangular* configuration of three oxygen atoms about a central coplanar atom of nitrogen or of carbon, the three oxygen atoms being ranged symmetrically about a trigonal axis, as in the schemes



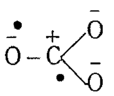
and



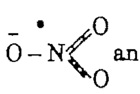
In order to preserve this trigonal symmetry, the ions in the crystal have been formulated[13] as



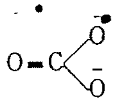
and



instead of

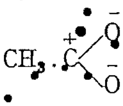


and

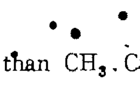


.

This planar configuration has been observed also in the acetate groups of basic beryllium acetate, where the two oxygen atoms are arranged symmetrically about a digonal axis, *e g.*, as in



rather than



Moreover, graphite, which was thought at one time to contain the same zigzag network of atoms that can be recognised in successive layers of a diamond, is now reported to contain a *flat* network of hexagons.[14] Since graphite has the structure of an aromatic hydrocarbon, and actually gives rise to mellitic acid $C_6(CO_2H)_6$ on oxidation, it is difficult to resist the conclusion that the characteristic form of the benzene ring may, after all be the traditional 2-dimensional hexagon rather than a zigzag hexagon in three dimensions.

---

[9] Our exact knowledge of the wave-length of X-rays was formerly limited in the upward direction to about 15 Å U, because no suitable crystals of larger molecular dimensions were available to provide a grating for their investigation. Thoraeus and Siegbahn (*Ark f Mat Astron och Fysik*, Stockholm, 1925, 18, 12), however, have recently measured wave-lengths up to 21 Å U by using as a grating a crystal of palmitic acid for which $2d = 71·19$ Å U

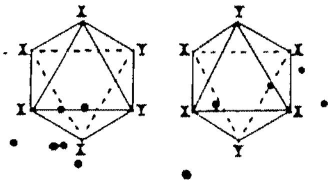
[11] Bragg, *Proc Phys Soc*, 1922, 34, 98.

[12] James and Wood, Manchester Memoirs, 1924–5, 69, No 5.

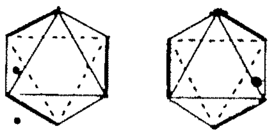
[13] *Trans Faraday Soc*, 1923, 18, 285 In these symmetrical formulæ the central atom carries only a sextet of electrons; this condition is, therefore, probably unstable except in the crystals, where the anion is surrounded symmetrically by six oppositely charged cations

CONFIGURATION OF CO-ORDINATION COMPOUNDS.

As in the case of carbon, the X-ray analysis of co-ordination compounds has proved the correctness of a configuration which had been deduced previously by purely chemical methods. Many years ago Werner concluded that the six chlorine atoms of potassium platinichloride, $K_2[PtCl_6]$, are all grouped round a central atom of platinum, instead of forming two groups, as in the formula, $2KCl, PtCl_4$. By studying the number of isomers that could be prepared of co-ordination compounds of different types, he was able to assign an *octahedral* configuration to the six co-ordinated radicals. Thus the existence of two isomers of the type MX_4Y_2 follows at once from the fact that substituents may occupy adjacent or opposite apices of the octahedron.



Werner's theory was finally established by the discovery, in compounds such as the cobalti-oxalates, $K_3[Co(C_2O_4)_3]$, of a new type of optical activity, which no one else had even suspected to be possible. This optical activity can, however, be explained immediately by means of an octahedral model, as in the following projection,[15] where the thick lines indicate the positions of the three oxalate groups.



X-ray analysis has now revealed, by direct mensuration, an octahedral configuration of the six halogen atoms in $K_2[SnCl_6]$, $(NH_4)_2[SnCl_6]$, $(NH_4)_2[PtCl_6]$, $K_2[PtCl_6]$ and $(NH_4)_2[SiF_6]$, as well as of the six atoms of chlorine which surround each atom of sodium in a crystal of rock salt. Even more important is the proof that the six molecules of ammonia in the ammoniate $NiCl_2$, $6NH_3$, are arranged in an octahedral pattern about the central atom of nickel,[16] since this confirms in the minutest detail the formulation of the compound as an *ammine* of the type $[Ni . 6NH_3]Cl_2$. Modern physics has thus provided a new and very secure foundation for an important item of belief, which has only recently been added to the chemists' creed.

IONISATION.

During a period of forty years, physical chemists have asserted that when an electrolyte is dissolved in water it is partially dissociated into free ions

$$NaCl \rightleftharpoons \overset{+}{Na} + \overset{-}{Cl}.$$

No adequate basis was provided for this "nonsensical hypothesis" (as Prof. Armstrong described it in a letter to NATURE of November 26, 1896), "which asserts that hydrogen chloride and a few other compounds are so loosely strung together that they fall to pieces when dissolved in water . out of sheer fright it would seem, as no valid motive is suggested for such self-sacrifice." An excuse for this strange conduct was afterwards found in the affinity of the ions for water, but at the time the 'dissociationists' preferred to use the 'blessed word' *allotropy*[17] as a mask to conceal the difficulty of explaining the supposed indifference towards one another of oppositely charged atoms of sodium and chlorine, as contrasted with the violent interaction of metallic sodium with gaseous chlorine and the still more violent interaction that might be expected between the atoms of the two elements. The more concrete suggestion that "the atoms of the dissolving electrolyte evolve heat by combining with their electric charges,"[18] was laughed out of court as being absurdly opposed to sound physical doctrine, since experience had shown that energy was always used up in the electrification of matter, and that the energy required to impart a given charge to a spherical conductor was inversely proportional to its diameter, and must therefore be enormous in the case of single atoms

Modern physics has turned this problem inside out, since it is the molecules, and not the ions, of a salt of which the existence is now questioned. Thus, according to current views, the metals are so ready to lose electrons and the non-metals to gain them, that the ions of a salt are more stable than the corresponding neutral atoms. It is therefore impossible for these ions to neutralise their opposite electrical charges in order to produce a neutral molecule of salt. The utmost that can be done is for two oppositely charged ions to cling together to form a loose doublet, which is always free to interchange ions with another similar doublet. This state of affairs prevails no doubt in the vapour, as well as in concentrated aqueous solutions. Dilution with water then produces a real 'electrolytic dissociation,' $\overset{+}{\mathrm{Na}}\overset{-}{\mathrm{Cl}} \rightleftharpoons \overset{+}{\mathrm{Na}} + \overset{-}{\mathrm{Cl}}$, in which ready-formed ions are merely separated from one another, *e.g.* by the intrusion of molecules of the solvent, instead of being created *de novo* from neutral molecules.

[15] *Chemistry and Industry*, March 9, 1923, 42, 224 This projection, which I suggested in 1923 as a substitute for that used by Werner, has the same hexagonal outline as the diagram commonly used to represent the derivatives of benzene It has the advantage of showing clearly that the metallic atom in the cobalti-oxalates is dissymmetric, but not asymmetric, since the model has one axis of 3-fold symmetry and three axes of 2-fold symmetry.

[16] Wyckoff, *J A C S*, 1922, 44, 1239

[17] Ostwald, "B A. Report," 1890, 333.

[18] NATURE, Dec. 17, 1896, p 151.

This revolutionary doctrine is supported by the X-ray analysis of salt, which reveals the fact that every atom of sodium is surrounded symmetrically by six atoms of chlorine and conversely. Since there is no difference in the distances which separate a given atom of sodium from six neighbouring atoms of chlorine, there is no experimental justification for asserting that any one of these atoms is combined selectively with the central atom of sodium to form a molecule. On the other hand, crystallographers state that the crystal of salt is not holohedral like Bragg's model, but hemihedral, so that there may be some factor in the structure of the crystal which is not revealed by examination with X-rays.

Physical chemists have not been slow in following up the lead thus given, and have been able to prove that many of the properties of dilute salt solutions can be explained by the *electrostriction* between oppositely charged ions, distributed just as in a crystal of rock-salt, but in a more irregular manner and at a greater average distance from one another.

CHEMICAL AFFINITY.

The combination of unlike elements, *e.g.* of metals with non-metals, which is so important in inorganic chemistry, was explained some twenty years ago by J. J. Thomson[19] as due to a process of *electron-transfer*, *e.g.* to the transfer of an electron from an atom of sodium to an atom of chlorine. The chemical affinity between sodium and chlorine was then attributed to the electrostatic attraction between oppositely charged atoms of the two elements.

In its most elementary form the new electrochemical theory was not very much in advance of that put forward a century before by Berzelius, since it gave no precise explanation to show why an atom of sodium should be ready to part with an electron or an atom of chlorine to accept one. Even in the hands of Ramsay,[20] therefore, it did not render any important help to chemists in solving the difficult problem of the nature of chemical affinity. When, however, we had not only learnt from J. J. Thomson of the existence of the electron, and of its presence as a common constituent of all atoms, but had also been taught by Moseley how to count the electrons in the atom of each element, the situation was altered profoundly. Thus it was at once apparent that potassium with 19 electrons has only to lose a single electron, as J. J. Thomson had supposed, in order to acquire the stable grouping of 18 electrons which is characteristic of argon; and conversely, that chlorine with 17 electrons can acquire this stable configuration by gaining one electron. A motive for the transfer of an electron, and an explanation of the origin of this polar type of chemical affinity, can therefore be found in the exceptional stability of a group of 18 electrons, as contrasted with the relative instability of a grouping of 17 or 19 electrons, around a positively-charged nucleus.[21] Indeed, only one important section of the problem now remains unsolved, namely, that we cannot explain why the properties of an inert gas should appear in successive members of the series

$$2+8+8+18+18+32 \text{ electrons},$$

or what feature of the quantum theory dictates the formation of the sub-groups of 2, 3, 4, or 6 electrons, which by their summation give rise to the large groups of Rydberg's series:

$$2\times1^2+2\times2^2+2\times2^2+2\times3^2+2\times3^2+2\times4^2 \text{ electrons}$$

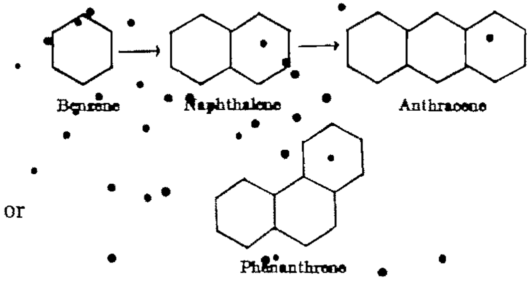
Apart from this, the whole phenomenon of *electrovalence*, as Langmuir calls it, with its attendant theory of the complete and permanent ionisation of mineral salts such as $\overset{+}{\mathrm{Na}}\overset{-}{\mathrm{F}}$ or $\overset{+}{\mathrm{K}}\overset{-}{\mathrm{Cl}}$, seems to be transparently clear.

Nevertheless, just as Berzelius' dualistic theory collapsed when faced with the facts of organic chemistry, so the theory of electron-transfer breaks down in face of the problem of explaining the mutual affinity of *like* elements. This is a serious fault, since the union of like atoms not only dominates the whole of carbon chemistry, but is also responsible for the formation of simple inorganic molecules such as H_2, O_2, N_2, or Cl_2. This second or 'non-polar' type of chemical affinity, however, has also received a clear explanation as a result of the study of atomic numbers. Thus it appears that two atoms, each of which is one electron short of the number required to produce the stable configuration of an inert gas, can acquire this configuration by a simple process of *electron sharing*.[22] In this process a *duplet*, or pair of electrons, is held in common as an integral part of the electronic configurations of the two atoms which it unites, just as the two aromatic rings in naphthalene are united by the two carbon atoms which are common to both rings.

---

[19] *Phil. Mag.*, 1904, 7, p. 262.
[20] *J.C.S.*, 1908, 93, 774.
[21] See especially Kossel, *Ann. d. Phys.*, 1916, 49, 229.
[22] G. N. Lewis, *J.A.C.S.*, 1916, 38, 762; "Valence," 1923, p. 74.

In this scheme of electron sharing there does not appear to be any *a priori* reason why two atoms should not be united by sharing *one* electron; and indeed Main-Smith[23] has postulated that this is a normal method of union in co-ordination compounds; but the evidence offered in support of this view is very slender and in general it appears to be a *pair* of electrons that performs this function, just as *pairs* of carbon atoms are shared when one six-atom ring is added to another on passing from benzene, C_6H_6, to naphthalene, $C_{10}H_8$, and then to anthracene or phenanthrene, $C_{14}H_{10}$.



Two electrons held in common are therefore the equivalent of a *single bond*, or *covalence* as Langmuir calls it, whilst four or six electrons held in common give rise to a *double bond* and to a *triple bond* respectively.

The groups of eight electrons in the Rydberg series are generally depicted as occupying the eight corners of a cubical octet. A single bond is then represented by a pair of cubes with a common edge, and a double bond by a pair of cubes with a common face; but on this basis the formation of a triple bond would result in a complete superposition of the two cubes, and would thus give rise to a quadruple bond, with four pairs of electrons held in common instead of only three. The new model, therefore, fails to represent the property of forming single, double, *and triple* bonds (and the impossibility of forming a quadruple bond) which are expressed so well by the sharing of a corner, an edge and a face of the tetrahedra of le Bel and Van't Hoff. Indeed, further progress is possible only when we abandon the cubical model in favour of a purely algebraic form of the theory, or else adopt a different geometrical model, *e.g.* by supposing that the octet contains four tetrahedrally arranged duplets instead of eight equally distributed single electrons. This tetrahedral model enables us to see why, in the elements of the first short period, there is no large change of boiling-point on passing from $F-F$ to $O=O$ and $N\equiv N$; but when we come to carbon, where a quadruple bond between two atoms is impossible, the boiling-point suddenly rises by 3500°. This dramatic rise of boiling-point is obviously due to the fact that the spare bonds, which are left over after uniting the atoms in pairs by single, double, or triple bonds, interlock, until both in diamond and in graphite the molecule extends to the boundary of the crystal, and vaporisation is only possible by disrupting atoms from this enormous molecular complex. If the cubic model were valid, this abrupt change should occur on passing from the double bond of oxygen to a prohibited triple bond in nitrogen, instead of on passing from the triple bond of nitrogen to a prohibited quadruple bond in carbon.

ORIGIN OF CHEMICAL AFFINITY.

By postulating alternative types of union, the electronic theory of valency enables us to recognise at a glance the existence of two types of chemical affinity, namely, a non-polar affinity between like atoms and a polar affinity between unlike atoms. It has the further advantage of referring both types of affinity to a common cause. This cause, long suspected to be electrical in origin, has at last been disclosed as depending on a mysterious force which compels the electrons, when under the influence of a positively-charged nucleus, to form stable aggregates of 2, 8, 18, or 32 electrons. The origin of these numbers, and of the sub-groups into which they can be further resolved, is, however, a secret which the quantum theory has not yet completely disclosed.[24]

TWO THEORIES OF VALENCY.

During the last fifty years, organic chemists have accepted Van't Hoff's tetrahedron as a correct working model of the carbon atom. This conception of valency was vigorously attacked, however, in 1905, by Werner, who, in his "Neuere Anschauungen" (p. 73 of the English translation), asserted that "Affinity is an attractive force which acts from the centre of the atom and is of equal value at all points on its surface. With such a definition of affinity it naturally follows that separate units of affinity do not exist." In this paragraph, Werner challenges both the limited number and the fixed orientation of the four positions which are available for the attachment of other atoms in Van't Hoff's tetrahedral model. Bearing in mind the distortion of the tetrahedral angles, which is permitted by von Baeyer's 'strain theory,' Van't Hoff's model of the carbon atom can be represented most conveniently by a sphere with four sockets, each socket carrying an elastic rod to represent a bond by which the carbon atom is united to another atom. Werner's alternative conception can be represented most conveniently by Emil Fischer's model, in which the 'atom' takes the form of a sphere covered all over with bristles, a sort of spherical scrubbing-brush, which resembles the involucre of a burdock in that two 'atoms' will stick together at any point of contact, and in any number up to the limits of space available.

---

[23] *Chem. and Ind.*, March 28, 1924, 43, 323.

[24] An interpretation of the periodic system, based upon the view that each planetary electron in the atom occupies a unique type of orbit characterised by *four* quantum numbers, has recently been described by Landé (*Die Naturwissenschaften*, July 1925, 13, 604), see also Sommerfeld (*Phys. Zeits.*, Jan 1, 1925, 26, 70-74), and Pauli (*Zeits. f Physik*, 1925, 31, 765-782).

Although Werner considered it necessary to denounce Van't Hoff's conception of valency as incompatible with his own more comprehensive views, it is now clear that these two theories are not in fact competing alternatives, since each is correct in its own domain, but incorrect if applied outside it. Thus Werner's theory of valency gives us an ideal representation of the behaviour of the closely packed ions in a crystal of rock-salt, and agrees precisely with the behaviour which we should expect of compounds which are held together only by *electrovalence, i.e.* by the mutual attraction of oppositely charged ions. It is, however, incapable of explaining the open lattice structure of the diamond, which can only be arrived at by limiting the number of points of attachment to four, and at the same time fixing their orientation around the atom, precisely as in Van't Hoff's model. This behaviour is characteristic of all compounds in which the atoms are held together by *covalence, i.e.* by the real *bonds* of the organic chemist. We therefore have alternative conceptions of valency, namely, Werner's theory, which expresses the type of chemical affinity that is dominant in mineral chemistry, and Van't Hoff's theory, which expresses the phenomena of organic chemistry; and we now find that these two theories correspond precisely with alternative aspects of the electronic theory of valency, which predicts the possibility, and compels us to recognise the real existence, of both types.

THE TWO TYPES OF VALENCY.

In general the two types of valency can be distinguished by merely counting the electrons. Thus, since the potassium ion and the chlorine ion have each a complete outer shell of eight *M*-electrons, we cannot replace the electrovalence by a covalence, since this would create a surplus of two electrons over and above those required to complete two stable 'argon' systems. On the other hand, a molecule of chlorine, with a total of only $2 \times 7 = 14$ *M*-electrons, must be held together by a covalence, *i.e.* by sharing two electrons, since if the atoms were torn apart we could only assign a complete octet of *M*-electrons to one atom, leaving the other with a sextet or incomplete group of six electrons. The conversion of the covalence into an electrovalence, as represented by the equation

$$\mathrm{Cl_2} \rightleftharpoons \overset{+}{\mathrm{Cl}} + \overset{-}{\mathrm{Cl}},$$

may perhaps occur when the bond is broken by the rupture of the molecule when undergoing chemical change; but this ionisation of the bond can only give rise to an unstable condition, which would always tend to revert to a more stable one in which each atom is able to complete its octet.

We can also distinguish the two types of valency by noticing that the 'polar' type of chemical affinity is indefinitely divisible, like Werner's uniform 'spheres of affinity,' but that the real bond of Van't Hoff's model cannot be divided. Thus in rock-salt the chemical affinity of each 'univalent' sodium atom appears to be divided equally amongst six 'univalent' atoms of chlorine and conversely; but in the diamond the four bonds of the 'quadrivalent' carbon atom are used as integers, each bond serving to unite two atoms, and two only. Whenever, therefore, mention is made of residual affinity, or of partial valencies, I at once suspect that these valencies must be *polar* rather than *non-polar* in character. This view was foreshadowed in 1899 by Thiele,[25] when formulating his new theory of *conjugation*, and I do not know of any evidence which would contradict it.

Even more important is the fact that, whilst an electrovalence can act in any direction round the atom, a real bond or covalence is fixed in direction. In the former case there is nothing to prevent the ions from being packed as tightly as their volumes will permit. This condition is realised in the crystal-structure of rock-salt, $\overset{+}{\mathrm{Na}}\overset{-}{\mathrm{Cl}}$, which is a close-packed aggregate of equal numbers of ions of opposite signs, and of fluorspar, $\overset{-}{\mathrm{F}}\,\overset{++}{\mathrm{Ca}}\,\overset{-}{\mathrm{F}}$, where there are twice as many ions of one sign as of the other. On the other hand, the atoms of carbon in diamond are very far from being close packed, since each atom is surrounded immediately by only *four* other atoms, whereas each of Werner's spheres would be able to make contact with *twelve* other spheres of equal size. Indeed, it can easily be calculated that, if Werner's conception were correct in this particular case, and Van't Hoff's conception were wrong, the close packing of the spheres would increase the density of the crystal in the ratio of 6·5 to 8. Similar open lattices are found in many other crystals, and it is safe to assert that they can always be associated with the presence of valencies which are limited in number and fixed in direction, precisely as postulated by le Bel and Van't Hoff. Thus, if ice and quartz were mere aggregates of oppositely charged ions,

$$\overset{+}{\mathrm{H}}\,\overset{--}{\mathrm{O}}\,\overset{+}{\mathrm{H}} \text{ and } \overset{--}{\mathrm{O}}\quad\overset{++++}{\mathrm{Si}}\quad\overset{--}{\mathrm{O}}$$

we should expect them to crystallise in the same form as fluorspar, where also there are twice as many ions of one sign as of the other. Actually, both ice and quartz crystallise in a totally different manner; and the lattice-work of ice is so open that the density of the aggregate is less than 1. We can therefore assert that the atoms of both compounds are united by real bonds and not by the mere electrostatic attraction between oppositely charged ions. A similar argument has already been applied in the case of iron pyrites, FeS_2, where the sulphur atoms are all paired, instead of being distributed uniformly like the atoms of fluorine in fluorspar. The compound is therefore not a sulphide of quadrivalent iron $\overset{--}{S}\ \overset{++++}{Fe}\ \overset{--}{S}$; but a ferrous disulphide, $\overset{++}{Fe}\ \overset{-}{S}\text{——}\overset{-}{S}$, in which each pair of sulphur atoms is held together by a bond, in addition to carrying a double negative charge. It is, indeed, clear from these examples that the X-ray analysis of crystals provides a very precise experimental method for distinguishing between the two types of valency, and is of fundamental importance for this purpose.

---

[25] *Ann.*, 1899, 306, 87.

POLAR, SEMI-POLAR, AND NON-POLAR DOUBLE BONDS.

Three years ago I pointed out[26] that since single bonds can be of two types, namely:

(i) Polar, as in $\overset{+}{Na}\overset{-}{Cl}$.
(ii) Non-polar, as in Cl—Cl, H—H or $CH_3 . CH_3$;

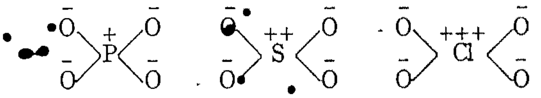
double bonds should be of three types, namely:

(i) Polar, as in $\overset{++}{Ca}\ \overset{--}{S}$,
(ii) Non-polar, as in O=O,
(iii) Mixed (or semi-polar), as in $Me_3\overset{+}{N}\text{—}\overset{-}{O}$.

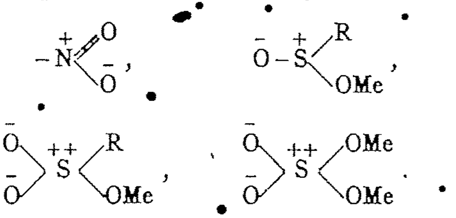
In particular, a mixed or semi-polar double bond was postulated in trimethylamine oxide

$$\overset{+}{N}Me_3-\overset{-}{O}\ (\text{compare } \overset{+}{N}H_4\overset{-}{Cl}),$$

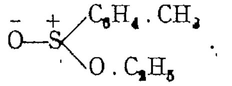
and in the ions of oxy-acids[27]



The existence of this new type of double bond has now been established by two independent experimental methods, depending respectively on the study of molecular volumes and on the detection of molecular dissymmetry. The work on molecular volumes, begun more than half a century ago by Kopp, has culminated in the recent researches of Sugden,[28] who has discovered a function of the molecular volume which is (i) independent of the temperature of observation, (ii) a strictly additive function of the constituent atomic volumes. In these investigations the molecular volumes are reduced to *equal surface tensions*, by making use of a function $\gamma^{\frac{1}{4}}\frac{M}{D-d}$ (where γ = surface tension, M = mol. wt., D = density of liquid, d = density of vapour), which Sugden describes as the *parachor*. The value of this function is increased by 23 units by each *non-polar* double bond, whatever the atoms which it joins, *e.g.* $>C=O$, $>C=C<$, $>C=N-$, $-N=O$; but the *semi-polar* double bonds in the systems $>SO$, $\geq NO$ and $\geq PO$ were found to produce a minute *decrement* of molecular volume.[29] In this way the nitro group was shown to contain only one non-polar double bond, whilst the sulphinates, sulphonates, and sulphates do not contain any



More important still is the proof given by Phillips,[30] that the sulphinates (in which the existence of semi-polar double bonds was established by Sugden's measurements of density and surface tension) can be obtained in optically-active forms, as in the case of the ethyl tolylsulphinate of the formula



If the sulphur and oxygen were united by a symmetrical non-polar double bond, the compound would, on the basis of the older space formulæ, be obviously symmetrical. Moreover, since none of the earlier theories of valency was capable of predicting the asymmetry of these compounds, the experimental realisation of this new type of optical activity provides an excellent illustration of the value of the electronic theory of valency, as well as a decisive vindication of the more specialised conception of mixed or semi-polar double bonds. We have here, indeed, a further example of the general rule, already illustrated in the case of Werner's theory of co-ordination, that each new development of the theory of valency has been accompanied by, and has received its final sanction from, the discovery of a new kind of optical activity.

Our Bookshelf.

Studies in Psychology.

Behaviorism. By Prof. John B. Watson. Pp. iv+248. (London: Kegan Paul and Co., Ltd., 1925.) 12*s.* 6*d.* net.

IN his new book Dr. Watson gives a vigorous exposition of his methods and results already familiar to readers of his earlier works, notably "Psychology from the Standpoint of a Behaviorist." It contains, however, some fresh material and foreshadows an ambitious attempt to apply the principles of behaviouristic psychology to all the mental and social sciences. All categories involving reference to consciousness, such as knowing, feeling, striving, are to be eliminated and their place is to be taken by a purely naturalistic study in terms of reflexes and their 'conditioning.' His attitude to the problem of the nature of instinct is more drastic than in his earlier writings. All alleged human instincts are, according to his present view, really habits built up by selection from original responses by processes of conditioning. Emotions, of which there are only three primary ones—namely, fear, [illegible]e, and love—are nothing but visceral responses. [illegible] 'unconscious' of the psycho-analysts consists, in [illegible], of bodily and visceral habits that have never [illegible]balised and cannot be recalled. Modification [illegible]viour or 'learning' is due to the conditioning [illegible]nses and the formation of habits. Thinking is [illegible]ng, and is made up of laryngeal habits.

[illegible] Dr. Watson's exposition is aggressively [illegible]d confident, but he makes no real effort [illegible]h the difficulties of his position. This [illegible]icularly to his discussion of 'memory,' [illegible]nd 'thinking,' in each of which recent work [illegible]o bring out the inadequacy of explanations [illegible]uch factors as recency and frequency of [illegible]e, to which alone he appeals. The book [illegible]number of records of observations, particu[illegible] dealing with the behaviour of infants, [illegible]mportant and useful, but on the theoretical [illegible]rks no advance, and the claim that the [illegible]embodied in it are destined to revolutionise [illegible]eligion, sociology, and other social sciences [illegible]t strike the reader as naively extravagant.

M. G.

[illegible]ology of Handwriting.* By Robert Saudek. [illegible]-288. (London: George Allen and Unwin, [illegible]25.) 12*s.* 6*d.* net.

[illegible]GY, the study of handwriting in popular con[illegible] placed on something of the same level as [illegible] except that, in the case of the former, experts [illegible]nes called upon to give evidence as to matters [illegible] the law courts. It will therefore, perhaps, [illegible] surprise to some to find a volume of no small [illegible]s devoted to the study of the subject on scientific lines, and further, to find that it contains a chapter on the history of the subject. Attempts at 'characterological' interpretation of handwriting begin with a book by Camille Boldo, published at Capri in 1622. In 1830 there was a school of interpretation to which Bondinel, Bishop of Amiens, Cardinal Régnier, and Abbé Flandrin belonged; but the history of graphology really begins with Abbé Hipolite Michon, a pupil of the last named, who was followed by Crépieux Jamin, the most eminent of the French graphologists. It was, however, in Germany that an attempt was made by Georg Meyer and Ludwig Klages, at the end of the last and the beginning of the present century, to place the study on a truly scientific inductive basis.

The author of the present work, in addition to an exhaustive study of the methods of both French and German schools, has had twenty-five years' experience in the study of handwriting, and here puts before his readers the results of his adaptation of these methods to English and American styles and methods in handwriting. So far as they go, his methods, taking into account mechanical and material conditions and the physiology of writing, must be accepted as sound in principle and method. It is when he comes to the psychology of writing that he is on less certain ground. It must be admitted, however, that his reasoned analyses of specimens of handwriting of well-known individuals do indeed appear to tally with the facts so far as generally known.

Animal Life.

Our England: Twelve Open-Air Lessons. By Patricia Johnson. Pp. viii+104. (London: Methuen and Co., Ltd., 1925.) 2*s.*

THIS little text-book, which is neither purely geographical nor historical, but contains a little about everything, deserves more than passing mention. In the first place, it represents in substance some of the first broadcast lessons ever given by radio: they were broadcast from the London station in the spring of 1925; and secondly, because they are excellent of their kind. Few books of this size contain so much excellent matter packed within so small a space. The weather, domestic animals, the farmer's year, wild animals, archæology, history, geography, folklore, economics, and the history of traditional civic institutions in England, all find a place, treated in such a way as to stimulate rather than to satisfy inquiry.

The Aquarium Book. By E. G. Boulenger. Pp. 208+16 plates. (London: Gerald Duckworth and Co., Ltd., 1925.) 10*s.* 6*d.* net.

THE greater part of this book is devoted to popular accounts of a large number of species of aquatic animals. The value and history of aquarium-keeping are also briefly surveyed and hints given on the management of aquaria.

The book is very attractively written and should have a wide appeal. Its perusal will greatly enhance the interest of visits to the Zoological Society's aquarium and stimulate the enthusiasm of amateur aquarists. It is a great pity, therefore, that care has not been taken to avoid the far too numerous errors, exaggerations, and loose statements in the information provided. Examples of such are a statement on p. 34 that all protozoa have a flagellum, and one on p. 107 that steam-trawling destroys the eggs of the plaice. Misprints and mistakes in punctuation are numerous. On p. 166 the author confers knighthood on Isaak Walton. The few photographs are excellent: the drawings, in some cases good, in others leave much to be desired. On p. 50 the cotton-spinner, *Holothuria nigra*, is misrepresented by a drawing of quite a different species. It is hoped a second edition will appear, carefully edited to remove such blemishes from an otherwise attractive and useful book.

Reproduction in the Rabbit. By John Hammond. With Foreword and Chapter on the Formation of the Corpus Luteum by F. H. A. Marshall. (Biological Monographs and Manuals, No. 4.) Pp. xxv+210+20 plates. (Edinburgh and London: Oliver and Boyd, 1925.) 15*s.* net.

THIS is an admirable book, containing not only an excellent and up-to-date account of the reproductive phenomena of the rabbits, but also a mass of original results derived from the personal investigations of the author. The book is prefaced by an excellent short outline of the processes involved in the sexual cycle, by Dr. F. H. A. Marshall, who also appropriately contributes the chapter upon the formation of the corpus luteum.

Mr. Hammond's work is clearly written and is well illustrated by charts and half-tone blocks. It will be found indispensable by all specialist students of mammalian reproduction, but will also prove most useful and most interesting to the ordinary biologist interested in a more general way in the phenomena of reproduction.

The Breeding of Foxhounds. By Earl Bathurst. Pp. xiii+132+8 plates. (London: Constable and Co., Ltd., 1926.) 21*s.* net.

THE scientific principles of animal breeding are still obscure: yet the success of the practical man, from the days of Jacob's matrimonial venture onwards, are for all to see. Probably the modern dog, particularly the sporting dog, provides the best example of man's skill in moulding wild animals to his purposes; for, if Darwin was right, the raw material was the wolf, the dingo, and the like—most unpromising material out of which to build up a being of almost human intelligence. This book, based, as it is, on the accumulated experience of nearly forty years of breeding hounds (the author being the well-known and successful Master of the V.W.H.-Cirencester Hounds), is deserving of the careful study of all—and they are many—who are interested in the practical problems of hound-breeding. Earl Bathurst is clearly a master of his subject, and does not object to disclosing, as so many practical breeders of animals do, the secrets of his methods. It is open to doubt, however, whether science, Mendelian or other, can do much to aid. The author devotes, it is true, a chapter to Mendelism, but the methods he applies owe their main justification to the practical success which has followed them. The qualities of the perfect hound, we are told, are "voice, nose, drive, stoutness, and looks." The geneticist would scarcely venture to describe these as Mendelian 'unit characters,' or even assert their dependence on 'genes.'

It is interesting to observe how the dread of inbreeding dominates the practical breeder. "Study the pedigrees," says the author, "so as to avoid breeding too closely." Yet we know that, as a matter of practice, close inbreeding was applied by all the great 'improvers' of cattle and sheep, and modern science asserts that inbreeding, in itself, is not harmful. Certain it is that fixity of type can be obtained by this practice and no other. The 'line' breeding which the author practises is, after all, simply a diluted system of this nature. The book is handsomely produced. The photograph of the author's Trouncer, 1923, will excite the envy of every hound lover.

Hygiene and Health.

(1) *The House of Health: What the Modern Dwelling Needs to Be.* By Sir John Robertson. Pp. 192. 2*s.* 6*d.* net.

(2) *Nursing in the Home: including First Aid in Common Emergencies.* By Stella Churchill. Pp. 197. 2*s.* 6*d.* net.

(3) *The Fight against Infection.* By Lieut.-Col. G. E
Stammers. Pp. 214. 2*s.* 6*d.* net.

cases. Directions are given for the treatment of emergencies (such as fits, drowning, and poisoning), and of some common minor ailments. No caution is given of the irritant effect of formalin in connexion with disinfection, and we have failed to find a mention of that common and alarming ailment of children—spasmodic croup.

(3) Col. Stammers has been able briefly to describe the causation and means of prevention of many of the ills to which flesh is heir. Two brief chapters serve to introduce to the reader the nature of parasites, vegetable and animal, and to give an account of some of the means by which the body resists infection. A fascinating narrative then follows of several important diseases, including plague, cholera, typhoid fever and sleeping sickness, and guinea-worm and tapeworm infections. A short chapter on scientific research is included, which should impart to the non-scientific reader some idea of what research work is.

The text is illustrated with figures of parasites and their intermediate hosts and charts of geographical distribution. We notice a slip in the legend of Fig. 13, where the diagram of the female guinea-worm is stated to be "highly magnified," though in the text the worm is rightly described as being about a yard in length. It would be better also, we think, not to refer to *Taenia solium* and *T. mediocanellata* as the "pig" and "beef" tape-worms respectively, as in the tape-worm stage they are essentially human.

Indian Forestry and Timbers.

India of To-Day. Vol. VI.: *India's Forest Wealth.* By E. A. Smythies. Second edition. Pp. xv + 137 + 12 plates. (London: Oxford University Press, 1925.) 3*s.* 6*d.* net.

FORESTRY is a subject on which the average politician is profoundly ignorant. A very high proportion of the Indian public have hitherto had very little direct interest in the forests. As a people they are extraordinarily economical both in the use of fuel and timber. Only a comparatively small proportion of the population live in the vicinity of the remaining forests. In spite of the fact that enormous quantities of produce are given away annually to rightholders (estimated very conservatively at 1,000,000*l.* worth), the general attitude of those directly interested in the forests is one of grievance against the restrictions of the Forest Department as to free fuel, timber and grazing. This grievance, coupled with the fact that the present annual surplus from Indian forests after approximately seventy years of conservation and development has only increased from 80,000*l.* to 1,300,000*l.*, is reflected in the attitude of the majority of Indian politicians, who in general are hostile to forest development. The present work, prepared by Mr. Smythies in collaboration with provincial officers, is therefore very timely. It emphasises the enormous indirect benefits derived from India's forest estates and their value to the population as a whole; it describes what the Forest Department has already accomplished; and it explains very clearly the urgent need of further investment of capital in the forests if the exchequer in the course, say, of the next fifty years is really to benefit directly from the investments already made.

An Elementary Manual on Indian Wood Technology. By Dr. H. P. Brown. Pp. xiii + 121 + 16 plates. (Calcutta: Government of India Central Publication Branch, 1925.) 4 rupees; 6*s.* 9*d.*

THERE has been a certain amount of prejudice in the past against the use of the microscope for the identification of timber, the reason generally given being that it is impracticable for use in the field. The number of different timbers, however, which now need to be distinguished has increased so enormously that opinion has veered to the other extreme, and many regard any attempt to identify a timber without the aid of the microscope as so much guess-work. J. S. Gamble's "Manual of Indian Timbers" has for many years been the only important work in this particular field, but unfortunately contains no microscopic data. There has consequently been a growing need of a text-book for the training of Indian forest officers in the anatomy of the timbers of India. As Dr. Brown points out in his preface, to teach students in terms of timbers which they will never handle is neither efficient nor conducive of the maximum possible interest. It is to remedy this defect that this volume has been written, and that it will go a long way towards doing so is not to be doubted. It should also prove of value to those interested in the timbers of tropical countries other than India.

The microscopic features of wood are described more fully than the gross features and physical properties, but the latter are quite clearly and concisely set out. Admirable use has been made of a large number of original photomicrographs and drawings, both of which are excellent, and a key is appended for the identification of sixty of the more important Indian woods.

L. C.

Earth Structure and History.

Geological Maps: the Determination of Structural Detail. By Robert M. Chalmers. Pp. vii + 175. (London: Oxford University Press, 1926.) 12*s.* 6*d.* net.

THE study of geological maps and structures is perhaps one of the most difficult parts of any advanced geological course, and until recent years there has been no guidance in the way of text-books available to students. There are now several books from which a selection may be made, and this, the most recent addition to the growing literature of the subject, seems likely to make the widest appeal. It is intended not only for geologists, but also for students of mining, and many of the examples in the text have been chosen to illustrate problems arising in the working of coal seams. The purely geological student, however, will find such difficult structures as recumbent folds quite adequately treated, and it is noteworthy that examples are taken from the Ballachulish and Appin folds.

The author has a wide knowledge of geological evidence and its interpretation, and besides dealing with the familiar topics, outcrops, thickness and dip of beds, faults, etc., chapters are also devoted to igneous rocks and geosynclines, while an appendix gives a brief account of the theory of isostasy. The book can be warmly recommended to teachers and students as a thoroughly successful text-book, while the publishers are themselves a sufficient guarantee that the book is well and attractively printed.

An Introduction to Earth History. By Prof. H. Shimer. Pp. viii+411. (Boston, New York and London: Ginn and Co., 1925.) 12*s.* 6*d.* net.

Prof. Shimer is to be congratulated on having achieved a very definite success in his attempt to compress into a small book a thoroughly adequate, well-proportioned, and completely up-to-date survey of geology and its border subjects. The treatment is far from following the conventional lines usually adopted. Part 1 deals with the 'evolution' of matter and stars, and so leads up to the birth of the solar system and the origin of the earth. The recent tidal theory of Jeans and Jeffreys is briefly summarised, and radioactivity is discussed with the view of applying it later to the measurement of geological time and the problems associated with the earth's internal sources of energy. Part 2 briefly describes the processes at work on the surface of the earth and within it; and at greater length the sequence of events, due to the interaction of these processes, which constitute geological history. Part 3 is devoted entirely to the history of life, and gives in broad outlines a most useful summary of the evidence for and the results of organic evolution.

From the most modern applications of radioactivity to dinosaurs' eggs the book reaches the newest fringes of a rapidly advancing subject, and presents it everywhere as a science in active growth towards maturity. The book is well written, cultured and philosophical in tone, and will serve alike for the general reader and the non-specialising student to give a general picture, described by an authoritative guide from a modern point of view, of the progress that has so far been made in our interpretation of the earth's history and that of its inhabitants.

A Text-Book of Geology: for use in Universities, Colleges and Engineering Schools. By Prof. James Park. (Griffin's Scientific Text-Books.) Second edition, revised and enlarged. Pp. xix+527+72 plates. (London: Charles Griffin and Co., Ltd., 1925.) 30*s.* net.

This comprehensive elementary text-book has enjoyed a quiet popularity for twelve years, particularly amongst mining men, to whom the author, Prof. James Park, is well known for his works on mining and metallurgy. This, the second edition, has been considerably revised, though not so fully as one would have wished, for in many respects it is not adequately up-to-date, and reference to the bibliography definitely shows that many important works of the last decade have not been utilised. Although the first edition contained 598 pages, the present volume is considerably larger because of the adoption of a bigger page-size. It includes new matter dealing with the history of geology, the origin of coral reefs and atolls, mountain building, and the formation of ore deposits. In the revision of the section discussing the age of the earth, the longer estimates of geological time are wrongly ascribed to Joly. The book begins with physical geology and includes a brief summary of mineralogy and petrology. The second part, dealing with historical geology, is noteworthy for the many excellent plates illustrating fossil forms. Special prominence is given to the comparative stratigraphy of Britain, North America, and Australasia. This section concludes with a useful chapter on the development of surface relief, though more attention might have been given to modern work on isostasy and the structure of the Alps. Part 3 deals in two chapters with economic geology and geological surveying.

For elementary students the book thus presents within one pair of covers a remarkably complete survey of the subject, clearly written, and thoroughly well illustrated. It is, however, conventional, after the manner of older text-books. Had it been brought more authoritatively up-to-date, it could have been warmly recommended to British students. As it is, and taking into consideration the high price, it is not likely to be widely adopted except in Australasia, where it should prove particularly useful as a general textbook.

The World in the Past: a Popular Account of What it was Like and What it Contained. By B. Webster Smith. (The Wayside and Woodland Series.) Pp. xii+355+111 plates. (London and New York: Frederick Warne and Co., Ltd., 1926.) 10*s.* 6*d.* net.

This new volume of the "Wayside and Woodland Series" can scarcely be said to reach the usual standard of that admirable collection. It is extremely difficult to write a satisfactory popular account of geological history. The successful author of such a book must be an artist in prose, and he should wander at ease through his subject, presenting it in an attractive and persuasive form and in a friendly and authoritative way; above all he must not patronise the reader or indulge in 'journalistic bromides.'

Judged by the unwritten ideal, this attempt is not altogether a success. It has an old-fashioned flavour and is sprinkled with sentences that will offend the fastidious. As examples of the author's style which justify this criticism we may quote a sentence on p. 100: "Silurian times, the Age of Lime, were not so extensive, perhaps, as their predecessor, the Age of Mud; nevertheless, a million years' duration is the least that can be assigned to them"; and the description of Stegosaurus on Pl. 66: "The last word in Dinosaurian ugliness." Although betraying superficial knowledge, the book is not faulty in its facts. It contains many vivid descriptions of ancient animals and landscapes and is generally light and interesting in style. Many of the illustrations are excellent, and have not appeared before in geological books. More maps should have been included, and a saving in cost might have been effected by omitting some of the colour printing.

Palæontology: Invertebrate. By Henry Woods. (Cambridge Biological Series.) Sixth edition. Pp. vi+434. (Cambridge: At the University Press, 1926.) 10*s.* 6*d.* net.

It is a compliment to this useful and well-known book to find that after five years still another edition has been called for, despite the fact that during the life of the fifth edition it had to compete with rivals that had not previously entered the field. The book has now been revised, with special attention to the ammonites and corals, in connexion with which groups the author acknowledges assistance from Dr. L. F. Spath and

Dr. Stanley Smith respectively. Some new figures have also been added, and a useful feature is the guide to the literature of the subject. For more than thirty years this little book has been indispensable to the elementary student of invertebrate palæontology, and it remains, as before, clear, concise, and authoritative.

Economic Geology.

Clay and what we Get from it. By Alfred B. Searle. Pp. 178. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1925.) 3*s.* 6*d.* net.

Except for a brief introductory account on the nature, mode of occurrence and origin of clays, and a closing chapter of quotations from prophets and poets, this book deals with the industrial applications of clay. It is, indeed, of special interest as showing to what a large extent clay figures as a thing of usefulness in human affairs. The author is full of knowledge of the subject, and in these interesting pages he has succeeded in conveying much of it, as well as some of his enthusiasm, to the reader. The book well deserves a place in the Popular Science series of the Sheldon Press.

Geological Survey, Scotland. The Economic Geology of the Ayrshire Coalfields. Area 1: Kilbirnie, Dalry and Kilmaurs. By J. E. Richey, G. W. Wilson and E. M. Anderson; with Contributions by C. H. Dinham. Pp. vi+91+2 plates. 2*s* 6*d*. net. Area 2: Kilmarnock Basin, including Stevenston, Kilwinning and Irvine. By E. M. Anderson; with Contributions by G. V. Wilson. Pp. vi+107+2 plates. 3*s*. net. Sheet 8: Vertical Sections illustrating the Ayrshire Coalfields, Areas 1 and 2. On the Scale of 40 ft. to 1 in. Arranged by E. M. Anderson and J. E. Richey. 2*s*. 6*d*. net. (Edinburgh and London: H.M. Stationery Office; Southampton: Ordnance Survey Office, 1925.)

These two volumes may be looked upon as the continuation of the series of memoirs on the coalfields of Scotland, a commencement on which was made some time ago with the Central Coalfield. The present volumes cover the greater part of the Ayrshire Coalfield, which for the purpose of description is divided into two areas, Area No. 1 comprising the main portion of the coalfields of central and northern Ayrshire, whilst Area No. 2 covers the southern portion of the coalfield, of which Kilmarnock may be looked upon as the centre.

The arrangement in both volumes is necessarily somewhat similar, commencing with an account of the general geological structure and then describing in detail each formation, beginning by the lowest known in the district. The coal seams are naturally described in much detail, but attention is also paid to the other minerals of economic importance, such as the ironstones, limestones, fireclay and other clays, building stones, sands, refractory materials, stones for road metal and other purposes. In the memoir upon Area No. 1 there is an appendix giving analyses of a number of these minerals of economic importance, and it is rather to be regretted that this excellent example has not been followed in the volume dealing with the second area.

It need scarcely be said that the work is admirably done, and that these two volumes contain a wealth of information which will be of the utmost value to the mines working in this important coalfield.

General Physics.

Marvels of Sound, Light and Electricity: an Introduction to some Physical Phenomena for Young Students. By Percival G. Bull. Pp. vii+221. (London: George Routledge and Sons, Ltd., n.d.) 6*s*. net.

This book, we are told in the preface, is not intended as a text-book, but is expected to fill the rôle of arousing such interest and enthusiasm as will induce the spare-time reader to proceed to a more detailed and systematic study of physics. If the reader is not an absolute beginner in physics, we are of opinion that the author has probably succeeded admirably in his task. But we are afraid that the opening pages of the book make too great a demand upon the absolute beginner. Such a reader must of necessity find the references to radiation, the spectrum, longitudinal waves, and the like (although these are explained in greater detail later), rather too difficult; which would be a great pity in view of the general excellence of the book once these first pages are passed.

The author begins with an explanation of the phenomena of wave motion and their application to sound. He then passes to the study of light and colour, and to the study of the invisible portion of the spectrum. The interpolation of a chapter on optical illusions is interesting and well done, but makes a break in the continuity of the theme. It is followed by a chapter on cathode and X-rays and radioactivity, after which the book is rounded off with a description of experiments with high-frequency electric currents and high-tension discharges. The style and production are both attractive, and we can confidently recommend a place for the book in all school libraries.

Elementary General Physical Science. By W. R. Jamieson. Pp. 63+88+147+x+16 plates. (Melbourne: Brown, Prior and Co. Pty., Ltd., 1926.) 8*s*. 6*d*. net.

We extend an unqualified welcome to this book. Published in Australia, it is the work of the senior chemistry master at the Scotch College, Melbourne. If it is to be taken as typical of the spirit that animates science teaching in the Commonwealth, then Australia has undoubtedly much to offer to British teachers of science in schools by way of example. If, on the other hand, it is not typical, then Mr. Jamieson is a pioneer worthy of every encouragement. He aims, in effect at the broadening of the approach to the study of science. This is a plea which has found increasing expression at the various conferences of the Science Masters' Association, and, so far as the physical sciences are concerned, the book under notice shows how well this can be done. Prof. Rivett, of the University of Melbourne, hints in a foreword at the advent of a companion volume on similar lines dealing with biological science, and we cordially hope this will speedily appear.

Want of space makes it impossible for us to go into details. We quote from the preface: "Without sacrificing in any degree the exactness and accuracy which are an essential feature of true science, the author has sought to inculcate ideas and express the spirit of science. . . . Broad treatment rather than minute and detailed study has been aimed at." Observing on the whole a historical sequence, the formal divisions of chemistry, physics, mechanics, and astronomy are all linked up and blended in the most interesting fashion; and if the shackles of tradition and examination make it difficult for the book to be adopted in many schools at home, we can at least contend that no teacher of science will be the poorer in ideas for the outlay which purchase of the book involves. I. B. H.

Quantum Theory.

Atomicity and Quanta: being the Rouse Ball Lecture delivered on May 11, 1925. By Dr. J. H. Jeans. Pp. 64. (Cambridge: At the University Press, 1926.) 2*s.* 6*d.* net.

Those who have at any time listened to Dr. Jeans are well aware of his skill and charm as a lecturer; these qualities were amply sufficient to make a success of a lecture which is on paper a little disappointing. Unfortunately, the necessities of a popular lecture on an abstruse subject inevitably lead to a certain superficiality, especially in dealing with its peculiar difficulties. For example, Dr. Jeans disposes in the usual way of the conflict between the quantum theory of radiation and the undulatory theory, by limiting the application of the two theories to different types of phenomena: the quantum theory applying to those arising from the interchange of energy between matter and radiation, and the undulatory theory to those connected with radiation travelling without interchange of energy with matter. When, however, he tries to bridge the gap, he does not adopt the almost mystical attitude towards this fundamental problem which many physicists have and may still feel obliged to maintain in spite of the advent of the new quantum mechanics, but resorts to arguments which seem unnecessarily crude. He emphasises the difficulty of obtaining reversibility in systems in which spherical waves play an important part, and suggests the introduction of 'advanced' as well as 'retarded' potentials in order to obtain it. The physical conception which this involves is, however, so difficult that it seems questionable whether any theory which requires it can ever be intellectually acceptable.

For those of Dr. Jeans's audience with the awakened mind and some familiarity with the subject, the lecture was excellent, vivid, with sufficient emphasis and balance of structure to make it striking and easily remembered. It must have given such a listener a clear-cut and manageable picture of much modern work that he had found puzzling before, and there will no doubt be many readers of the same type to whom the reprint will be profitable and congenial reading.

The Quantum Theory of the Atom. By George Birtwistle. Pp. xi+236. (Cambridge: At the University Press, 1926.) 15*s.* net.

The quantum theory in its applications to atomic physics has developed so rapidly, that a textbook, giving a fairly comprehensive and orderly account of the subject, has become an urgent necessity. Mr. Birtwistle has made a valiant and on the whole a very successful attempt to supply this need, and students of the subject will have cause to be grateful to him for his very clear exposition of it. The author has succeeded in compressing into his 233 pages of text a surprisingly complete account of the subject from the earliest speculations of Planck and Bohr to the latest work of Sommerfeld, Kramers and Heisenberg.

The treatment is entirely mathematical, and no attempt is made to discuss the physical and experimental basis of the subject. At the same time the author has, we imagine, had in mind the necessities of the student of pure physics, and very kindly and wisely has included chapters on those developments of classical mechanics—the Hamiltonian equations, the Hamilton-Jacobi equation, and Lagrangian methods—which, while they form the basis of much of the quantum mechanics, are unfortunately not part of the equipment of the average student of physics. These chapters add very considerably to the value of the book.

The writer of a textbook must adopt some kind of "Principle of Selection," and naturally some things are omitted which a reviewer might wish to have seen included. In particular Mr. Birtwistle passes over in, possibly discreet, silence the views of the ultra-modern school in which the quantum is handled as if it were a material particle; and, perhaps more seriously, the chapters on X-rays and γ-rays are somewhat inadequately treated. The author has, however, given us so much that is excellent that it would be unjust to complain because he has not included still more. We hope that the rapid exhaustion of this first edition will enable the author to keep the book as thoroughly abreast of the subject as it is at present.

Radio Communication.

Broadcast Reception in Theory and Practice. By J. Laurence Pritchard. Pp. xi+259. (London: Chapman and Hall, Ltd., 1926.) 8*s.* 6*d.* net.

During the last two or three years amateurs who are enthusiastic about radio communication have attempted, in some cases successfully, to increase their knowledge by reading standard books on the subject. Probably they began by constructing a radio set from given instructions. Wanting to learn the theory, many found that the ordinary books made too great a demand on their knowledge of the principles of electricity. This book has been written for their use. Formulæ are given but not proved. Confidence in them, however, is obtained by following out the working of numerical examples. The experimenter is then told how to construct his own coils, condensers and resistances, emphasis being laid on important practical details.

A useful chapter is given on how to detect and remedy faults in a receiving set. It is pointed out that the most probable seat of the trouble is the high-tension battery. This is indicated when the signal strength becomes weak, accompanied by crackling noises similar to atmospherics but more persistent. This is generally due to the H.T. battery becoming exhausted and internal disintegration being set up. The zinc containers of the cells get eaten through, soldered intercell connexions become affected, and gas is evolved which makes its way through the pitch or other filling used. The cells quickly polarise and the voltage falls. If a high-resistance voltmeter be available this fault is readily discovered. But if not, it is necessary to substitute a new battery for the suspected battery to find out if it is at fault. External connecting wires are sometimes broken inside their insulated coverings. Search should be made for this fault. Telephones occasionally give trouble. Every pair of telephones should give a healthy click on being connected to a battery composed of a penny and a shilling separated by a piece of wet tissue paper. If they are defective they should be sent to the makers for repair. Trouble is sometimes experienced by valve legs of the split type failing to make good contact. The remedy is simply to open the slits slightly by the aid of a knife.

Loud Speakers, their Construction, Performance and Maintenance: a Practical Handbook for Wireless Manufacturers and Traders and for all Wireless Amateurs; containing Notes on the Selection of a Loud Speaker and on the Detection and Remedying of Faults. By C. M. R. Balbi. Pp. xv+96. (London: Sir Isaac Pitman and Sons, Ltd., 1926.) 3s. 6d. net.

THE science of sound reproduction by means of a loud speaker is one of ever-growing interest and importance. This little book gives a brief but fairly complete résumé of the subject. The various forms of loud speaker can be classified under three main heads. The first class may be called electro-magnetic. In this class are the well-known Amplion, Brown, Western Electric and Lumière loud speakers In the second class are those which utilise the phenomena of friction or of the electrostatic attractions produced at the face of semi-conductors. The Frenophone is an example of the former and the Joh[illegible] Rahbek of the latter. In the third class are included many which depend on curious physical phenomena. In this class are the arc loud speaker invented by Duddell, the air-blast, the jet of water, the piezo electric, the crystal, the hot wire, the thermophone and the condenser loud speakers The mere enumeration shows the variety of physical principles employed all leading when applied to very similar results.

A good description is given of the Western Electric public address system It is now possible for a public speaker to address a million people at once, and the speaker's voice can be plainly heard at a distance of 1000 feet. The electric power required for these installations is about two kilowatts. With very large assemblies it has been found necessary to provide observing stations at various points in the audience. The observers stationed at these points communicate with the operator by portable telephone sets. A chapter of advice to those intending to purchase loud speakers concludes the volume. So many variables, such as the power and distance of the broadcasting station, have to be taken into consideration that it is only possible to give vague advice. Notes on various types of commercial loud speakers are given, but they would have been more useful if less praise and more criticism had been given.

The Radio Press Year Book 1926: the Wireless Book of Reference Edited by John Scott-Taggart and Percy W. Harris. Pp. 169. (London: Radio Press, Ltd., 1926) 1s. 6d.

MUCH interesting information is given in this little book which will be of value to those desirous of improving their radio-receiving sets. Short sections are contributed by well-known radio engineers. P. W. Harris, for example, compares American and English radio conditions.

As a matter of history, the first daily broadcasting of a programme was made from the well-known K D K A station at East Pittsburgh. In Great Britain Mr. Godfrey Isaacs and the Marconi Company broadcast concerts from Marconi House before the B.B.C. was formed.

In the early days, the Americans were greatly troubled by what they called 'squealing' receivers. To-day, thanks mainly to neutralised high-frequency couplings, the receivers sold in the United States are strictly non-radiating, and it is possible to listen to distant stations, even from the most crowded districts in New York and Chicago, without hearing the faintest trace of an oscillation. The U.S Government allots definite wave-lengths to the broadcasters and makes them adhere to them very closely. One regulation which sounds curious to British readers is the prohibition of what is called 'canned music,' that is, the music made by gramophone records and player pianos. A useful regulation by the U.S. Government which might be copied with advantage in Europe is that a certified operator is on watch during broadcasting hours, so that in the event of an S.O.S. signal being heard, the broadcasting transmission may be stopped. The section on how to select a valve is a useful one. Although many purchase dull-emitter and bright-emitter valves and talk glibly about them, yet few have any accurate knowledge of their main characteristics. Lists are given of practically all the valves on the market, and the values of their filament ratings, voltages, internal impedances, and amplification ratios are all given.

Many characteristic diagrams are given to illustrate their working. The list of amateur call signs now occupies 30 pages, and there is a long list of radio societies.

The Motor Car and its Engine.

The Book of the Light Car. By E. T. Brown. Pp. vii+155+12 plates. (London: Chapman and Hall, Ltd., 1926.) 7s. 6d. net.

THE modern light car has been so far perfected and the motor industry so well organised that it is possible and common for persons completely innocent of mechanical knowledge to motor with satisfaction and safety. Many readers of NATURE even may fall within this class and will, nevertheless, feel curious about the construction and working of what is so easily controlled from the driving-seat. For such, Mr. Brown has written clearly in a book well paragraphed and indexed, so that answers to most of the inevitable questions can be turned up in a moment. Here and there the fastidious may be tempted to query the scientific precision of statement or the literary elegance of motoring jargon, but such will probably be in the minority. Again, in places mention is made of certain important parts such as the 'accelerator' and 'throttle,' without any explanation of their construction and mode of operation, but such omissions do not seem numerous, and the book may be commended to those for whom it is intended.

H. J. H.

The Economics of Carburetting and Manifolding: Vaporising and Distributing Liquid Fuel in a Motor Car Engine. By Robert W. A. Brewer. Pp. vii + 176. (London: Crosby Lockwood and Son, 1926.) 12*s.* 6*d.* net.

This book deals with a problem which is of interest to both motor spirit producers and motor engineers. The great increase in the requirements of fuel for internal combustion engines during the past decade has necessitated the production of the maximum quantity of motor spirit from a given quantity of crude material. One method by which this is being effected is by raising the upper limit of the distillation range of the motor spirit fraction. The high boiling constituents, which are thereby included, have rendered it more difficult to vaporise the fuel completely. The author professes to deal with the problem of using such fuels in motor car engines satisfactorily and economically under all conditions of operation, and the book supplements the author's book on "Carburation," where fuels, principally of the more volatile nature, are examined.

The problem is attacked chiefly from the point of view of the design of the induction system (inlet manifold), and various interesting reports and papers which have been issued by the Bureau of Mines in the United States, Society of Automotive Engineers, and others are summarised. A brief account of the author's work on the design of inlet manifolds and descriptions of other systems are also given, and a chapter is devoted to the problem of the dilution of the crank case oil.

The book would appear to be primarily intended for motor engineers. In attempting to make clear to the technical reader the scientific principles involved in vaporising and distributing liquid fuels in motor car engines, the author has been led to use terms which are vague and undefined. The various units used are also somewhat confusing. The book, however, is useful in bringing to the notice of motor users and designers the problem of the efficient utilisation of the high boiling motor spirits which are now on the market.

Miscellaneous.

Recent Advances in Physical and Inorganic Chemistry. By Prof. Alfred W. Stewart. Fifth edition. Pp. [illegible]i + 312 + 6 plates. (London: Longmans, Green and Co., Ltd., 1926.) 18*s.* net.

Prof. Stewart's excellent and useful book is too well known to make any lengthy notice of it necessary. The present edition has all the good qualities of its predecessors, and keeps the student always stationed at the growing point of physical chemical knowledge. Only five chapters have survived from the 1920 edition, and a dozen new chapters have been written for this edition, dealing with hafnium, the isobares, the results of mass-spectrography, the segregation of isotopes, atomic structure, active hydrogen, new hydrides, intensive drying, and Tesla-luminescence spectra. On the whole, the discussion of these various topics has been very well done, and the general student of chemistry is fortunate in having within comparatively small compass all that he requires in order to understand the present position of knowledge in the respective fields.

Palgrave's Dictionary of Political Economy. Edited by Henry Higgs. Vol. 3: N-Z. Pp. xxiii + 849. (London: Macmillan and Co., Ltd., 1926.) 36*s.* net.

The editor and the publishers are to be congratulated on the completion, by the appearance of the third and last volume, of the new edition of Palgrave's standard work. Sixteen years have elapsed since the publication of the first edition; the present edition may be expected to serve the needs of students of economics for as long a period.

The third volume reaches the high standard of excellence to which the first two attained; like those, it reprints the articles as they stood in the original edition and supplements them by others either entirely new or in continuation of old themes. Thus the account of the National Debt is brought down to the year 1923; and problems of recent growth and importance are given ample and authoritative consideration. Social legislation in all its branches is brought up-to-date; there is a very useful statement on the Tariff Reform movement; the article on Socialism is full and instructive; and it is a sign of the times that the appendix contains an article on "The Need of Trained Inquirers into Social Conditions."

An outstanding feature of the volume is its provision of adequate biographies of both British and foreign economists, and not the least useful portion of these is the bibliography attached to each. Indeed, the book-lists throughout the work, like the detailed index at the end, will be found of exceeding great value.

Tin and the Tin Industry: the Metal History, Character and Application. By A. H. Mundey. (Pitman's Common Commodities and Industries Series.) Pp. xiii + 130. (London: Sir Isaac Pitman and Sons, Ltd.; n.d.) 3*s.* net.

The author of this book has succeeded in setting out, in inexpensive and handy form, a concise account of the numerous industrial applications of tin and its alloys. Very little is said about the mineralogy, geology and mining of tin ores, and smelting is referred to very briefly. The book is well illustrated, and should prove helpful to those interested in the commercial aspects of this very useful metal.

The States of Aggregation: the Changes in the State of Matter in their Dependence upon Pressure and Temperature. By Gustav Tammann. Authorised Translation from the second German edition by Dr. Robert Franklin Mehl. Pp. xi + 297. (London, Bombay and Sydney: Constable and Co., Ltd., 1926.) 24*s.* net.

Students and others interested in the heterogeneous equilibria of one-component systems will welcome this translation of Tammann's excellent work "Aggregatzustände," a notice of which appeared in these columns. It suffices to say that Dr. Mehl has produced an accurate and smoothly reading translation, and has thereby made the work available to an extended circle of readers.

Printed in Great Britain by R. & R. Clark, Limited, Edinburgh.
